A remodeling annuloplasty ring is essential for all repairs. This is a fundamental concept of Carpentier<sup>18</sup> and Duran,<sup>54</sup> both of whom developed mitral valve annuloplasty rings early in the history of mitral valve regurgitation surgery and advocated remodeling of the distorted annulus as a key principle of mitral valve repair. The annulus, after many years of regurgitation, is often deformed and in myxomatous disease, it is floppy and dilated. The best approach to conceptualize the dilated annulus in myxomatous disease is to consider it functionally too small for the anterior leaflet.

When dilated, the annulus will not provide the relatively stable support necessary for the anterior leaflet to spread out completely and thus coapt at the correct line and in the correct plane with the posterior leaflet. Rather, the floppy annulus will buckle and have an effectively smaller radius, and cause the anterior leaflet to appear as though it is “prolapsing” because the leaflet cannot spread out correctly. In reality the pathology is within the annulus. That is why we believe that oversizing the ring in degenerative disease is important. The ring then

**FIGURE 35-8** Transeptal exposure of the mitral valve. After the right atrium is incised, the septum is divided across the fossa ovalis, and stay sutures are placed. This incision allows very good access to the mitral valve and is an alternative to the Sondergaard plane.

recreates the relatively rigid, broad annulus that allows the anterior leaflet to spread out and coapt in the correct plane, at the correct coaptation line, without “prolapsing.” A structurally sound annulus is necessary for the correct physiologic function of the anterior leaflet. Hence, our protocol is to place the annuloplasty ring after posterior leaflet repair and then reassess for any anterior or complex leaflet pathology afterward. A annular pathology often falsely gives the appearance of leaflet pathology, and by following the steps outlined above, many unnecessary procedures will be prevented.

By utilizing the two principles outlined above, the proper and necessary attention is given to the correct physiologic functioning of the valve in a manner that is surgically relevant. The height of the posterior leaflet is reduced to prevent SAM as well as to allow the correct coaptation plane. The two leaflets are made to coapt at the correct line by reinforcing the annulus with a remodeling ring. As outlined above, in our experience at the Brigham and that of others,<sup>55</sup> in most cases, the so-called “bileaflet prolapse” is completely eliminated by adequate posterior leaflet resection and a large remodeling annuloplasty ring without any further anterior leaflet intervention.

There is clear evidence supporting the integral and essential necessity of the ring for a lasting repair. In an early paper on mitral valve repair, we compared a repair group that had no annuloplasty ring to another group in whom a ring was implanted at the time of valve repair.<sup>56</sup> All valves were competent at the time of surgery, but after several years of follow-up, the rate of mitral regurgitation in the no-ring group was five times that of the ring group. Recent studies have supported the importance of ring annuloplasty.<sup>57</sup> Thus, a remodeling ring is critical to a long-lasting physiologic mitral valve repair.

## SPECIFIC SURGICAL TECHNIQUES

### Posterior Leaflet Quadrangular Resection

The most common mitral valve pathologies (approximately 80%) encountered in the myxomatous, degenerated valve are ruptured and elongated chords from the middle section of the posterior leaflet (Fig. 35-9A). In one approach limited resection of this diseased section of leaflet is shown in

**FIGURE 35-9** Repair of P2 with flail segment with ruptured chordae. (A) The classic flail P2 segment. (B) Resection of this flail segment. (C) and (D) The classic sliding valvuloplasty and advancement, in which each segment of the valve adjacent to the resected P2 segment is separated from the annulus. The valve is then reattached with the gap eliminated. At the same time, the height of the posterior leaflet is reduced. (E), (F), and (G) Completion of the classic sliding valvuloplasty. (H), (I), and (J) Placement of the annuloplasty stitches and ring placement. Sizing of the ring is done by the size of the anterior leaflet.

Fig. 35-9B. To fill the gap produced by removing the pathologic section, leaflet advancement of the remaining leaflet sections is carried out (Fig. 35-9C and D) and the cut edges of the valve are reapproximated with running monofilament suture (Fig. 35-9E, F, and G). An annuloplasty ring is then implanted (Fig. 35-9H, I, and J). This scenario is the most common pathophysiology encountered and operative strategy employed. Interestingly, recent results by Perier<sup>58</sup> and Lawrie<sup>59</sup> have reported successful results with use of only artificial PTFE chords to preserve the posterior leaflet instead of resecting it, a technique that has traditionally been applied only to the anterior leaflet.

For cardiac surgeons who perform a modest number of valve repairs, incising the posterior leaflet off the annulus may be somewhat daunting. In our own experience, a prolapsed leaflet without ruptured chordae at P2 may simply be obliterated by a few sutures to bring the leading edge of the prolapsed leaflet to the underside of the annular connection, thus reducing the height, preserving all the chords, and

accomplishing what might be done with a resection.<sup>61</sup> This has been termed a “folding valvuloplasty.”

If the repair includes a resection of a flail segment, then some form of the leaflet advancement technique popularized by Carpentier should be employed.<sup>60</sup> In this technique, the two remaining sections are advanced upon each other to close the gap produced by the resected area. This includes separating each remaining segment off the annulus for a short segment. Of all the traditional techniques, this is the one that has produced some concern for surgeons who perform only moderate numbers of valve repairs because of the necessity of incising the posterior leaflet off the annulus and then reanastomosing the leaflet to the annulus.

We have evolved a simplified technique for limited PML resections in which leaflet advancement may be more easily performed, and yet still accomplish the exact same result in much less time. We have named this the “fold-over leaflet advancement.” In this technique the remaining enlarged segments of P2, on either side of the elongated resected leaflet

**FIGURE 35-10** The fold-over leaflet advancement. Performed for a prolapsed and flail P2 segment here, the fold-over advancement accomplished the same goals as the classic sliding valvuloplasty, but with simpler surgical techniques. After resection of the flail P2 segment (B), the cut edges of each side of the resulting gap are sewn to the annulus as they are “folded down.” This is done for each side of the gap for half of the original height of each side. The top halves are then sewn together (E). The result is that the leaflet gap is eliminated and the height of the leaflet reduced.

with supporting chordae, are simply folded over by a continuous polypropylene suture to the annular gap produced by the limited posterior leaflet resection, without any further incision (Fig. 35-10). The fold-over advancement accomplishes the same goals as the traditional leaflet advancement. The small gap distance, created by the small area of resected flail segment, is eliminated and the height of the posterior leaflet is reduced. We have found the fold-over advancement to be extremely effective for small resections of the posterior leaflet in any position without the necessity of incising the leaflet off the annulus.

That being stated, many situations exist with true Barlow syndrome with elongation and elevation of almost the entire posterior leaflet. In essence, the whole posterior leaflet is elongated. In these particular pathologic situations, the classic techniques are necessary. The entire posterior leaflet on both sides of the resected area, including P1 and P3, must be incised

off the annulus and careful and detailed valve advancement carried out, beginning at each commissure, with running 4-0 polypropylene (see Fig. 35-9C and D). The height of the leaflet is lowered to avoid creation of SAM and provide a good coaptation point for the anterior leaflet. Because some of these leaflets may be as high as 3 to 4 cm, if the height of the leaflet is not shortened significantly, SAM is highly likely. While performing the leaflet advancement, imbrication of PML segment areas may also be effective if there is focal enlargement at a particular area of the leaflet. This simplifies the surgical technique, reduces operative time, and achieves the same result. Multiple interrupted mattress sutures may be used.

### Commissural Prolapse

As the most straightforward example of pathologic valve prolapse, chordal rupture or elongation at the anteriorlateral or

**FIGURE 35-11** Commissuroplasty. Simple horizontal mattress stitches placed in the ruptured commissure eliminate regurgitation without need for further leaflet resection, even with ruptured chordae.

posterior-medial commissure provides the surgeon with the most obvious strategy of repair. Many surgeons still recommend resection of this area, but commissuroplasty is by far the most simple, direct, and efficient way to handle this particular problem. The prolapsed area is obliterated by one to three polypropylene mattress stitches (Fig. 35-11), eliminating the regurgitation at that point. A small obliteration of this area at A1 and P1 or A3 and P3 will not make any significant difference in the overall cross-sectional area of the mitral valve, so mitral stenosis is of no concern with this technique. Several other reports<sup>62,63</sup> have also documented this technique as an effective and long-lasting method to treat commissural prolapse.

### Anterior Leaflet Prolapse

Though uncommon, true prolapse of the anterior leaflet engenders significant concern to surgeons because such pathology is associated with less successful long-term repair results than posterior leaflet pathology.<sup>64</sup> The height of the chordae underlying the anterior leaflet must be assessed and chords may be grossly elongated or ruptured and make the AML flail. This

problem may be addressed by a variety of techniques and the long-term follow-up on many of these techniques has been quite promising. There are four basic techniques to repair true prolapse of the anterior leaflet. They are (1) reduction of the chordal height by implantation techniques; (2) artificial PTFE chordae; (3) chordal transfer from the posterior to anterior leaflet; and (4) the edge-to-edge technique.

### Resection of the Anterior Leaflet

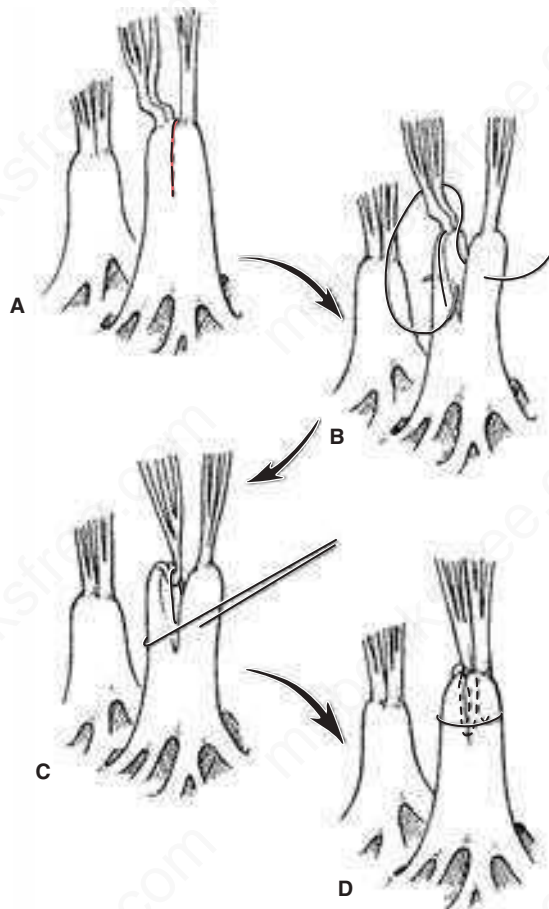

It has been well established that the body of the anterior leaflet should be treated with great respect, and preservation of AML tissue is important. Resections can be carried out, but only as a small triangular resection for ruptured chords to reduce the bulk of a large anterior leaflet.<sup>81</sup> For anterior mitral valve prolapse associated with idiopathic hypertrophic subaortic stenosis, or as an alternative technique for reduction of the AML height, creation of a longitudinal periannular anterior leaflet resection with reconstruction of the leaflet has also been advocated to reduce the height of the anterior leaflet with some success.<sup>82,83</sup>

## Chordal Shortening by Implantation into Papillary Muscles

One of the first techniques developed by Carpentier<sup>10</sup> of chordal shortening involves incising the papillary muscle, placing the redundant anterior leaflet chords within the muscle, and then sewing the papillary muscle over the chord, thus entrapping the chordae and shortening it (Fig. 35-12). This is a simple technique, but it has gone out of favor, as reports by Cosgrove and coworkers<sup>65</sup> have demonstrated that additional chordal ruptures may occur after use of this technique. They postulate that the potential sawing action of the papillary muscle on the buried chord is the cause. Other techniques of this type include papillary muscle repositioning<sup>66</sup> and chordal plication and free-edge (AML) remodeling.<sup>67</sup>

## Chordal Transfer

The third technique for true anterior prolapse is chordal transfer from the posterior leaflet to the anterior leaflet. This

**FIGURE 35-12** Anterior leaflet chordal shortening. The papillary muscle is incised and the redundant chord folded into it. The excess chord is held in place with pledgeted sutures.

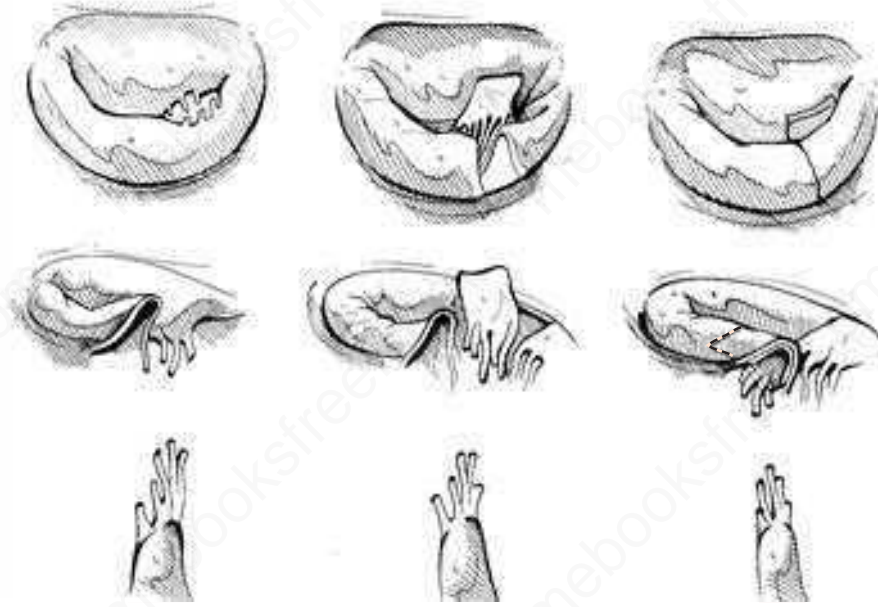

was originally described by Carpentier<sup>10</sup> and has been popularized by the Cleveland Clinic<sup>65</sup> and Duran and coworkers.<sup>72</sup> Figure 35-13 illustrates the operative steps. A resection of the flail chordae of the anterior leaflet is carried out, and an adjacent segment of the posterior leaflet is then resected from the posterior leaflet and then transferred to the gap produced by the anterior leaflet resection. This technique has had reportedly good long-term results, but may involve both leaflets when only single leaflet pathology exists.<sup>73</sup>

## Edge-to-Edge Technique

The edge-to-edge repair is a technique in which the anterior leaflet and posterior leaflet are sewn together at the coaptation line, producing a double-orifice mitral valve.<sup>74</sup> This has gained considerable popularity and even percutaneous interventional attempts to emulate this surgical maneuver are being pursued.<sup>75</sup> Developed by Alfieri and coworkers,<sup>76</sup> their theory is that with Barlow syndrome or truly redundant anterior leaflets, apposition of the midportion of the anterior leaflet to the midportion of the posterior leaflet will prevent the elevation of the anterior leaflet above the level of the posterior leaflet, thus eliminating mitral regurgitation. This technique greatly simplifies the repair of the true bileaflet prolapse and has been adopted as standard therapy for AML pathology by several groups, especially in those patients with a high probability of postrepair SAM. In particular, with anterior leaflet chordal rupture or marked elongation of the chordae to the anterior leaflet, repair consists of a single stitch carefully placed.

Figure 35-14 illustrates our technique. A figure-of-eight braided polyester suture is placed at the apposition points of the anterior and the posterior leaflet. We use this stronger suture, because there have been reports of the more commonly used polypropylene sutures rupturing. An important point of the surgical technique is our strong belief that the stitch should be placed only with myxomatous valves, so as to avoid producing mitral stenosis as has been the case with ischemic MR.<sup>77</sup> To ensure the adequacy of each orifice created by the edge-to-edge technique, we also measure the diameter of each orifice and confirm that it is at least 2 cm in diameter. If the orifices are less than 2 cm in diameter, the technique is abandoned. This technique is a very valuable adjunct in patients who have the potential for SAM of the mitral valve.<sup>78,79</sup> In fact, prevention of SAM may be the best utilization of this technique at present. In our small series of 20 patients with SAM potential, all were treated and SAM was prevented in all patients. A competent mitral valve was maintained in all at 8 years postoperatively without mitral stenosis.<sup>78</sup>

Medium-term results of this surgical maneuver are satisfactory and compatible with all other commonly used repair techniques, according to studies by Alfieri and coworkers,<sup>76,80</sup> but there have been no comparative, prospective, randomized studies comparing the classic repair techniques to this approach in the long term.

**FIGURE 35-13** Chordal transfer. For an isolated flail anterior leaflet segment, first the prolapsed section of anterior leaflet is resected. An adjoining section of posterior leaflet is then resected and transposed over to the gap created by the anterior resection.

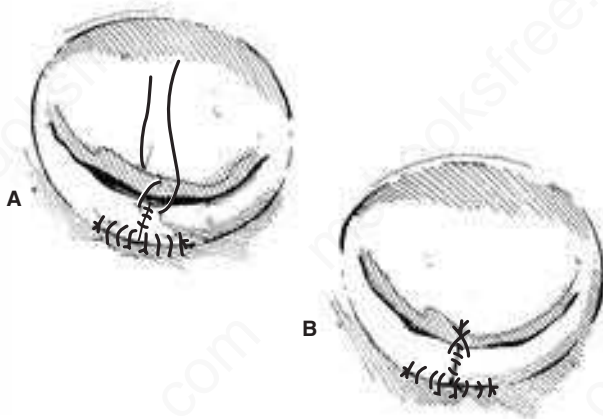

## Artificial Chordae

The mitral subvalvular apparatus is a sophisticated structure that couples intact mitral valve function with support of left ventricular function. Mitral valve replacement, naturally, eliminates this important and fine connection. The use of artificial chords during mitral valve repair procedures, while “respecting rather than resecting” the mitral leaflets tissue, has the potential of restoring mitral valve anatomy and function. The goal of performing a repair while using neochords is to eliminate any regurgitation get, while preserving both leaflets and keeping the mitral annular symmetry. The use of artificial chordae for mitral valve repair, dates back to the 1960s, and during the evolution of

this technique, a number of materials were used as artificial chordae, including silk and nylon. Today, most, if not all surgeons, use expanded polytetrafluoroethylene (ePTFE) chords, and this technique is perhaps the most popular current technique for AML pathology. Originally described by Frater and Zussa,<sup>68,69</sup> this technique has grown in popularity over the past several years.<sup>64,70</sup> Lawrie<sup>59</sup> has also recently reported excellent results in applying PTFE neochords for the anterior and posterior leaflet repair. Duran has devised a method for more precise measurement of the correct height for these new chordal structures.<sup>70</sup> This technique (Fig. 35-15) involves a number of technical steps to establish a path for successful repair.

1. Attachment to the papillary muscle
2. Attachment to the leaflet
3. Length adjustment
4. Tighing of the PTFE neochord, before or after insertion of an annuloplasty ring.

We usually place a mattress suture with a pledget on the papillary muscle to which the redundant or ruptured chord has been attached. The two ends of the double-armed PTFE are then brought up through the edge of the leaflet that needs to be lowered. The critical part of this technique is determining the degree to which the leaflet is lowered and hence how tightly the stitch is tied down. This is determined by ascertaining the optimal position of the two leaflets in systole. Both the anterior and posterior leaflets should be in apposition at this point, and thus the leaflet’s height in systole should be the level to which the chords are adjusted. We have used tenting of the posterior leaflet as our guide while carefully tying down the chord (Fig. 35-15B). Other techniques describe using multiple loops (David technique), using a fixed length loop

**FIGURE 35-14** Edge-to-edge technique. The technique involves a braided polyester figure-of-eight stitch at apposition of A2 and P2.

**FIGURE 35-15** Artificial PTFE chords for the anterior leaflet. (A) Pledged PTFE stitches are placed through a papillary muscle and brought through the leading edge of the anterior leaflet. Using the tented-up posterior leaflet (B), the correct length of artificial chord is created.

technique using a caliper (von Oppell and Mohr), using a fixed length loop technique without using a caliper (Mandegar). Tam described a modification of the loop technique that involves only a single pass through the papillary muscle.

Whatever the technique employed, the end result should be that the anterior leaflet now coapts at the same level as the posterior leaflet with left ventricular contraction. Some surgeons advocate neo chordae, as opposed to leaflet resection, as the repair technique of choice for leaflet prolapse.<sup>61</sup>

Long-term histology results of neochord placement demonstrate that ePTFE neochords become covered with fibrous tissue as described by Bortolotti et al<sup>93</sup> This is consistent with our own experience demonstrated by Fig. 35-16.

## SPECIAL PROBLEMS AND CONSIDERATIONS

### The Calcified Annulus

Calcification, particularly of the posterior annulus, is a complicating aspect of mitral valve repair. Calcification makes repair more difficult, as stitches are more difficult to place and the risk of paravalvular leak is increased. Severe annular calcification, however, does not necessarily rule out an effective mitral valve repair. Partial or total removal of the calcified

bar may be done safely. Carpentier has promulgated removal of the entire calcified bar in radical fashion, which in essence partially detaches the LV from the left atrium.<sup>84</sup> Partial and selective calcification removal may also be quite effective and potentially safer.<sup>85</sup> Partial removal of calcium with leaflet advancement can be performed without the need for a radical debridement in many patients. Only the amount of calcium should be removed that allows adequate stitch placement and leaflet and annular flexibility. Obviously, calcification of the chordae or a substantial part of the leaflet tissue is a poor prognostic factor for long-term freedom from valve repair, and an extensively calcified valve usually indicates valve replacement.

### Systolic Anterior Motion of the Mitral Valve

As mentioned above, persistent SAM of the anterior leaflet is an adverse outcome after valve repair. In this condition, the anterior leaflet obstructs the LVOT. Clearly, increased redundancy of leaflet tissue is a risk factor with a small annuloplasty ring. After repair, if the line of leaflet coaptation is displaced anteriorly, then the anterior leaflet will be displaced into the LVOT and cause LVOT obstruction.<sup>86,87</sup> The etiology is usually inadequate reduction of the height of the posterior leaflet, which then pushes the anterior leaflet into the LVOT. SAM

**FIGURE 35-16** (A and B) Gross anatomy of an excised anterior mitral leaflet 3 years after neochordae implantation. (C) H&E stain of a neo chordae cross section. (D) Giemsa stain of the same cross section.

is particularly prevalent in patients with true bileaflet prolapse or those with extremely enlarged anterior leaflets. Thus, the PML height reduction has to be meticulously carried out, and in myxomatous valve disease, an upsizing rather than a downsizing of the mitral valve annuloplasty ring should be done. As indicated above, if the anterior leaflet is supported by a relatively small annulus, the anterior leaflet will not spread out and instead will appear to have redundant tissue above the correct plane of coaptation, predisposing to SAM.<sup>78</sup>

Several investigators have looked at the potential echocardiographic risk factors for SAM. Echocardiographic details that are associated with a high risk of SAM include proximity of the mitral valve coaptation point to the interventricular septum, as well as asymmetry between the anterior and posterior leaflets. If the posterior leaflet is relatively large with respect to the anterior leaflet, then SAM is potentiated. If the medial portion of A2 is larger than the medial portion of A1, then SAM is also potentiated. We look for this information before surgery and take such data into account as the repair strategy is finalized in the operating room.<sup>78,79</sup>

If the probability is high that SAM will occur, our practice is to use the Alfieri edge-to-edge technique to reduce such a risk after lowering the height of the posterior leaflet.<sup>78</sup> By forcing the coaptation line to be correct with a single stitch in the situation of high SAM probability, the probability of

SAM is reduced. Another strategy to consider in this circumstance is implantation of PTFE anterior chordae to lower the AML. That will reduce the height of the anterior leaflet, and thus further reduce the potential of SAM. In our own experience long-term competency is maintained in this group.

If SAM appears by TEE following what appears to be an excellent repair, filling the LV with fluid volume postcardiopulmonary bypass will relieve SAM in approximately 90% of patients. In rare circumstances, if an adequate reduction of the posterior leaflet has not been carried out, more posterior leaflet may have to be resected or the ring size increased. The most common alternative in our clinic is the edge-to-edge technique, as mentioned above, for situations where postrepair SAM still exists despite all techniques to reduce it.<sup>78</sup>

### Remodeling Ring Annuloplasty

Remodeling the annulus by ring annuloplasty after mitral valve repair is essential to a complete and long-lasting repair. The remodeling concept, promulgated by Carpentier<sup>18</sup> and Duran<sup>54</sup> is that the distorted mitral annulus requires restorative structural support. There is debate on which type of ring should be used for remodeling: rigid or soft, complete or partial? It is probably not critical which type of ring is used for myxomatous valve degeneration as long as there is a relative

upsizing of the ring and a secure attachment to the trigone area of the anterior mitral leaflet. There is some evidence to suggest that flexible rings may incur less possibility of SAM and that partial rings are safer with respect to SAM.<sup>88</sup> As none of this has been studied in a prospective randomized fashion, these opinions will continue to exist. Though we prefer the Cosgrove ring for mitral valve prolapse, our belief based on over 2000 mitral valve repairs is that the existing evidence is not compelling for any particular ring, and that the type of ring implanted is far less important than a correctly performed operation and appropriate sizing of the ring.

The technical aspects of ring implantation are important to avoid circumflex artery compromise, atrioventricular dissociation, or dehiscence of the ring. Implantation of currently available annuloplasty rings requires the placement of mattress sutures, parallel to the annulus, at the junction of the posterior leaflet and the annulus. Radially oriented bites are to be avoided because by definition they exert radial stresses and thus will pull to some extent on the circumflex artery. Bites should be deep with the needle entering the annulus, then into the left ventricular cavity, and then coming out on the atrial side again. Of paramount importance is the requirement that the plane of the needle bite should be orthogonal to the annular plane. If this is done, it is impossible for the stitch to impinge or distort the circumflex artery. That is why such bites may be made deep. Wide bites are taken such that there is not an excess number of a suture. A partial mitral ring should require approximately 9 to 15 sutures depending on the size of the annulus. The sutures are not pledgeted unless there is extreme fragility of the annular structures. Annular

integrity will of course depend on the pathology. Sutures are then passed through the fabric part of the ring. The central stabilizer frame is kept in place to maintain the ring shape while the sutures are tied down, thus preventing crimping of the cloth rings in the nonrigid or semirigid rings.

In the past decades, more than 40 mitral valve annuloplasty rings of various shapes and consistency were marketed for MR, although the effect of ring type on clinical outcome remains unclear. Until demonstrated otherwise, surgeons may choose their ring upon their judgment, tailored to specific patient needs.

Sizing is the most important aspect of ring placement. We believe that slight oversizing of the ring in myxomatous degenerated disease is appropriate. This corrects for the degenerative annulus that is functionally too small. Sizing is typically done by two techniques. Placement of aortic trigonal stitches (Fig. 35-17) allows for measurement of the intertrigonal distance. Many ring-sizing devices have notches on the rings to facilitate this. Except in rheumatic disease, we do not rely on this measurement. In myxomatous disease, the height of the anterior leaflet from the annulus to the highest point on the leaflet when it is stretched is the most important criterion for sizing, a concept originally espoused by Carpentier.<sup>10</sup> This height of the leaflet is the critical dimension that must be carefully measured so that during systole there is minimal redundancy that may lead to SAM. Using trigonal sizing may, in fact, downsize the ring and cause either SAM or ring dehiscence because of the huge disparity between ring size and annulus size. In our re-repair series, either improved sizing or placing the ring below the commissures were the most common

**FIGURE 35-17** Ring annuloplasty sizing and insertion. The ring for degenerative disease should be slightly oversized. Sizing should be done to match the height of the anterior leaflet, not the distance between the trigones or commissures. Nine to 11 mattress sutures are usually needed.

**FIGURE 35-18** Etiology of mitral regurgitation determines longevity. (Reproduced with permission from DiBardino DJ, ElBardissi AW, McClure RS, et al: Four decades of experience with mitral valve repair: analysis of differential indications, technical evolution, and long-term outcome, *J Thorac Cardiovasc Surg.* 2010 Jan;139(1):76-83.)

remedies.<sup>89</sup> Therefore, using the sizer to evaluate anterior leaflet size is the most critical maneuver. Echocardiographic dimensions of the anterior leaflet correlate well with in vivo sizing, and calculating the anterior leaflet size by standard echocardiogram techniques is performed in every case. Deployment of a ring matching the anterior leaflet size in our experience has been most efficacious and has rarely led to SAM.<sup>78</sup>

## Results

Based on long-term studies, the probability of a durable mitral valve repair at 10 years is greater than 90%.<sup>42,53,56,64,90</sup> Thromboembolic incidence is also exceedingly low; long-term anticoagulation is not required unless patients are in atrial fibrillation. Recently, we reviewed our personal operative experience (LHC) over four decades of mitral valve surgery.<sup>91</sup> This study has confirmed many commonly believed relationships between the etiology of MR and the durability of mitral valve repair. Etiology of regurgitation was noted to be the primary determinant of repair longevity and freedom from reoperation. Although repair of rheumatic disease was noted to ultimately require reoperation, myxomatous repair resulted in outstanding long-term freedom from recurrent MR and reoperation (Fig. 35-18).

# Mitral Valve Repair: Rheumatic

Javier G. Castillo • David H. Adams

After recovery from an initial episode of rheumatic fever, approximately 60 to 65% of patients will develop heart valve disease (rheumatic heart disease, RHD) and possibly secondary conditions such as atrial fibrillation, endocarditis, and heart failure.<sup>1</sup> Rheumatic heart disease is one of the leading noncommunicable diseases in developing countries with a global prevalence of up to 19.6 million in 2005 and an incidence of 282,000 new cases per year.<sup>2</sup>

In Western countries, economic and sociopolitical changes together with prophylactic initiatives led by the American Heart Association and the World Heart Federation contributed to eliminate rheumatic fever by the 1980s (current prevalence in the United States is 0.05/1000). Much of the morbidity and mortality due to RHD has been proven to be effectively prevented by secondary prophylaxis including long-acting penicillin, oral anticoagulants, and surgical interventions.<sup>3</sup> However, the costs of prophylaxis continue to burden low-income and middle-income countries as well as certain concentrated populations of higher-income countries (demographic shifts due to immigration).<sup>4</sup> In this context, an estimated of up to 468,164 patients die each year from RHD and or its clinical complications. Interestingly, recent

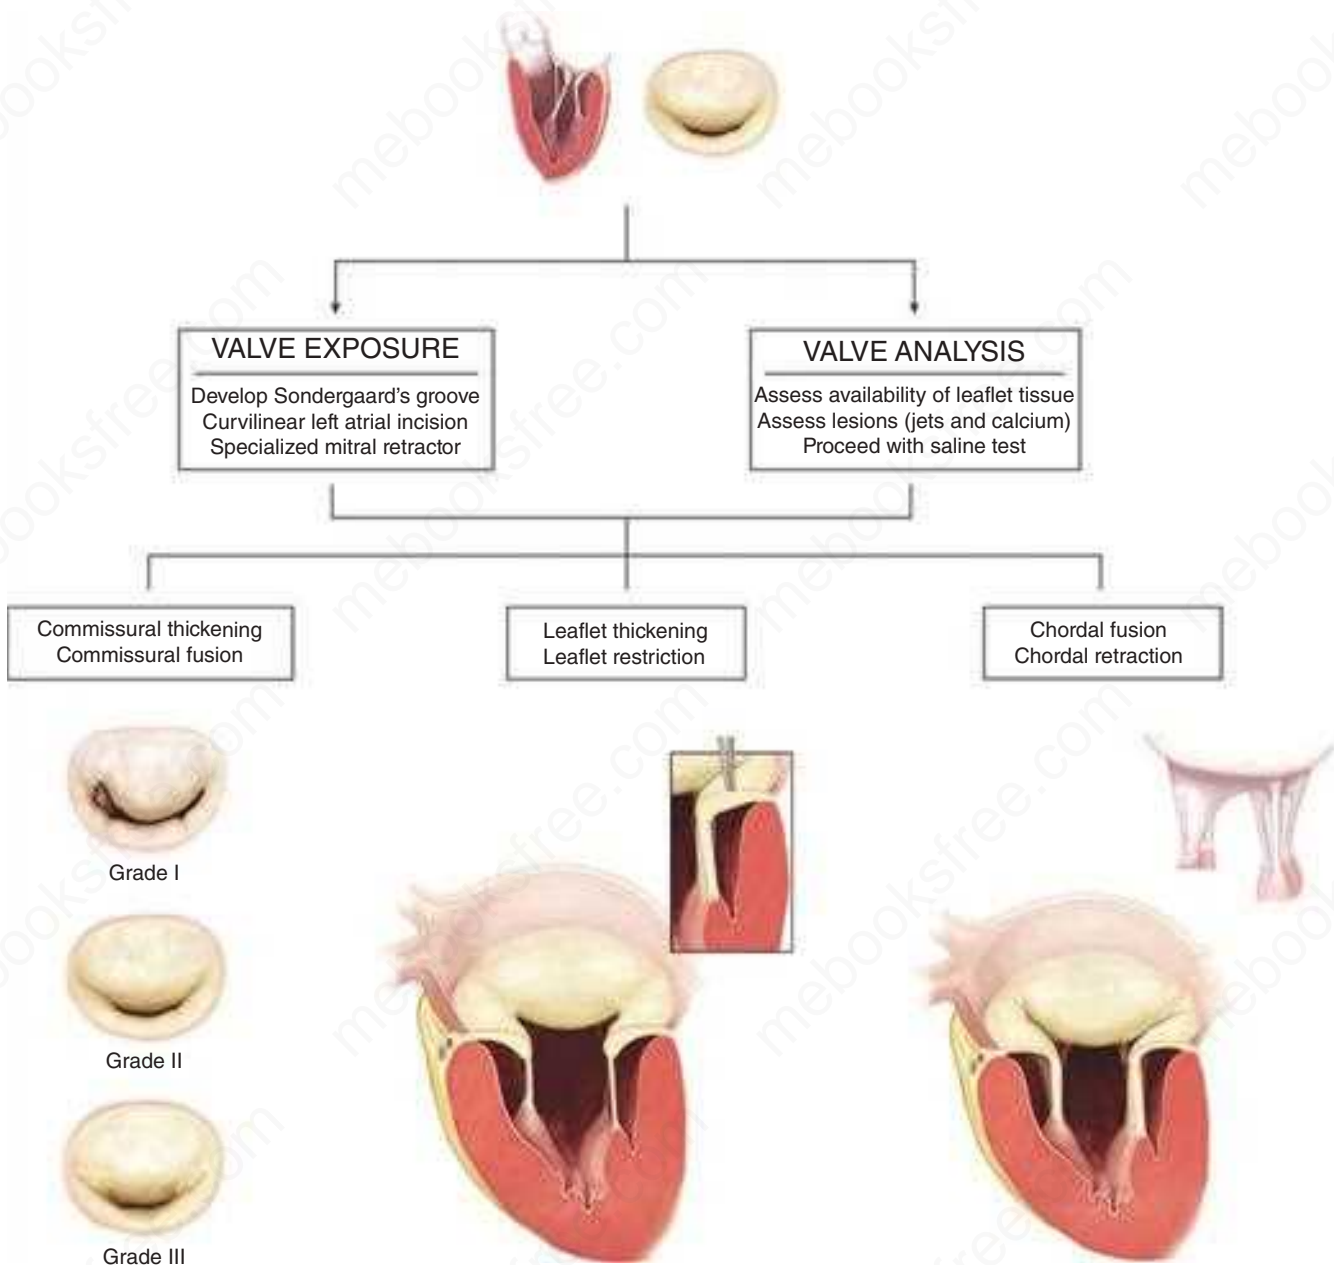

echocardiographic data have shown that the true prevalence of the disease is significantly higher than the current global estimate if we take into consideration subclinical RHD.<sup>5</sup>

Rheumatic heart disease is unarguably the most common cardiovascular disease among individuals aged <25 years worldwide, and has a peak age group of 25 to 35 years (female predominance) in developing countries<sup>6</sup> (Fig. 36-1). Conversely, patients with RHD in industrialized countries are either old (mostly above 50 years of age) or young immigrants. In this setting, the mitral valve is affected in 50% of patients and results in mitral regurgitation, mitral stenosis, or both.<sup>7</sup> In younger patients, mitral regurgitation is predominant, but mitral stenosis becomes more prevalent with age and calcification of tissues. Regurgitant mitral valves are edematous with fibrotic thickening, and annular dilatation and anterior leaflet pseudoprolapse are often seen, whereas stenotic mitral valves present with stiff, nonpliable, and severely restricted leaflets, fusion of the subvalvular apparatus and commissures and often annular calcification<sup>8</sup> (Fig. 36-2). Clinical assessment and two-dimensional echocardiography are paramount to detect and assess mitral stenosis, particularly in asymptomatic patients.<sup>9</sup>

((Adapted with permission from Zühlke L, Engel ME, Karthikeyan G, et al: Characteristics, complications, and gaps in evidence-based interventions in rheumatic heart disease: the Global Rheumatic Heart Disease Registry (the REMEDY study), *Eur Heart J*. 2015 May 7;36(18):1115-1122a.)

### Rheumatic mitral valve disease

**FIGURE 36-2** Analysis for patients with rheumatic mitral valve disease. Valve exposure and analysis are considered part of the repair due to their impact in achieving optimal surgical outcomes. The most common lesions encountered are commissural thickening and fusion, leaflet restriction and retraction, and chordal fusion and retraction.

### PATHOPHYSIOLOGICAL IMPLICATIONS

The main consequence of RHD and more particularly rheumatic mitral valve disease (RMVD) is mitral stenosis.<sup>10</sup> This circumstance results in an increase of diastolic gradients across the mitral valve with invariable measurements of the mitral area due to moderate-to-severe commissural fusion. From a hemodynamic standpoint, transvalvular flow and heart rate

are considered to play an important role in the perioperative management of patients with RMVD.<sup>11</sup> Mean mitral gradient increases in parallel with cardiac output (importance of atrial contraction) or with fast heart rates.

Increasing mitral gradients trigger left atrium enlargement due to chronic escalating left atrial pressures. This in turn favors the occurrence of atrial fibrillation leading to annular dilatation and thrombus formation. The logical rise in pulmonary artery pressure leads to pulmonary hypertension

and late in the course to right ventricular hypertrophy, right ventricular dilatation, secondary tricuspid regurgitation and eventually right ventricular dysfunction (inherent surgical risk). This is important to understand why patients undergoing mitral valve repair often receive adjuvant tricuspid valve repair and a Maze procedure.<sup>12</sup> Finally, it is important to emphasize on the role of rhythm control therapies and central vasodilators during the preoperative period and medical optimization for surgery.

## SURGICAL CONSIDERATIONS

Although mitral stenosis was the first mitral valve dysfunction treated surgically (Elliot Carr Cutler performed a closed trans-ventricular mitral commissurotomy with a cardiovalvulotome in 1923), nowadays most of the patients with mitral valve stenosis receive a percutaneous balloon valvuloplasty unless the lesions are not amenable to balloon dilatation (or there is a high risk of embolic events), there is concomitant regurgitation, or a previous balloon valvuloplasty has failed.<sup>13</sup> When surgery is indicated, mitral valve repair is always preferred to mitral valve replacement due to lower perioperative mortality rates,<sup>14,15</sup> superior preservation of left ventricular function,<sup>16</sup> lower thromboembolic complications<sup>17</sup> and risk of endocarditis (critical in patients with deficient socio-economic conditions), and greater long-term durability.<sup>18</sup> This is particularly important in young patients. However, although repair rates have been shown to be near a 100% in prolapsing valves or patients with isolated annular dilatation, repair techniques are feasible in only 50 to 75% of patients with RMVD (percentage varies according to age, leaflet dysfunction and degree of calcification).<sup>19,20</sup> This difference is attributable to the vast spectrum of lesion complexity found in patient with RHD and therefore the need for more complex surgical techniques that often cannot guarantee long-term durability. In addition, when deciding about repair versus replacement, the evolving nature of the rheumatic process, which implies a progressive distortion of the subvalvular apparatus even beyond a successful repair, needs to be part of the equation. In this context, it is crucial to distinguish between the lesions in patients from developing countries (the histological rheumatic process is active) and that of patients from industrialized countries where the process is controlled.

From a strictly technical point of view, several aspects have recently transformed the field of mitral valve repair in patients with RMVD. The first one is introduction of polytetrafluoroethylene neochordoplasty to either replace diseased chords or reinforce leaflet segments which has significantly impacted surgical outcomes.<sup>21</sup> Neochordoplasty has actually replaced many of the subvalvular techniques originally described and promoted by Carpentier such as chordal shortening, chordal transfer, or papillary muscle reposition.<sup>22</sup> Additionally, although leaflet extension is not a new technique,<sup>23</sup> the relatively recent introduction of gluteraldehyde-fixed pericardium has avoided shrinkage, thickening and calcification of the autologous pericardium potentially leading to more durable results.<sup>24</sup>

## Type I Dysfunction

Two mechanisms may lead to type I dysfunction<sup>25</sup> in patients with RHD. The first one is rapid left ventricular dilatation and subsequent mitral annular dilatation due to pancarditis (early stages), which often impacts left ventricular contractility due to an acute inflammatory reaction (myocarditis). The second mechanism is annular dilatation secondary to chronic atrial fibrillation. Atrial fibrillation (very common in patients with RHD) impairs atrial contraction thus increasing left atrial pressures. This in turn results in left atrial dilatation and pure mitral annular dilatation.

## Type II Dysfunction

The most frequent lesions encountered leading to type II dysfunction<sup>25</sup> are true prolapse and pseudoprolapse of the anterior leaflet. In the setting of true prolapse of the anterior leaflet, the leaflet overrides the coaptation plane during systole resulting in mitral regurgitation. Causes of true anterior prolapse in patients with RMVD include elongation or rupture (secondary to an acute inflammatory reaction) of the chordae tendinae or papillary muscles, or secondary rupture caused by bacterial endocarditis (facilitated and exacerbated by a dysfunctional rheumatic valve as occurs in patients with severe underlying degenerative mitral valve disease).

In the setting of anterior leaflet pseudoprolapse, as opposed to true anterior leaflet prolapse, the anterior leaflet does not override the plane of coaptation during systole (minor prolapse of the free edge of A2 due to distention and posterolateral displacement of the paramedical chordae). This lesion is often found in patients with opposing dysfunction, this being a combination of type IIIb dysfunction of the posterior leaflet (restricted motion) and consequent anterior leaflet pseudoprolapse (also known as type IIa/IIIp). In this case, mitral regurgitation is secondary to the lack of coaptation between the anterior and the posterior leaflets, which permits full unfolding of the anterior leaflet (there is no coaptation surface against the posterior leaflet) without overriding the plane of coaptation or annular plane.

## Type III Dysfunction

Type III is the most frequent dysfunction<sup>25</sup> in patients with RMVD. In the early stages of rheumatic valve involvement, mild degrees of leaflet fibrosis (incipient symmetric bileaflet restriction) might create mild mitral regurgitation and very subtle hemodynamic changes. Moreover, mitral regurgitation at this stage might be often aggravated by certain degree of annular dilatation. When the inflammatory process induces a more significant fibrotic reaction both leaflets present greater degrees of restricted motion with important hemodynamic consequences. This circumstance might certainly impede leaflet coaptation in systole leading to severe mitral regurgitation. However, in this setting, the more advanced fibrotic thickening of both leaflets as well as the fusion of both commissures and the subvalvular apparatus also impedes leaflet opening in diastole resulting in mitral stenosis. When restricted motion

mainly affects valve opening during diastole owing to isolated commissural fusion or further rheumatic changes pure mitral stenosis is predominant.

## MITRAL VALVE REPAIR TECHNIQUES

The use of a prosthetic-ring or prosthetic-band annuloplasty is currently a standard technique in all patients receiving mitral valve repair (obviously pediatric patients are an exception requiring biodegradable or pericardial rings or bands) regardless of the etiology of mitral valve disease.<sup>26</sup> Except in rare cases of pure mitral stenosis (with preserved ventricular function and mild atrial enlargement and therefore no secondary annular deformation), annular dilatation is present in the majority of patients with RMVD and mandate correction with a prosthesis size based on the surface of the anterior leaflet or on the intertrigonal distance (any discrepancy between two sizes should lead the surgeon to choose the larger size always). The use of ring annuloplasty has been shown to reduce the incidence of both mitral and tricuspid regurgitation (and subsequent reoperations) in patients with RMVD. In the setting of pure mitral stenosis with obvious annular dilatation, ring annuloplasty contributes to prevent commissural leaks by providing better surface of coaptation between both leaflets (commissurotomy might result in valve regurgitation in the presence of severe annular dilatation).

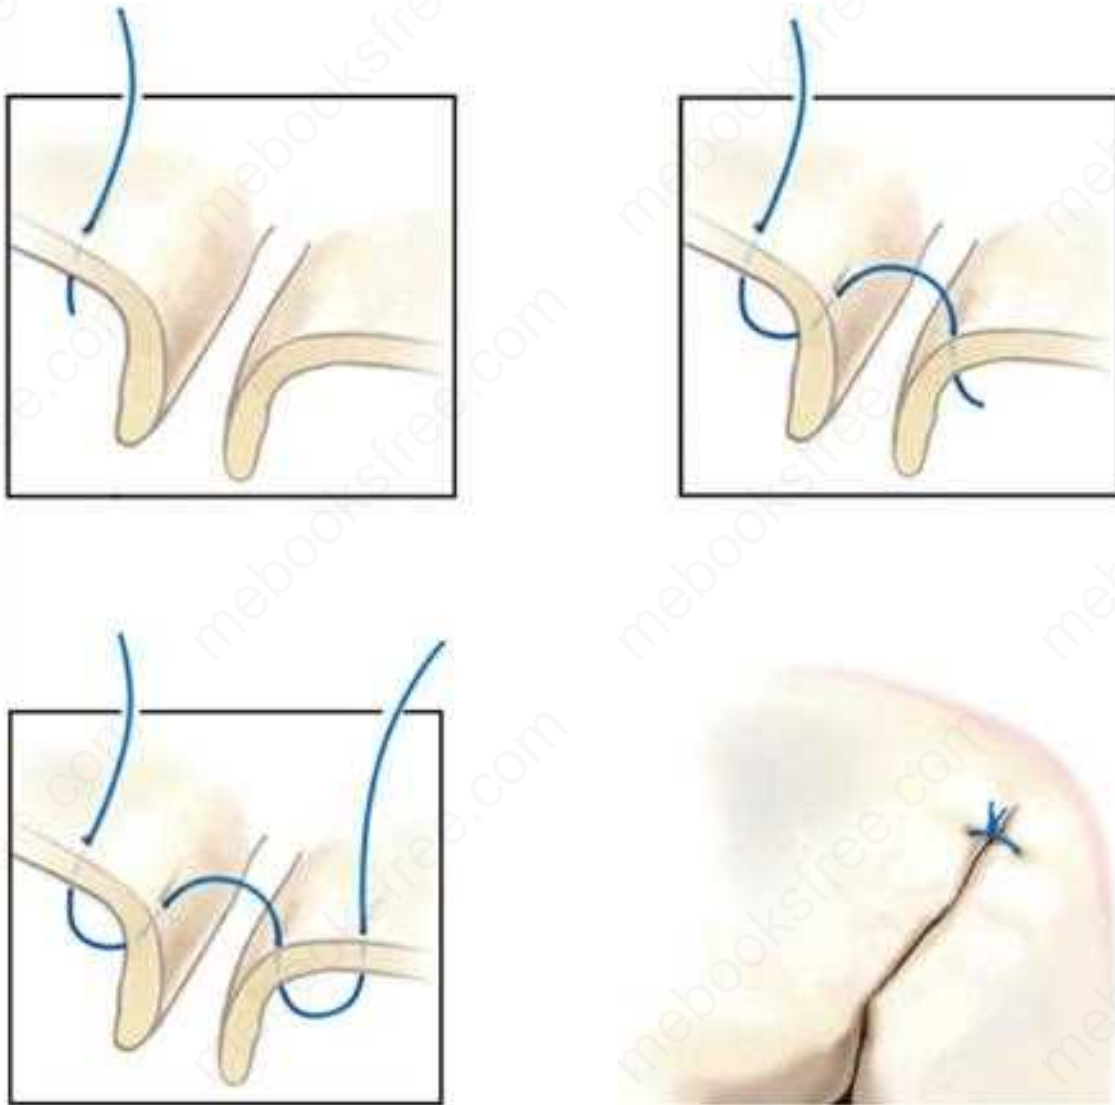

## Commissurotomy

Commissural fibrosis and fusion leading to mitral valve stenosis is by far the most frequent lesion encountered in patients with RMVD. According to the severity of commissural fusion, three categories have been described: Grade I—partial fusion of the commissures with chordal preservation; Grade II—complete fusion of the commissure with preserved delineation between the anterior and the posterior leaflets; and Grade III—complete fusion of the commissures with absence of leaflet delineation and calcium deposition (Fig. 36-2).

Commissural fusion is treated by a commissurotomy (Fig. 36-3). Traction of the anterior leaflet with a nerve hook helps to identify the commissural line that delineates anterior and posterior leaflets. Subsequently, using a #11 blade, an incision is made about 5 mm from the annulus (preservation of tissue equivalent to a commissural leaflet) and extended towards the mitral orifice. The incision is then discontinued about 5 mm from the orifice and the commissural chordae are identified and isolated with a nerve hook. The incision is then carried down to the head of the papillary muscle (leaving chordae on each side of the defect) thus creating a subcommissural orifice (the papillary muscle splitting can be further completed by a fenestration). In cases of severe commissural fusion (where an aggressive commissurotomy and debridement might be required), cases of concomitant excessive annular dilatation, or in the setting of acute bacterial

**FIGURE 36-3** Commissurotomy. Commissural fusion (A) traction of the anterior leaflet with a nerve hook helps to identify the commissural line that delineates anterior and posterior leaflets (B) using a #11 blade, an incision is made about 5 mm from the annulus and carried down to the head of the papillary muscle (C) Chordae are preserved on each side of the defect creating a subcommissural orifice (D). (Adapted with permission from Carpentier A, Adams DH, Filsoufi F: *Carpentier's Reconstructive Valve Surgery*. St. Louis: Saunders/Elsevier; 2010.)

**FIGURE 36-4** Carpentier's commissuroplasty "magic suture" (top). Commissural resuspension with a CV-5 double-armed polytetrafluoroethylene suture (bottom).

endocarditis (additional commissural destruction and prolapse), commissural resuspension or reconstruction might be necessary (Fig. 36-4). This is best accomplished with a "magic suture" or commissuroplasty (4-0 polypropylene sutures).

### Leaflet Resuspension (Subvalvular Techniques)

Leaflet mobilization and resuspension is achieved with subvalvular techniques, mainly chordal resection and fenestration. In dramatic cases of excessive fibrosis and fusion of the subvalvular apparatus, splitting of the papillary muscle as well as resection of marginal chords and subsequent replacement (neochordoplasty) are considered valid repair options (Fig. 36-5).

Identification of secondary chordae is critical to achieve leaflet mobilization without inducing leaflet prolapse.

The secondary chordae to be resected should be identified and isolated with a nerve hook. The attachment to the papillary muscle is usually cut first (easier visualization) to subsequently expose the leaflet attachment by gentle traction. In severe cases (rarely amenable to repair), marginal chordae can be also resected as long as there is one marginal chordae every 4 mm to support the free edge of the leaflet. If this axiom is not possible, chordal replacement with polytetrafluoroethylene artificial chordae (neochordoplasty) is required (the use of artificial chordae has displaced classic techniques such as chordal transfer or chordal transposition in advanced disease). Fused marginal chordae contributing to subvalvular obstruction are not resected but fenestrated. Fenestration is usually carried down thus spilling the corresponding papillary muscle.

Finding a healthy chord in the setting of RMVD might be more than challenging, therefore techniques such as chordal

**FIGURE 36-5** Subvalvular techniques include resection of secondary chords (top) and chordal fenestration (bottom).

transfer, chordal transposition or the posterior leaflet flip have been abandoned. The alternative is polytetrafluoroethylene neochordoplasty (and variants such as the loop technique or the loop in loop technique), which has been increasingly used in mitral valve repair. A CV-5 double-armed polytetrafluoroethylene suture is passed and looped through the fibrous tip

of the papillary muscle. Next, the two ends of the artificial chord are passed through the leaflet margin (approximately with a 3-mm distance between them) and two slip knots are tied (Fig. 36-4). After functional adjustment (insufflation of saline test after remodeling annuloplasty to assess the plane of coaptation and chordal height), a minimum of six knots are then completed to secure the new chord.

### Leaflet Augmentation with a Gluteraldehyde-fixed Autologous Pericardial Patch

Although leaflet augmentation with autologous pericardium was introduced in the 1960s,<sup>23</sup> optimal results were not achieved until the late 1980s due to the introduction of gluteraldehyde fixation. Briefly, a piece of autologous pericardium (approximately 5 cm × 5 cm) is freed from adhesions, unfolded onto cardboard (secured with clips), and immersed in 0.625% buffered gluteraldehyde solution for 10 minutes. Subsequently, the patch is rinsed in saline for 10 to 15 minutes (some authors recommend different baths of 5 minutes each).<sup>27</sup> Fixation prevents shrinkage (stabilizes collagen cross-linkages), reduces tissue antigenicity, and minimizes enzymatic degradation and cell viability (avoidance of calcification and fibrosis).

Leaflet augmentation, most commonly of the posterior leaflet (depending on the type and extent of lesions), is performed to increase leaflet surface area in patients with type IIIa dysfunction and severe leaflet retraction (when mobilization cannot be achieved with subvalvular techniques) or to replace leaflet segments where severe calcification has led to a significant defect after resection that cannot be closed primarily. Before proceeding with leaflet augmentation, pliability of the anterior leaflet is assessed by pushing the anterior leaflet with a pair of forceps; if the leaflet rebounds into position then fibrosis probably precludes repair techniques (Fig. 36-2). The technique starts with placement of traction sutures in order to unfold the leaflet as much as possible (Fig. 36-6). Next, a transverse incision is made about 5 mm from and parallel to the annulus (the extent of the incision depends on the degree of leaflet retraction). All secondary chordae are then resected

**FIGURE 36-6** Posterior leaflet augmentation with a gluteraldehyde-fixed autologous pericardial patch. After placement of traction sutures, a transverse incision is made about 5 mm from and parallel to the annulus (A) secondary chordae are resected to free and resuspend the leaflet (B) A semilunar autologous pericardial patch is tailored to the leaflet defect adding a 2-mm margin for suturing (C) an oversized ring (one size larger) or classic ring is selected in order to fully accommodate the posterior leaflet.

to free and resuspend the leaflet. Finally, a semilunar autologous pericardial patch is tailored to the leaflet defect adding a 2-mm margin for suturing. The height of the patch should provide a 15-20-mm posterior leaflet. The patch is then sutured using continuous 4-0 polypropylene sutures. Interlocked bites are used on the leaflet side to prevent a potential purse-string effect. An oversized ring (one size larger) is selected in order to fully accommodate the posterior leaflet.

Pericardial patch augmentation of the anterior leaflet is similar to that of the posterior leaflet with an only particular difference, the leaflet incision might be transverse or vertical (rare occasions) depending on the leaflet morphology. The resulting opening after incision will guide our decision about the size and shape of the corresponding patch.

### Decalcification Techniques

The main goal before proceeding with mitral valve repair in patients with RMVD is ensuring (as much as possible) leaflet mobility and pliability. This is achieved with a multistep repair algorithm that should be tailored to every individual patient. The initial step is to interrogate the commissures and the subvalvular apparatus. Subsequently, if the leaflets are not pliable, decalcification techniques can be applied including leaflet shaving, leaflet peeling or leaflet (cuspal) thinning. The latter should be always performed in leaflet areas amenable to a potential patch augmentation (leaflet thinning may lead to secondary windsock deformity and perforation). Calcified areas can be shaved off the leaflet and the annular hinge to facilitate leaflet excursion. Additionally, the thick fibrotic layer of tissue that accumulates on the atrial surface of the leaflet can be peeled off. Finally, if all these techniques do not compensate for leaflet retraction and scarring, leaflet extension is performed.

### OUTCOMES

Mitral valve replacement has been traditionally considered as the predominant procedure for patients with RMVD,

particularly if we take into account that unfortunately many patients with prolapsing valves (a mitral lesion with a near 100% repair rate) still receive mitral valve replacement.<sup>28</sup> However, relatively recent sophistication in reconstructive techniques has contributed to the expansion of mitral valve repair, and this has had a potential impact on outcomes regardless of disease etiology.<sup>29</sup> The most current series on rheumatic mitral valve repair reported an increment of the repair rate from 42 to 69% (within the same surgical group) in the last decade.<sup>30</sup> This represents a great improvement in comparison with previous series which have reported repair rates around 25% in experienced hands.<sup>31</sup> However, the literature needs to be interpreted with meticulous caution. If one analyzes the study population in every large series, can see that those with lower repair rates include a significant larger percentage of patients with mitral stenosis (more complex lesions of uncertain durability if repaired) and older patients (more likely to have subvalvular fibrosis and calcified lesions)<sup>32</sup> (Table 36-1).

It is well known that repair for RMVD (particularly in the setting of pure or concomitant mitral stenosis) cannot be consistent.<sup>33</sup> Regardless of geographical location and length of follow up, reoperation rates (when adjusted to survival) are higher in patients receiving mitral valve repair mainly due to fibrosis (particularly commissural) and calcification of the subvalvular apparatus and the disease progression.<sup>34</sup> Other authors have reported age and mitral regurgitation at the acute phase as significant factors for repair failure.<sup>35</sup> The estimated failure rate of mitral valve repair in patients with RMVD is 2 to 5% per year (vs 1 to 2% per year in patients with degenerative mitral valve disease).<sup>30,36</sup>

There is scarce data comparing outcomes (particularly late outcomes) after mitral valve repair to those achieved with mitral valve replacement, especially in the adult population. In this context, Shuhaiber et al conducted a systematic meta-analysis of clinical outcomes following surgical correction of mitral valve disease (including RMVD) and demonstrated consistent findings favoring a lower operative mortality in patients receiving mitral valve repair with the one exception of those patients with active RMVD (OR

# Surgery for Functional Mitral Regurgitation

Matthew A. Romano • Steven F. Bolling

Functional mitral regurgitation (FMR) is a complication of ischemic or dilated cardiomyopathy, occurring secondary to left ventricular (LV) geometrical distortion from tenting, inferobasilar migration, apical displacement, annular dilation and posterior leaflet restriction, and/or regional LV wall dysfunction. MR leads to a vicious cycle of LV volume overload, increased geometric distortion and progressive MR. FMR complicating congestive heart failure predicts a poor survival. Mitral surgery, to treat FMR has been undertaken with an acceptably low operative mortality. However, the exact MR surgery (repair or replacement) for which patient and what benefit, remains controversial.

Congestive heart failure is one of the world's leading causes of morbidity and mortality. As our population ages, the number of patients suffering from end-stage heart failure will continue to rise. In the United States alone, there are nearly 7 million patients suffering from heart failure. In 2012, heart failure "therapy" cost the United States over \$50 billion. This total includes health care services, medications, and lost productivity. Yet of the 700,000 new congestive heart failure (CHF) patients diagnosed each year, less than 3000 are offered transplantation due to limitations of age, comorbid conditions and donor availability. Even fewer are presently served with a mechanical assist device. One of the most common (up to 50% of patients) and serious problems in cardiomyopathy is the development of functional or secondary mitral regurgitation. Functional mitral regurgitation (FMR), nonorganic mitral valve (MV) disease, may eventually affect almost all heart failure patients as a preterminal or terminal event.<sup>1</sup> FMR is not caused by intrinsic disease of the valve, but by left ventricular (LV) remodeling, dilation, and dysfunction leading to geometric reconfiguration of the mitroventricular apparatus, including papillary muscle displacement and annular dilation. MV leaflets become tethered, with failure of anterior-posterior leaflet coaptation, resulting in symmetric or asymmetric regurgitation.<sup>2,3</sup> The progressive dilatation of the left ventricle initially gives rise to FMR that begets further ventricular dilatation and more FMR. FMR is associated with poor quality of life and a reduction in long-term survival. Mitral surgery, while not addressing the underlying ventricular

pathology, hopefully could interrupt this cycle of ventricular deterioration through the restoration of mitral competency.

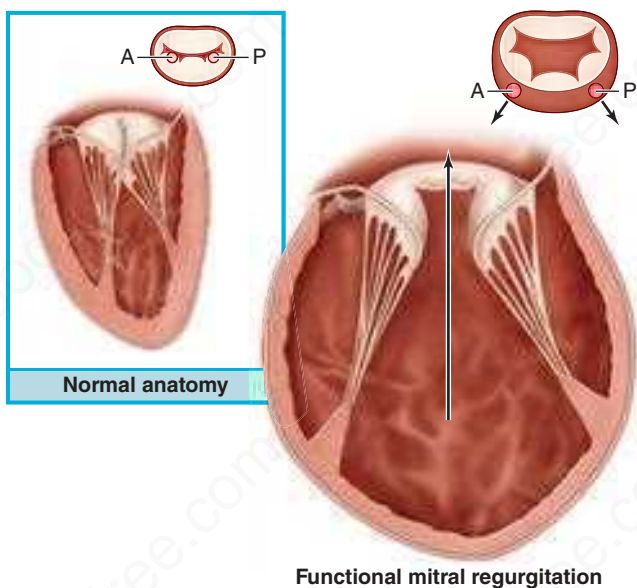

## BACKGROUND

It has been well documented that even small amounts of FMR are harmful in CHF patients. Grigioni et al<sup>4</sup> showed that when FMR regurgitant volume was >30 ml the 5-year survival was <35% compared to 44% for a regurgitant volumes of 1 to 29 ml and 61% for CHF patients with no MR. Bursi<sup>5</sup> also examined the role of FMR and its impact in CHF. CHF patients (469) were followed for mortality according to severity of their FMR. Their 5-year survival was 83% in patients with no/1+ FMR, 64% in 2+, 58% in 3+, and 46% in 4+ ( $p < .0001$ ). The association between FMR and Major Adverse Cardiac and Cerebrovascular Events (MACCE) was strong and independent in this propensity matched analysis. A further study<sup>6</sup> denoted that among 303 patients post MI, ischemic MR was present in 194 (64%), and was a significant independent predictor of long-term mortality (relative risk, RR [95% confidence interval, CI] = 1.88,  $p = .003$ ).<sup>1</sup> Additionally, in a study from the Duke Cardiovascular Data-bank,<sup>7</sup> 3-4+ FMR was present in 30% of 2057 HF patients with an left ventricular ejection fraction (LVEF) < 40%, and was an independent predictor of 5-year mortality (adjusted hazard ratio [95% CI] = 1.23).<sup>2</sup> Lastly, the Mayo Clinic<sup>8</sup> looked at the prognostic implications of FMR in patients with advanced systolic CHF in a heart failure clinic. Of 558 NYHA III-IV patients, those with at least moderate MR had a 5-year survival of only 27%. These studies demonstrate that FMR is not just a sign of advanced CHF, but an independent determinant of CHF death. That FMR is bad for CHF patients is supported by many other studies that show that the severity of MR impacts quality of life, as well as survival. Furthermore, there is a strong association between the presence of ischemic FMR severity and heart failure hospitalizations. However, while the presence of FMR predicts a poor prognosis in patients with left ventricular dysfunction and heart failure, unfortunately, "proof" that correction of FMR improves prognosis remains elusive.

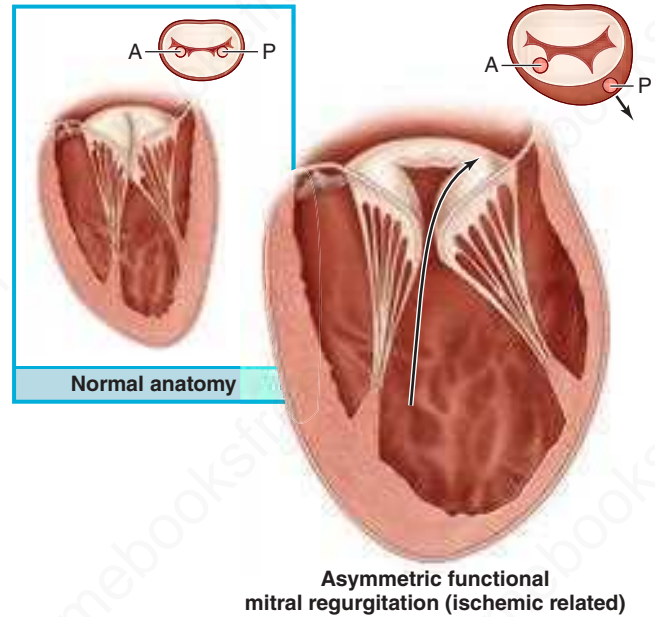

Historically, the surgical approach to FMR was nonvalve sparing MV replacement, at a time when little was understood of the interdependence of ventricular function and the annular-papillary muscle continuity. Consequently, patients with low EF who underwent MV replacement with removal of the subvalvular apparatus had prohibitively high mortality rates. As explanation the erroneous concept of a beneficial “pop-off” effect of FMR was conceived. This idea erroneously proposed that mitral incompetence provided low-pressure relief during systolic ejection for the failing ventricle, and that removal of this effect through mitral replacement was responsible for the perioperative deterioration of ventricular function. Consequently, MV replacement in patients with heart failure and FMR was discouraged.

## FMR ANATOMY

A firm understanding of the anatomy of the MV is fundamental to the surgical management of FMR. The MV apparatus consists of the annulus, leaflets, chordae tendineae, and papillary muscles as well as the entire left ventricle. These structures form a “closure cylinder” with the papillary musculature directly aligned beneath the annulus. Most importantly, the maintenance of chordal, annular, and subvalvular continuity is essential for the preservation of mitral geometric relationships, as well as ventricular twist mechanics and systolic power. MR in heart failure is not primarily related to the valve but to ventricular pathology. The degree of LV distortion reflects the degree of MR. As the ventricle fails, progressive dilatation of the LV results in outward papillary muscle migration, alteration of the closure cylinder, and thus loss of the zone of coaptation (Fig. 37-1).

**FIGURE 37-1** LV geometric distortion in FMR.

**FIGURE 37-2** Asymmetric FMR noted with ischemic related LV changes due to posterior infarction.

The end result of progressive FMR and global ventricular remodeling is similar regardless of the etiology of cardiomyopathy. The primary lesion in ischemic FMR is leaflet tethering, which results from ventricular remodeling associated with an ischemic insult. Posterior-lateral and apical displacement of the papillary muscles, which correlates with a measurable “tethering distance,” leads to apical tenting and restriction of the free margin of the leaflets and poor leaflet coaptation. Tethering of secondary chordae can lead to a “seagull” deformation of the anterior leaflet. Although both papillary muscles may be displaced, the posterior papillary muscle usually predominates, which leads to tethering of the “P3” leaflet segment.<sup>9,10</sup> This is seen in posterior infarction related to the posterior descending artery distribution and the mitral regurgitation jet is usually eccentric and posteriorly directed along the P3 area which is restricted (Fig. 37-2). In contrast, left anterior descending infarction leads to more global remodeling involving both papillary muscles, and more diffuse leaflet tethering with large central jets of mitral regurgitation. Although annular dilatation and ventricular remodeling accompanies all MR, it is usually an associated finding, as opposed to a primary causal lesion in ischemic mitral regurgitation. The degree of annular dilatation is much less in ischemic mitral regurgitation than in degenerative mitral regurgitation, which is one of the reasons that “downsizing” of the mitral ring annuloplasty may best address leaflet tethering in ischemic MV regurgitation. Conversely, FMR associated with dilated cardiomyopathies tends to have more symmetric distortion with more annular dilation than asymmetric ischemic FMR.<sup>11,12</sup> Because of this difference in geometric distortion, as well as patient comorbidity profiles, it may be that dilated and ischemic FMR patients should be thought of and treated in somewhat different manners.

## THERAPY OF FMR

Despite the underlying pathology, the goals of therapy for FMR patients are to improve symptoms and quality of life, reduce heart failure hospitalization, and, hopefully to improve survival. The therapies shown to be most effective for FMR are those directed at the underlying LV dysfunction, most importantly guideline-directed medical therapy (GDMT) for HF.<sup>1,13-15</sup> Cardiac resynchronization (with or without a defibrillator) if indications are met (wide QRS > 150 ms) should also be considered when appropriate.<sup>16,17</sup> Finally of course, coronary revascularization should be performed in patients with ischemia and myocardial viability. While all patients with FMR should receive GDMT for management of CAD, LV dysfunction and heart failure, unfortunately morbidity and mortality of patients with CHF and secondary FMR remains high. A recent study showed that among 404 FMR patients treated with GDMT, 4-year cardiac mortality occurred in 43 and 45% with moderate and severe MR, respectively, compared to only 6% with mild MR ( $p = .003$ ).<sup>13</sup> Furthermore, moderate or severe FMR was also shown to be a high independent predictor of new onset HF in patients with ischemic LV dysfunction (RR = 3.2,  $p = .0001$ ). The role of surgical MV repair or replacement is to potentially interrupt the vicious cycle of LV volume overload causing LV dilatation leading to secondary MR, which further increases LV volume overload and dilatation further increasing MR.

## FMR SURGERY

The present AHA/ACC Valve Guidelines (2014) and the ESC/EACTS Guidelines<sup>18,19</sup> have separate guidelines for functional or secondary ischemic mitral regurgitation (FMR). As noted, these guidelines state that treating ischemia with coronary artery bypass grafting or percutaneous methods should be primarily undertaken for FMR. Additionally, all FMR patients should have guideline GDMT, with consideration for CRT, if they have a QRS greater than 150 ms. However, if the patients remain symptomatic with severe mitral regurgitation or stage D disease, they may be considered for “MV surgery” as a 2B indication. Yet, from the surgeon’s perspective, while it is recommended that surgical correction of FMR should be considered exactly how to successfully correct FMR remains unclear. Currently, the most common technique to restore valve competence is placing an undersized or restrictive annuloplasty ring to reduce mitral annulus size and increase leaflet coaptation. Unfortunately, ischemic FMR may persist or recur after restrictive MV annuloplasty. Persistent or recurrent FMR in post op patients is understandably associated with unabated ventricular dilatation, an escalation of CHF symptomatology and possible reduction in long-term survival.

Surgical mitral annuloplasty improves symptoms in patients with CHF and it has been shown that mitral repair is feasible with a low mortality. Several authors have demonstrated 30-day mortality rates as low as 1 to 5% for mitral repair for MR in CHF. Recently, Geidel reported that the

late results of restrictive annuloplasty in patients with FMR and advanced cardiomyopathy demonstrated a 3% 30-day mortality and 91% 12 months survival with little postoperative recurrence of significant MR. Similarly, data from Germany in transplant candidates, showed a 7% operative mortality and no difference in survival after MV repair versus transplant indicating that high risk MV surgery in patients with cardiomyopathy and FMR may offer a mid-term alternative treatment for patients with drug refractory heart failure and FMR.<sup>20-22</sup> Perhaps, the most compelling data for the safety and efficacy of MV repair for FMR comes from the MV surgery alone arm of the prospective Acorn trial (CorCap Cardiac Support Device, a prospective, randomized, multicenter trial). The Acorn trial showed a 98% 30-day survival rate, 2% repeat reoperation, and 85% 24 months survival and significant improvements in quality of life, exercise performance, and NYHA class. Furthermore, in the MV surgery arm, improvement in LV volumes, mass, and shape was sustained out to 5 years with little recurrence of significant MR.<sup>23</sup>

However, the “achilles heel” of MV repair in many series of FMR is persistent, residual or recurrent MR.<sup>24-27</sup> It was learned that the intertrigonal distance is not stable in FMR, with dilatation occurring along, not only the insertion of the posterior leaflet, but also in the anterior portion. This intertrigonal portion dilates and although once considered to be a “measurable” standard by which to size annuloplasty rings, it is now known from a landmark paper of Hueb that this is not the case.<sup>28</sup> Therefore, previous methods of FMR sizing were incorrect and “undersizing” rings has become the standard for these functional MR patients. This may partly explain the operation “failing” and recurrence of mitral regurgitation in functional MR patients when using too large “classic-sized” rings or when using a partial or flexible rings.

However, despite undersizing rings, there is significant disparity in recurrence rates among FMR series. The lack of a mortality benefit may be partially explained by the absence of a durable repair. When McGee and Gillinov<sup>24</sup> showed no mortality benefit in FMR after mitral repair, they also noticed the rate of recurrent significant MR to be 30 to 40% at 1 year. Others have shown even higher rates of return of FMR, up to 80%.<sup>29</sup> This has led to an attempt to identify surgical predictors of recurrent MR and for improved surgical techniques that result in a more permanent repair.<sup>30</sup> In order to observe a survival benefit in these patients after mitral repair, FMR must be fixed permanently, as residual and recurrent MR may obscure or obliterate any possible survival benefit.

## PREDICTORS OF RECURRENT MITRAL REGURGITATION

Many of the mechanisms of recurrent functional MR have been elucidated and include annular level and subvalvar components. Major predictors of recurrent FMR include LV size greater than 65 mm, a coaptation depth of greater than 1 cm below the annular plane and angulation of the MV apparatus, all of which indicate degree of LV distortion. In patients

with a posterior leaflet angle  $> 45^\circ$  (high posterolateral restriction) undergoing restrictive annuloplasty for ischemic MR, preoperative echo was shown to accurately predict persistence of MR and 3-year survival. Also studies show that the angle between the tip of the anterior leaflet and the annular plane is a predictor of MR recurrence. An anterior leaflet angle greater than  $25$  to  $40^\circ$  was a predictor of MR recurrence. Many have also shown LV function or degree of MR as determinants of recurrent MR while others point out the importance of both LV sphericity and tethering depth as predictors.<sup>31-33</sup>

One of the most important LV predictor of recurrent MR may be left ventricular end diastolic dimension (LVEDD)  $> 65$  mm. In patients with preoperative LVEDD of  $65$  mm or less, restrictive mitral annuloplasty with revascularization provided a mortality benefit for ischemic mitral regurgitation and heart failure; however, when LVEDD exceeded  $65$  mm, outcome was poor and a different approach to CHF should be considered. Perhaps, the most important mechanistic predictor of recurrent FMR is an increased anterior-posterior or septal-lateral mitral annular diameter. This is the most significant determinant of FMR as leaflet coaptation and therefore mitral competency, is dependent upon the diameter of the MV annulus. The MV is thought to have roughly twice the amount of coaptive surface as needed. This redundancy allows for LV volume changes and explains why obligatory FMR occurs when the LVEDD approaches  $65$  mm. Furthermore, this may explain why FMR is evanescent. Studies of FMR reveal that decreasing filling and systemic vascular resistance lead to reduction in dynamic FMR. This is attributed to a reduction in the mitral orifice area relating to decreased LV volume and annular distension.<sup>34</sup>

This complex relationship between mitral annular area and leaflet coaptation may explain why an undersized “valvular” repair may help a “ventricular” problem. Three-dimensional magnetic resonance imaging and echo studies showed that the mitral annulus flattens and significantly increases its AP diameter. This CHF-related change has been shown not only in animal models, but in humans as well. Kongsarepong et al<sup>35</sup> found that the strongest predictor of recurrent FMR following mitral repair was a residual large AP diameter, that is, a “too large” ring. Lastly, Spoor demonstrated that the use of flexible rings (which flex and allow the largest AP diameter) as opposed to a rigid complete ring was associated with a five times higher recurrent mitral regurgitation rate. Presently numerous rigid, complete FMR specific rings with stable AP dimension reduction are available.<sup>10</sup>

Interestingly, acute remodeling of the base of the heart with complete rigid, undersized rings may also play a beneficial role in FMR hearts. These disease-specific rings may reestablish an ellipsoid shape to the LV, as evidenced by the acute decreased sphericity index and LV volumes. Restoration of LV geometry is of paramount importance in CHF patients. This has been demonstrated by the Restore—MV trial. In that trial ischemic FMR patients, requiring coronary artery bypass graft (CABG) did better with a direct LV reshaping device (Coapsys), than with CABG with the addition of an undersized mitral ring, even though they had slightly more

residual MR. This study pointed out the differential effects of MR and the LV.<sup>36</sup> In summary, patients with predictors of failure should be considered poor candidates for FMR repair, and alternatives should be contemplated. Unfortunately, progression of ventricular disease may have the worst predictive outcome for these patients. This is not amenable by mitral repair and one must be aware that fundamentally FMR is a ventricular disease.

## INDICATIONS FOR FMR SURGERY

The indications for surgery for FMR are more cautious than those for primary, degenerative MR due to the recognition that surgical outcomes are linked to underlying LV remodeling. Secondary FMR can acutely be corrected by MV surgery, however, it has never clearly been demonstrated that reducing or eliminating FMR alters the natural history or improves survival.<sup>37,38</sup> Moreover, whether the response to surgery is different in secondary MR due to ischemic versus nonischemic cardiomyopathy has also not been established. One-year mortality after MV surgery for severe ischemic MR (with or without CABG) is up to 17%. Therefore, the benefit of MV repair in patients with FMR and heart failure is unclear. Wu et al showed no mortality benefit in FMR patients treated with MV repair, although they did not examine the effect of recurrent mitral regurgitation. In ischemic cardiomyopathy patients, several nonrandomized studies showed that MV repair in addition to CABG for ischemic FMR did not alter long-term functional status or survival when compared with CABG alone.<sup>16-19</sup> Trichon demonstrated a survival advantage in ischemic cardiomyopathy patients who underwent CABG plus MV repair only compared with medical management, as there was no difference between CABG plus MV repair versus CABG alone.<sup>6</sup> Conversely, far more other nonrandomized studies, have demonstrated that MV repair plus CABG does improve survival compared with medical therapy or CABG alone in patients with FMR due to ischemic cardiomyopathy.<sup>37-39</sup>

## MODERATE FMR

The first published randomized prospective FMR trial for moderate FMR was by Fattouch et al<sup>40</sup> This study describes 102 patients with moderate chronic ischemic MR (mean MR grade 2+ and LVEF 43%) and moderately dilated left ventricles (mean LVEDD 59 mm) that were randomized to CABG plus MV repair ( $n = 48$ ) or CABG alone ( $n = 54$ ). Postoperative and follow-up MR grade, NYHA class, and LV remodeling were improved in the MV repair group. That trial was not powered for mortality analysis and in-hospital and 5-year survival was not statistically different between groups. Interestingly, exercise echo at 1 year in these patients showed far better hemodynamic response and less occurrence of MR in the mitral repair group.

Reinforcing this finding, Deja published in *Circulation* the results of the mitral surgery arm for all patients with FMR

and an EF of <35% from the STICH trial. This report of 1212 patients, showed not only a quality of life improvement, but hinted at a survival benefit from the addition of MV repair to CABG in these high risk patients.<sup>37</sup> Finally, Chan reported results from a randomized, prospective survival trial of CABG with or without MV repair for FMR in the RIME trial. At 1 year of follow-up, FMR patients who had the addition of MV repair had lower LV end-systolic volume index (LVESVI), brain natriuretic protein (BNP) and MR grade, as well as better sphericity and exercise performance.<sup>40</sup> Conversely, in a recent NIH-sponsored, multicenter randomized controlled trial (RCT) conducted by the Cardiothoracic Surgery Trials Network (CTSnet), despite MV repair with CABG being significantly more effective than CABG alone in reducing or eliminating moderate ischemic MR, there were no differences at 1-year in LVESVI or rates of major adverse cardiac and cerebrovascular event.<sup>41</sup> Longer follow-up could reveal whether differences in residual/recurrent MR will manifest in clinical endpoints such as death and rehospitalization for heart failure. Of note, in these randomized trials of mitral repair for moderate ischemic FMR, there appears to be no operative mortality penalty for the addition of an undersized ring.<sup>42</sup> Given the improvements seen with MR correction in patients with only moderate MR and moderate LV dysfunction, it is tempting to hypothesize clinical benefits at longer follow up.

## SEVERE FMR

There are very few randomized trials of surgery for severe FMR. Nonrandomized evidence including the meta-analysis by Vassileva et al<sup>43</sup> favoring mitral repair is a compilation of retrospective and single center studies. Conversely, Lorusso et al<sup>44</sup> demonstrated no difference in short- or long-term mortality between patients treated with MV replacement versus repair in severe FMR.

In a further study,<sup>44</sup> the CTSnet enrolled 251 patients with severe ischemic MR and coronary artery disease between 2009

and 2011 and randomized them to either receive undersized MV repair (126 patients) or chord-sparing replacement (125 patients). The primary endpoint was LV reverse remodeling assessed by LVESVI measured at 12 months. At 12 months, LVESVI was 54 mL/m<sup>2</sup> in the repair group versus 60 mL/m<sup>2</sup> in the replacement group. There was no significant difference in LVESVI. The 1-year mortality rate was 14.3% in the repair group versus 17.6% in the replacement group. However, the repair group showed a significantly higher rate of recurrence of moderate or severe MR at 12 months (32.6 vs 2.3%). There were no significant differences in the rate of a MACCE, functional status or quality of life at 12 months. In this propensity-matched study MV repair was the strongest predictor of need for valve reoperation, with a recurrence of MR in surviving patients at 1 year of 32.6% and at 2 years of 46% (Fig. 37-3).<sup>7</sup> Interestingly, however, in a subgroup analysis of MV repair<sup>45</sup> patients who did not have recurrent FMR, LV reverse remodeling was significantly better than in patients who had MV replacement. Mitral repair without recurrent MR was also far better than those with a “bad” repair (ie, significant recurrence of MR) (Fig. 37-4). This may imply that a “good” FMR repair without significant recurrence is better than a replacement. However, the high recurrence rate of significant FMR is problematic. The choice of repair versus replacement remains controversial since MV repair may be associated with lower short- and intermediate-term morbidity and mortality, while at the same time MV repair of FMR is associated with high recurrence rates of moderate/severe FMR, but equal survival and CHF status.

Lastly, the role for MV repair in nonischemic cardiomyopathy patients has been less extensively studied. Bolling et al described excellent survival following MV repair in a series of cardiomyopathy patients without coronary artery disease.<sup>20,21</sup> Another report of idiopathic dilated cardiomyopathy patients treated with MV repair had significant resolution of mitral regurgitation and heart failure symptoms, with excellent long-term survival.<sup>46</sup> DeBonis et al

**FIGURE 37-3** Survival in the CTSnet “Severe” FMR repair versus replacement trial.

LVESVI (ml/m <sup>2</sup> )	Repair	
	Recurrence	No recurrence
	62.6 ± 26.9	42.7 ± 26.4

**FIGURE 37-4** Resultant reverse remodeling in the CTSnet “Severe” FMR trial: “Bad” (with recurrence of significant MR) versus “Good” (no recurrence of MR).

demonstrated 81% survival at 3.5 years, with excellent freedom from MR and heart failure symptoms, in a smaller series of nonischemic FMR patients undergoing MV repair.<sup>47</sup> Despite these excellent outcomes, there are very little data comparing surgery to medical management in patients with nonischemic FMR.

## ECHO DEFINITIONS OF FMR

When examining the reports of FMR surgery, it must be remembered, that there is disparity among the guidelines as to what constitutes moderate versus severe FMR. All the guidelines agree that EROA  $\geq 0.4$  cm<sup>2</sup>, RgV  $\geq 60$  mL, and RgF  $\geq 50\%$  constitute severe *primary* MR. However, the recent ACC/AHA Guidelines on valvular heart disease propose a new definition for severe FMR at an EROA  $> 0.2$  cm<sup>2</sup>. This lower threshold accounts for the possibility that the actual EROA is larger than calculated by PISA in FMR, as well as the fact that “moderate” or more FMR in the setting of a cardiomyopathy has been associated with an adverse prognosis. However, it is not clear what to do with an FMR patient with a EROA of 0.2 cm<sup>2</sup>, nor are there convincing data showing that correction of “severe” FMR at the lower threshold improves patient outcomes in FMR. Therefore, this new recommendation remains controversial.<sup>48</sup>

## TECHNIQUES OF MITRAL SURGERY FOR FMR

For FMR operations, meticulous attention should be paid to myocardial preservation and cardiopulmonary perfusion. At the time of exposure of the MV, it can be noted that the MV appears “normal”. The reduction in AP diameter and orifice area of the MV is an overcorrection and overcompensation for a disease of the ventricle. This “undersizing” of the mitral ring was first proposed by Bolling, in 1995 and has become a standard technical approach for FMR repair. When undersizing a mitral ring, it is recommended that one use numerous annular sutures, as compared to degenerative MR repairs, to distribute the workload of annular reductive force. These sutures may be put very closely together, or even on a diagonal. Some advocate the use of pledgeted sutures, or the use of an extra row or a few pledgeted reinforcement sutures posteriorly, once the ring is tied in place.

In terms of FMR ring sizing, the normal mitral annulus is roughly proportional to a patient's thumb and forefinger in a circle. One must “downsize” from there. There are some who have advocated double downsizing, meaning two sizes below that measured at the time of operation; however, the vast majority of patients may be well served with a “small” 26 or 28 mm ring. Although initially in FMR patients there was concern for both systolic anterior motion of the anterior leaflet (SAM) and/or mitral stenosis from such downsizing, these have not resulted in significant clinical sequelae in long-term FMR follow-up series. However, it must be noted that some investigators have reported “functional” mitral stenosis with provocative (dobutamine) testing with undersized rings.<sup>49</sup>

The type of ring utilized for FMR repairs is an important technical consideration. As noted, in a landmark paper by Hueb, the fibrous portion of the mitral annulus anteriorly between the two mitral trigones dilated proportionally and as much as the posterior muscular annulus. Magne reported failure rates of up to 80% at 6 months postoperatively with large flexible and/or partial bands for FMR patients. Silberman et al<sup>51</sup> reported on predictors of residual and recurrent mitral regurgitation in FMR and the two largest multivariate predictors were LV size and the type of ring. In fact, the type of ring was a better predictor than LV size. That study showed that small rigid and complete rings were best for FMR. In the specific disease of FMR, large partial or incomplete rings probably do not result in a durable repair and are not favored technically. Presently, there are numerous specific small rigid and complete FMR rings with a disproportionate AP diameter dimension reduction. While none of these rings have shown clinical outcome differences between them, they are probably most favored for the repair of FMR.<sup>51</sup>

There are some FMR patients that should be approached with clinical caution. Silverman showed the larger the ventricle, the worst the outcome for FMR patients. This was also shown in a study from Dion which demonstrated that LVEDDs over 65 mm had a much poorer outcome than those starting at a smaller LV size. Probably, there are some ventricles that are “too far gone” and mitral repair will not be beneficial in these patients. Furthermore, patients with poor RV function and very high PA pressures should be carefully evaluated and perhaps avoided.

When coming off cardiopulmonary bypass there should be no mitral regurgitation seen on intraoperative postop transesophageal echocardiography. And not only should there be no mitral regurgitation, the zone of coaptation should be measured and should be at least 8 to 10 mm long. If this is not the case then the patient certainly has a much higher incidence of recurrence of mitral regurgitation when they are awake and removed from the unloading effects of general anesthesia.

There are other adjunct therapies that have been used for the FMR repair. In the dilated FMR MV, there are often deep clefts between P1/P<sub>2</sub> and P2/P<sub>3</sub> which should be closed. Borger has advocated the use of lysis of secondary chords to both the anterior and posterior leaflets to allow for a longer zone of coaptation. While this method has been technically

successful, there is no long-term follow-up and the effect of disrupting any chordal structures on LV function is unknown.

FMR is a ventricular disease and surgeons have tried to add adjunctive and inventive “ventricular” therapies to an undersized mitral ring, thereby directing operative therapy to the ventricle itself. Kron has advocated the use of “ring and string” by placing a Goretex traction suture in the posterior papillary muscle and bringing it up towards the annular plane. Hvas has demonstrated the use a double annular ring, placing a standard annular ring at the annulus level and then a second one of Gortex, woven around the papillary muscles to recreate the normal cylinder of closure. Many authors have reported moving papillary muscles or even sewing them together. None of these operations have had long-term follow-up. Some surgeons have advocated augmenting the anterior or the posterior leaflet with bovine pericardium to improve the length of the zone of coaptation. While these approaches increase the technical difficulty of the operation, they are certainly appealing on the basis of altering the underlying problem. Other types of ventricular therapies which have been utilized: the ACORN restriction jacket, the Coapsys ventricular tether, a silicon lifting pad behind the posterior inferior ventricular wall amongst others. None of these therapies have long-term follow-up.<sup>52-54</sup>

## MITRAL VALVE REPLACEMENT IN FMR

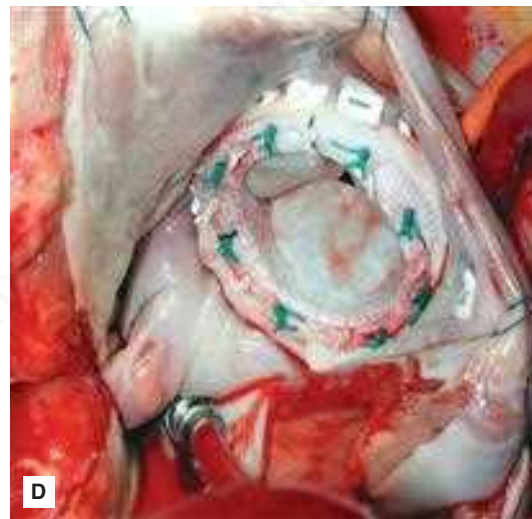

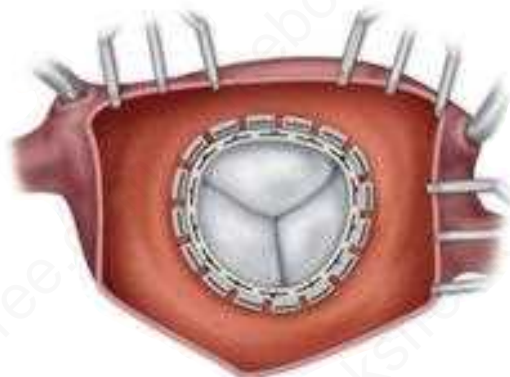

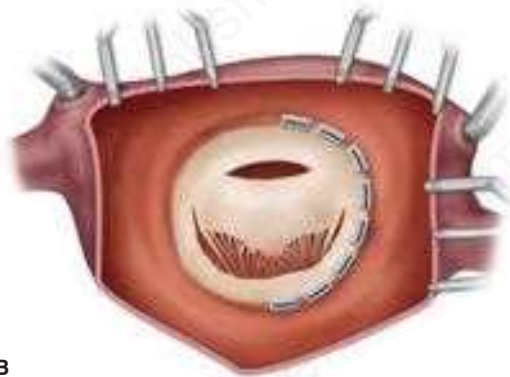

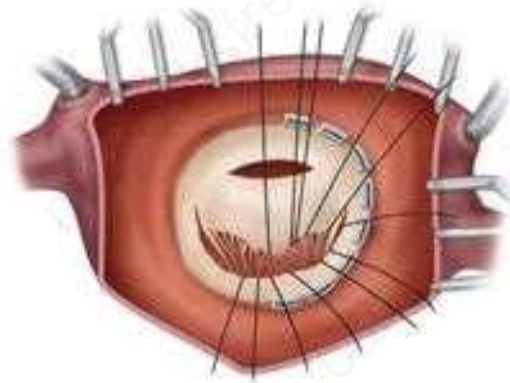

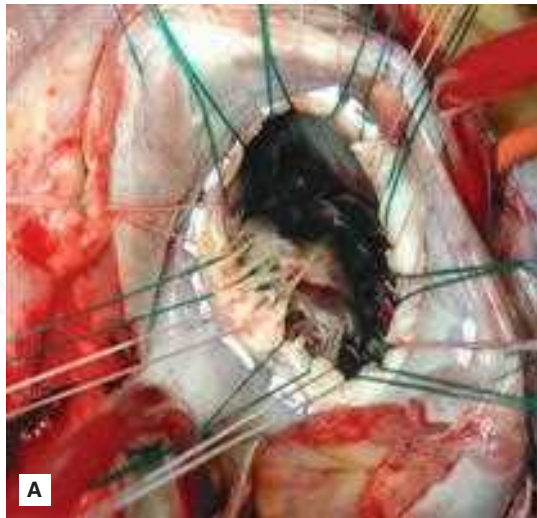

Which FMR valves to replace primarily remains controversial. The recent reports in the NEJM have added to our decision-making knowledge base. Perhaps the most important is the summary paper by Lancellotti.<sup>9</sup> In this report the predictors of failed FMR repair are mild annular dilatation, coaptation depth more than 1 cm, reverse angulation of the posterior leaflet or LV remodeling greater than 65 mm or a LVEDV greater than 100 mm indexed. Kron has also shown in the follow-up paper to Acker (NEJM) that posterior-basilar dyskinesia or akinesia is associated with a high rate of MR recurrence, even with an undersized repair.

While which patient to replace in FMR remains controversial, there is a consensus on the technical aspects of MV replacement for FMR. MV replacement should be a total valve sparing replacement. Yun demonstrated in a randomized trial comparing partial versus complete chordal sparing MV replacement, that the effects on left ventricular volume and function were much better preserved with complete versus posterior leaflet sparing. Nonvalve sparing mitral replacement should be abandoned. There are numerous techniques for total valve sparing MV replacement in FMR including anterior flip-over, in which a C-shaped incision is placed in the anterior leaflet and the entire anterior apparatus is moved posteriorly. Following appropriate valve sizing, pledgetted stitches are placed through the posterior annulus, the edge of the posterior leaflet, and the “flipped” anterior leaflet, placing both chordal apparatus and leaflets behind the MV prosthesis (Fig. 37-5). A second method of achieving total valve sparing is to remove the center of the anterior leaflet then rotating the

remaining portions of the anterior leaflet to the left and right. Valve sizing for FMR should be prudent and not “oversized”. With modern MV prostheses there should not be undue worry of stenosis and overly large bulky valves may impair LV dynamics in these already poor LVs. Acker showed in severe FMR patients, a total valve sparing operative mortality of 4.2%, which was only slightly higher than the operative mortality of 1.6% mitral repair for FMR patients.

## PERCUTANEOUS FMR OPTIONS

Percutaneous mitral therapy could theoretically offer improved safety as compared to surgical MV surgery and may be suited for the treatment of higher risk FMR patients. Taramasso reported a nonrandomized comparison of 91 patients undergoing surgical for FMR, and compared them against 52 patients undergoing MitraClip. All patients had severe FMR, were symptomatic despite GDMT and had ischemic or idiopathic dilated myopathies. The decision to perform surgical correction versus MitraClip therapy was based on logistic EuroSCORE and frailty. Patients were followed 18 months for surgery and 8 months for MitraClip. The surgical group underwent concomitant CABG 35%, tricuspid valve repair 25%, and atrial fibrillation ablation (26%). The MitraClip group was older, had a two-fold higher logistic EuroScore, Bigger LVs (LVEDD 70 mm vs 66 mm), and TR grade was higher. For the surgical group, in-hospital mortality was 6.6%, postoperative LOS was 11 days. No patient had pre-discharge MR grade  $\geq 3+$ , and 1-year freedom from MR  $\geq 3+$  was excellent at 94% with 89% surviving. For the MitraClip group, in-hospital mortality was 0%, postoperative LOS was 5 days, 9.6% had pre-discharge MR grade  $\geq 3+$ , and 1-year freedom from MR  $\geq 3+$  was 79% with 88% surviving. At 1-year follow-up, 89% of the surgery patients were NYHA Class I/II (22% NYHA Class I). In the MitraClip group at 1-year, 84% of the patients were NYHA Class I/II (48% NYHA Class I).<sup>55</sup> Additionally, Franzen<sup>56</sup> reported 6-month follow-up on 50 subjects with FMR with LVEF  $\leq 25\%$ , MR  $\geq 3+$  and in NYHA functional Class III or IV. After a mitralclip procedure, MR  $\leq 2+$  was present in 92% and 30-day and 6-month mortality was 6% and 19%. There were improvements in functional class, but only mild favorable LV remodeling at 6 months. Lastly, Aurichio<sup>57</sup> described 51 symptomatic nonresponders to CRT with FMR grade  $\geq 2+$  treated with a Mitralclip. They reported two procedural deaths, an additional 30-day mortality of 4.2%, and a 12-month mortality of 18%. These MitraClip reports are interesting, as there are few reports of MitraClip in subjects with FMR at high surgical risk. While none of these studies were randomized, the COAPT trial (MitraClip therapy in FMR vs GDMT) is currently underway in the United States to investigate the safety and effectiveness of the MitraClip in comparison to GDMT for FMR. The primary effectiveness endpoint is heart failure rehospitalizations at 24 months. Although the trial is not powered for mortality, this endpoint will be examined. This trial will be one of the largest studies in FMR and is expected to shape future surgical and

**FIGURE 37-5** Valve sparing MV replacement technique: anterior leaflet “flip-over.”

transcatheter FMR trials. Finally, new percutaneous devices for FMR, including annuloplasty and total mitral replacement are on the near horizon.

## SUMMARY

In summary, FMR is a ventricular disease, not a valvular disease. FMR leads to a vicious cycle of LV volume overload, and progressive MR. FMR complicating CHF predicts a

poor survival. Mitral surgery, to treat FMR has been undertaken with an acceptably low operative mortality.<sup>58</sup> However, one must decide on specific patient factors whether or not intervention to correct FMR is warranted in CHF patients, as a clear survival impact has not been shown compared GDMT or revascularization therapy alone. If surgery is undertaken, undersizing repairs with a complete rigid ring and valve sparing replacement is recommended. While “good” mitral repair probably leads to better LV remodeling,

patients identified to be at high risk for FMR recurrence after annuloplasty should have MV replacement. More complex mitral operations and percutaneous devices have shown promising results, but remain investigational. However, we do know that FMR is bad for CHF patients, and its elimination should be a therapeutic goal for these interesting and complex patients.

# Surgical Treatment of Mitral Valve Endocarditis

Gösta B. Pettersson • Syed T. Hussain

Mitral valve infective endocarditis (IE) is one of the more devastating complications of mitral valve disease, and if left untreated, it is universally fatal, like any other form of IE. In surgical practice, mitral valve endocarditis is usually less common than aortic valve endocarditis, with most infections occurring in native mitral valves. Although the distribution of causes of mitral valve dysfunction has changed in recent years, the overall incidence of IE has increased during the past 3 decades.<sup>1-6</sup> Rheumatic valve disease, which was a frequent predisposing factor to IE in the 1980s, is now rare in industrialized nations.<sup>6-7</sup> Predisposing factors more frequently encountered today, several of which are consequences of advances that characterize modern medicine,<sup>1-7</sup> include degenerative valvular disease, prosthetic valves, other intravascular prostheses and devices, hemodialysis, nosocomial infections, intravenous drug abuse, and immunosuppression. Repaired valves have a low risk of endocarditis compared with prosthetic valves. (To learn more about the epidemiology of IE, see Chapter 31.)

More effective antimicrobial agents have improved the early and long-term outcomes of patients treated for endocarditis. However, endocarditis is still associated with high rates of complications, morbidity, and mortality and frequently requires an operation for cure.<sup>1-13</sup> Increased experience and advances in surgical techniques have improved the success of these challenging operations.

## PATHOLOGY

### Native Mitral Valve Endocarditis

Native valve endocarditis (NVE) begins with endocardial injury, which allows deposition of fibrin and platelets with subsequent attachment of bacteria.<sup>6,14</sup> Endocardial injury may be secondary to rheumatic valvulitis or other leaflet disease, or valvular or annular calcification. Although vegetations may be seen anywhere on the leaflets or chordae, the usual site at which infective NVE of the mitral valve causes valvular destruction and invasion is the base of the atrial aspect of the mitral valve leaflets. Annular or

subannular invasion is more likely to cause atrioventricular (AV) separation when the invasion site is underneath the leaflet and is exposed to high ventricular pressure. Invasion into the AV groove with abscess formation is more serious and difficult to radically debride and sterilize (Fig. 38-1).<sup>15</sup> Fortunately, mitral annular invasion more often opens toward the atrium and is therefore shallow in most cases; invasion is generally more common and deeper in aortic valve IE.<sup>16</sup>

Destruction of the fibrous trigones and intervalvular fibrosa between the anterior mitral valve leaflet and the aorta is usually a consequence of aortic valve endocarditis with secondary mitral involvement.<sup>17</sup> An infected aortic valve may seed the anterior mitral leaflet or the tensor apparatus of the mitral valve, resulting in double-valve endocarditis; the mechanism may be a large vegetation hitting and directly infecting the anterior mitral leaflet or a jet lesion from aortic regurgitation that becomes infected.<sup>18</sup>

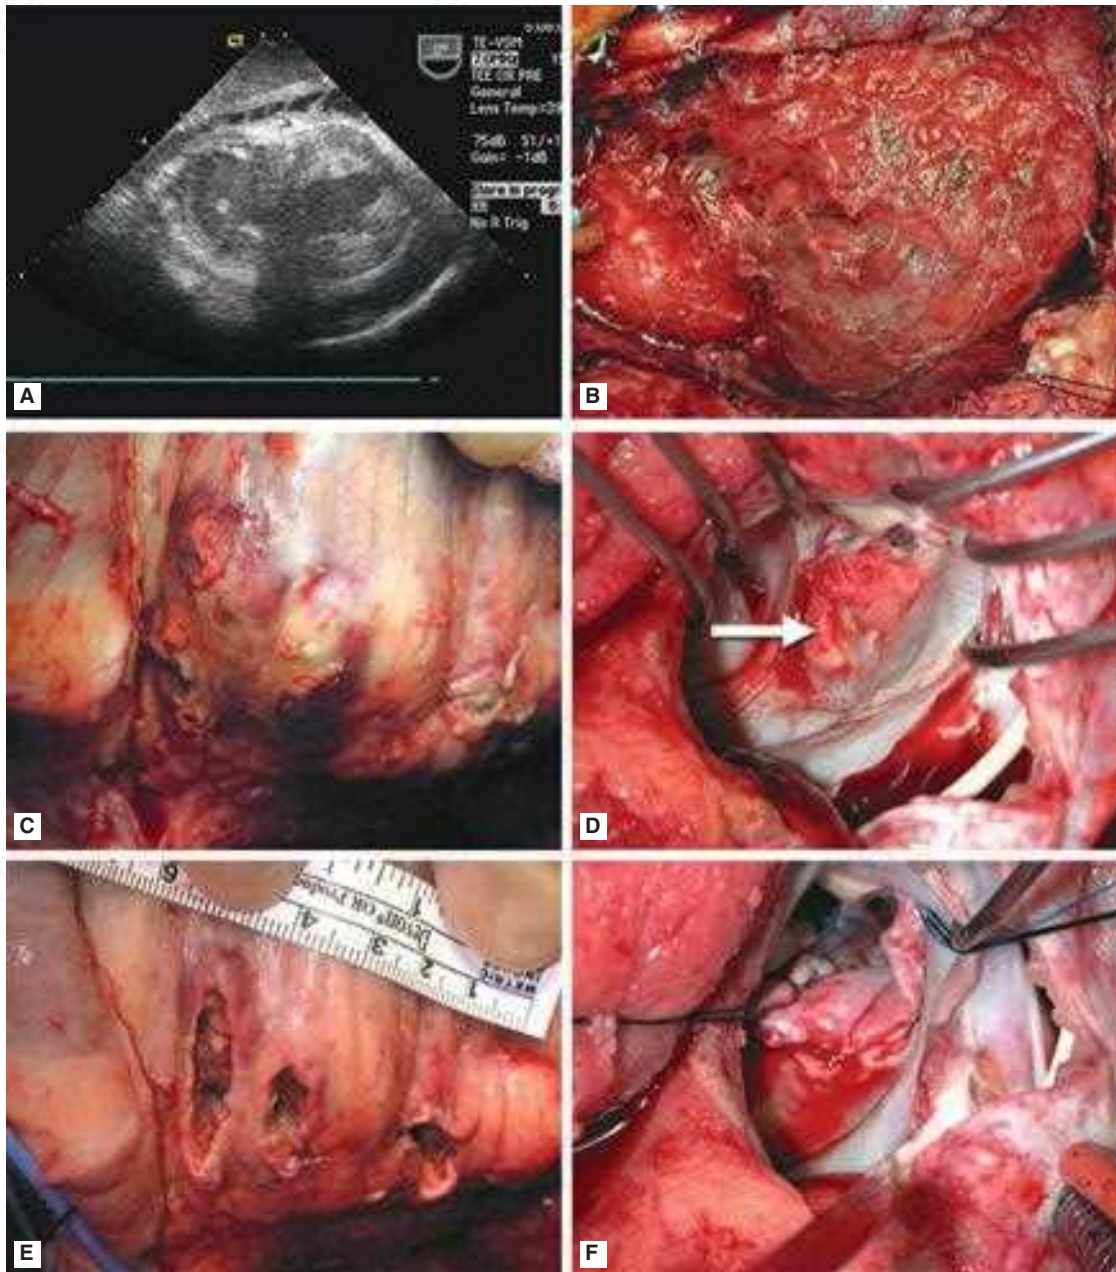

### Prosthetic Mitral Valve Endocarditis

Prosthetic valve endocarditis (PVE) is on the rise as the number of patients with prosthetic valves continues to increase. PVE is more common in the aortic than the mitral position.<sup>16</sup> This is because a majority of mitral valves are repaired, and repair is associated with a lower risk of endocarditis.

PVE within the first postoperative year is considered early endocarditis, and cases appearing more than 1 year after operation are termed late.<sup>6,19</sup> The risk of early PVE appears to be greatest approximately 5 weeks after valve implantation and declines thereafter.<sup>19</sup> The overall incidence of early PVE is 1%,<sup>20</sup> and the incidence of late PVE is 0.5 to 1% per year.<sup>21-23</sup> The type of prosthesis (mechanical vs bioprosthesis) does not influence the risk of PVE.

Early PVE is usually the result of intraoperative infection. Common portals of entry for bacteria that cause PVE are dental procedures, intravascular catheters, and skin infection.<sup>6,24</sup> Nosocomial infections contribute to late PVE, particularly in patients with medical comorbidities that require frequent

**FIGURE 38-1** A case of very advanced invasive mitral valve endocarditis. (A) Transesophageal echocardiogram showing circumferential pericardial effusion with fibrin stranding posteriorly. (B) Severe hemorrhagic pericarditis. Patient was septic and not responding to adequate antibiotic therapy. (C) After peeling fibrinous capsule off heart, these multiple necrotic spots, suggesting abscesses along the AV groove, became apparent. (D) Vegetations were found on the base of P<sub>3</sub> scallops of posterior leaflet. (E) After debridement, multiple abscess cavities in the AV groove were seen to communicate with both the left atrium and pericardium. Intact coronary vessels bridge the infected groove. (F) Annulus defect and communication were closed from inside the left atrium with an autologous pericardial patch. Groove was allowed to drain to the pericardium. (Reproduced with permission from Petterson GB, Hussain ST, Shrestha NK, et al: Infective endocarditis: an atlas of disease progression for describing, staging, coding, and understanding the pathology, *J Thorac Cardiovasc Surg* 2014 Apr;147(4):1142-1149.e2.)

hospital admissions or instrumentations (eg, hemodialysis) or immunosuppression (eg, organ transplantation).

Early PVE usually affects the sewing ring or the interface of the prosthetic valve and the annulus (often a site of clot formation). Involvement of the sewing ring starts locally but eventually becomes circumferential. Enzymatic degradation

of the tissue holding the sutures results in dehiscence of the prosthesis and periprosthetic leak. Progression of the infection and invasion may lead to tissue necrosis, abscess, and pseudoaneurysm formation. Mitral PVE may extend anteriorly to the fibrous trigone or posteriorly, causing AV separation.

## MICROBIOLOGY

Endocarditis of native valves is most often caused by *Streptococcus viridans*, *Staphylococcus aureus* or *epidermidis*, or *Enterococci*, with proportions varying according to valve (native vs prosthetic), pathology stage (noninvasive vs invasive), source of infection, patient age, and coexisting conditions.<sup>2,3,6,24-26</sup> *S. aureus* accounts for 25 to 30% of all infections and is also the most common organism in each major risk group, including intravenous drug users and those with intracardiac devices.<sup>4,6,25</sup> In our study, *S. aureus* was the most common pathogen for NVE (27.6%) and the second most common cause of PVE (22.1%), for which coagulase-negative *Staphylococcus* was most common (24.1%).<sup>8</sup> Among the major causative organisms, *Staphylococcus* species are most likely to be associated with invasive endocarditis (49%) and *Streptococcus* least likely (11%).<sup>16</sup> (IE microbiology is discussed in more detail in Chapter 31.)

## DIAGNOSIS

### Clinical Presentation

The diverse nature and evolving epidemiologic profile of IE ensure that it remains a diagnostic challenge.<sup>6</sup> The clinical presentation varies according to causative organism, preexisting cardiac disease, comorbidities, and complications. Mitral IE may present as an acute, rapidly progressive infection or as a subacute or chronic disease. Up to 90% of patients present with fever, often associated with systemic symptoms of chills, poor appetite, and weight loss.<sup>6</sup> Other findings include a new murmur (85%) or a change in an existing murmur. Embolic phenomena may cause petechiae, Roth spots, Osler nodes, and Janeway lesions. Embolic events occur in 20 to 50% of patients. Neurologic events develop in 20 to 40% of all patients with IE and are mainly the consequence of embolism of vegetation material, while mycotic aneurysm is much less common.<sup>6</sup> Splenomegaly may be present in both NVE and PVE. A high index of suspicion and low threshold of investigation to exclude IE are essential to diagnose and treat these affected patients early.

Laboratory findings include an elevated white blood cell count, anemia, and hematuria. Blood cultures from separate sites are usually positive in patients with bacterial endocarditis; two positive cultures out of three are considered diagnostic. However, cultures in patients with fastidious organisms or fungi may take more than 3 weeks to become positive, although diagnostic methods have improved. When IE is suspected, ideally three or more blood cultures should be collected before antibiotics are initiated, and at least two should be obtained immediately from different peripheral sites. Additional blood cultures should be obtained a few hours later. Unless the patient is septic, it is appropriate to hold off on starting antibiotics until an adequate number of blood cultures have been collected. Cases of IE in which blood cultures are negative (10%) may reflect either patients treated with antibiotics before the blood culture was drawn or

infections caused by fastidious organisms.<sup>3</sup> For cases caused by fastidious organisms, serologic testing or valve or blood polymerase chain reaction (PCR) assay can identify the pathogen 60% of the time.<sup>3,6</sup>

### Echocardiography and Imaging Studies

The present gold-standard diagnostic modality for documenting IE is transesophageal echocardiography (TEE). Specificity for TEE is approximately 90% and sensitivity is 90 to 100%.<sup>6</sup> In contrast, transthoracic echocardiography (TTE) is more operator dependent, and images may be compromised by surrounding structures; it is only 50% sensitive and 90% specific for IE.<sup>6</sup> Echocardiography must be performed as soon as IE is suspected.<sup>6</sup> TTE should be performed first, but often both TEE and TTE need to be performed.<sup>6</sup> Echocardiographic findings of IE include vegetations, periprosthetic leakage in patients with PVE, intracardiac fistulae, and abscess cavities. The echocardiographic examination is very good at evaluating valve function, but less reliable for assessing the severity and invasiveness of the infection. A negative echocardiogram does not exclude the diagnosis of IE. In situations with strong suspicion of IE, the diagnosis may be pursued by magnetic resonance imaging (MRI). In most patients with IE, MRI will demonstrate abnormal consistency of tissue in the annulus.

Metastatic infection is a possibility, and patients with IE and abdominal symptoms should undergo computed tomography (CT) scanning to rule out splenic or hepatic abscesses. Embolic infection of viscera is typically caused by staphylococcal organisms, and the brain is the most important and frequent site for emboli.<sup>3,6</sup> Any neurologic deficit or abnormality should trigger investigation with CT or MRI of the brain, fundoscopic examination, and occasionally cerebrospinal fluid examination. We require a CT or MRI of the brain irrespective of symptoms if the patient is going to undergo operation. Preoperative coronary angiography is indicated in all patients age 40 years or older, particularly if they have a history of coronary artery disease or previous revascularization procedures, or if coronary embolization is suspected. Clinical judgment must be exercised in patients with renal dysfunction.

### Diagnostic Criteria and Their Limitations

The Duke (and modified Duke) criteria for IE, based on echocardiographic results along with clinical, microbiologic, and pathologic findings, provide high sensitivity and specificity (~80% overall) for the diagnosis of IE (Table 38-1).<sup>27</sup> The Duke criteria, discussed in more detail in Chapter 31, are useful for the classifying IE, but do not replace clinical judgment for diagnosing IE when blood cultures are negative or when infection affects a prosthetic valve or pacemaker lead.

**TABLE 38-1: Duke Criteria for Native Valve Endocarditis and Prosthetic Valve Endocarditis**

**Major Criteria**

**Positive Blood Cultures for Infective Endocarditis**

Typical microorganism for infective endocarditis from two separate blood cultures: *Streptococcus viridans*, *S. bovis*, and HACEK group or community-acquired *Staphylococcus aureus* or *enterococci* in the absence of a primary focus, or

Persistently positive blood cultures, defined as recovery of a microorganism consistent with infective endocarditis from:

Blood cultures drawn >12 hours apart or

All of three or most of four or more separate blood cultures, with the first and last drawn at least 1 hour apart

**Evidence of Endocardial Involvement**

Positive echocardiogram for infective endocarditis

Oscillating intracardiac mass on valve or supporting structures or in the path of regurgitant jets or on implanted material in the absence of an alternative anatomic explanation, abscess, new partial dehiscence of prosthetic valve, or new valvular regurgitation (increase or change in preexisting murmur not sufficient)

**Minor Criteria**

Predisposition: predisposing heart condition or intravenous drug use

Fever: temperature  $\geq 38$  C (100.4°F)

Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhage, and Janeway lesions

Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor

Microbiologic evidence: positive blood culture but not meeting major criterion as noted previously or serologic evidence of active infection with organisms consistent with infective endocarditis

Echocardiogram: consistent with infective endocarditis but not meeting major criterion as noted previously

New-onset heart failure

New conduction disturbances

HACEK group = Haemophilus spp., Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens, and Kingella kingae  
Data from Pérez-Vázquez A1, Fariñas MC, García-Palomo JD, et al: Evaluation of the Duke criteria in 93 episodes of prosthetic valve endocarditis: could sensitivity be improved? *Arch Intern Med.* 2000 Apr 24;160(8):1185-1191.

**INDICATIONS FOR SURGERY**

Surgery plays a pivotal role in managing native mitral valve endocarditis. Indications for surgical intervention in patients with NVE and PVE are presented in Table 38-2.

Congestive heart failure is the most common indication for surgery. Our indications for surgery have gradually moved toward earlier intervention to avoid devastating complications.

The majority of patients with PVE will require surgery for cure.<sup>6,28</sup> Indications for surgical intervention in patients with PVE include heart failure, new heart block (much less common with mitral valve IE than aortic valve IE), ongoing sepsis, valve dehiscence, recurrent systemic embolism, relapse of infection, and fungal infection. Surgery should be considered in all cases of early PVE, because most are caused by *staphylococci* or other aggressive organisms.<sup>6,19</sup>

Operation for large mobile vegetations to prevent embolization in both NVE and PVE remains a controversial indication in the absence of hemodynamic compromise or other surgical indications.<sup>6</sup> The risk of embolism is highest during the first 2 weeks of antibiotic therapy and is related to the size and mobility of the vegetation. The decision to operate early to prevent embolism thus depends on size and mobility of

vegetations, previous embolism, type of microorganism, and duration of antibiotic therapy.

Fungal mitral valve PVE is uncommon and characterized by large vegetations, and these infections are even more

**TABLE 38-2: Surgical Indications for Native Valve Endocarditis and Prosthetic Valve Endocarditis**

1. Severe mitral regurgitation, with or without symptoms of congestive heart failure
2. Uncontrolled sepsis despite proper antibiotic therapy
3. Presence of an antibiotic-resistant organism
4. Fungal endocarditis or endocarditis caused by *Staphylococcus aureus* or gram-negative bacteria
5. Presence of mitral annular abscess, extension of infection to intervalvular fibrous body, or formation of intracardiac fistulas
6. Onset of a new conduction disturbance
7. Large vegetations (>1 cm), particularly those that are mobile and located on the anterior leaflet, and thus at high risk for embolic complications
8. Multiple emboli despite appropriate antibiotic therapy

difficult to cure than is PVE caused by other organisms. Lifelong oral suppressive antifungal therapy after completion of intravenous therapy is often recommended.<sup>6</sup>

## TIMING OF SURGERY

Many patients with NVE and a majority with PVE require surgical intervention, and the challenge for the surgeon is to determine the appropriate timing of surgery.<sup>3,6,24,29-32</sup> It is our belief that in most cases, the operation should not be delayed once surgical indications are present. It is, however, important to know the sensitivity of the organism to ensure appropriate antibiotic coverage at the time of surgery. The presence of locally uncontrollable infection indicates a need for early surgery in patients with NVE. Early surgery is required for most patients with PVE before it is complicated by heart failure, severe prosthetic dysfunction, or abscess. Patients with PVE caused by *S. aureus* risk rapid progression and invasion. The same principle applies to PVE caused by fungal or other highly resistant organisms.<sup>6</sup> However, delaying surgery is usually advised in the presence of cerebral complications.<sup>6,32,33</sup> Before valve surgery, patients with IE should undergo careful neurologic evaluation, and all should be evaluated by head CT or MRI. The standard recommendation is that surgery should be delayed for 1 to 2 weeks in patients with non-hemorrhagic strokes, and for 3 to 4 weeks in patients with hemorrhagic strokes, to reduce the risk of further intracranial bleeding during heart surgery.<sup>6,32</sup> Intracranial hemorrhage in the setting of PVE has been associated with mortality as high as 28 to 69%. To exclude a mycotic aneurysm, an angiography is required. Nonhemorrhagic embolic stroke has a low risk of transformation into a hemorrhagic infarct during heparinization and cardiopulmonary bypass. The risk of worsening neurologic symptoms as a consequence of operation is time related, decreasing with increasing interval from the initial neurologic event. The risk of worsening the stroke symptoms must be weighed against the indications for surgery and the risk of additional emboli during the waiting period. If cerebral hemorrhage has been excluded by CT or MRI and neurologic damage is not severe (ie, coma), surgery can be performed with a relatively low neurologic risk (3 to 6%) and good probability of complete neurologic recovery.<sup>6</sup>

## OPERATIVE TECHNIQUES

### General Principles

Operations for endocarditis are guided by some basic principles: optimal timing of surgery as discussed above, good exposure of the valve, radical debridement, optimal choice for reconstruction of the heart and repair or replacement of the valve, and adequate postoperative antibiotic treatment. Radical debridement with removal of all infected and necrotic tissue and foreign material is difficult to accomplish in mitral cases with AV groove invasion, necrosis, and abscess formation (Fig. 38-1). Aortic root infections are much easier to lay open and debride. In addition, reconstruction after invasion

of the AV groove and AV separation entails closing off the infected space and leaving it without drainage.

### Native Mitral Valve Endocarditis

Intraoperative TEE should be performed in all cases to carefully evaluate the valve before commencing the procedure. For NVE, our approach is to attempt repair if feasible. Mitral valve repair can be performed provided there is sufficient remaining tissue to allow valvular reconstruction.<sup>12,34-43</sup> Successful repair can be achieved by an experienced surgeon in up to 80% of patients.<sup>41</sup> If repair is not technically feasible and valve replacement is needed, the choice of a tissue or mechanical valve is based primarily on consideration of age, life expectancy, presence of comorbidities, and compliance with anticoagulation.<sup>7,32</sup> Although there is some experience with the mitral valve allograft for treating mitral valve IE, it remains experimental, with too few data available to support this strategy.<sup>44</sup>

Operations for NVE are best conducted through a full median sternotomy. Cannulation for cardiopulmonary bypass involves arterial return via the ascending aorta and bicaval cannulation for venous drainage. It is advisable to arrest the heart before manipulating it too much. Myocardial protection is achieved using antegrade and retrograde blood cardioplegia. We have a preference for opening the right atrium and placing the retrograde cardioplegia cannula directly into the coronary sinus through a purse-string suture.

The mitral valve is exposed either via a left atriotomy through the interatrial groove or transeptally through the right atrium, which is our preference. If the left atrium is small, an extended transseptal-dome approach is used. Opening the aorta allows dual exposure and is helpful in many cases for debridement and suture placement and for avoiding unnecessary damage to the aortic valve. Once good exposure of the mitral valve is accomplished, the valve is evaluated to assess for presence of paravalvular abscesses, intracardiac fistulae, or intervalvular fibrous body/ventricular involvement. Radical resection of all necrotic tissue is performed. All grossly infected tissue is removed without too much concern for the possibility of repair. Unaffected leaflet, chordae, and papillary muscles are preserved to support the posterior annulus. Specimens are divided and sent for both pathologic and microbiologic examination and need for PCR is considered.

### Anterior Leaflet Repair

Kissing lesions of the anterior mitral leaflet encountered with aortic endocarditis can be repaired with autologous pericardium.<sup>45</sup> A patch of pericardium is sutured to the remaining tissue of the anterior leaflet with running polypropylene suture (Fig. 38-2). More extensive destruction involving both the aortic valve and the anterior leaflet of the mitral valve can be repaired using a freestanding aortic root allograft with the anterior leaflet of the mitral valve still attached. The allograft's attached aortomitral curtain can be used to reconstruct the base of the native anterior mitral leaflet.<sup>17</sup>

**FIGURE 38-2.** Repair of anterior leaflet perforation using a patch with autologous pericardium followed by annuloplasty.

Involvement of the free margin of the anterior leaflet can be managed with triangular resection. Anterior leaflet chordal rupture can be repaired with chordal transposition from the posterior leaflet or transfer of secondary chorda to the free margin of the anterior leaflet. Artificial chordae may also be used to replace ruptured anterior leaflet chordae.

### Posterior Leaflet Repair

The middle scallop ( $P_2$  segment) of the posterior leaflet is frequently affected by the infectious process. Repair can be performed with triangular or quadrangular resection of the middle scallop. A sliding repair is useful to close the gap between the remaining two scallops (Fig. 38-3). Extensive destruction of the posterior annulus requires removal of all necrotic tissue and annular reconstruction with autologous pericardium. Occasionally, repair of the annulus and the posterior leaflet can be accomplished with the same patch if chordal support to the leaflet is good. Any patch needs to be generous, and suture lines must be tension free. Running polypropylene sutures (4-0 or 5-0) are used on the entire patch. If replacement is required, a mechanical or bioprosthetic valve may then be inserted, affixing the prosthesis to the patch.<sup>15</sup>

Use of a prosthetic anuloplasty ring in NVE may be necessary to provide a durable repair and has a low risk of reinfection.<sup>39,40</sup> A good and durable repair outweighs the added low risk of reinfection associated with the anuloplasty ring.

### Prosthetic Valve Endocarditis

Operations for PVE are reoperations, preferably performed via a median sternotomy. A preoperative chest CT is valuable to avoid adverse events during reentry. A right anterolateral thoracotomy in the fourth intercostal space is an alternative; this approach is suggested by some as particularly useful in patients with multiple previous sternotomies, bypass grafts near the sternum, or a history of mediastinal radiation and/

**FIGURE 38-3.** Quadrangular resection and sliding repair for posterior leaflet vegetation with ruptured chordae. (A, B) Segment of posterior leaflet is resected and a portion of leaflet detached from the annulus. (C) Leaflet remnants are sutured to the annulus, taking deep bites to reduce leaflet height. Leaflet edges are re-approximated in the center. Anuloplasty completes the repair.

or mediastinitis.<sup>46,47</sup> However, a right thoracotomy for mitral reoperations allows limited access, sometimes denies aortic clamping, and may be associated with a risk of stroke. We uniformly use sternotomy for these reoperations.

### Myocardial Protection

Cardiopulmonary bypass is instituted using the ascending aorta and bicaval cannulation, and myocardial protection is achieved using antegrade and retrograde blood cardioplegia. Open direct cannulation of the coronary sinus is preferred.

### Mitral Valve Exposure

Our usual approach to the mitral valve is via the right atrium and atrial septum. If the left atrium is large and adhesions modest, a standard left atriotomy may be used. Exposure may be enhanced by dividing the superior vena cava and extending the left atriotomy under the aortic root, toward the left auricle. This approach provides good exposure even when the left atrium is small. Releasing the left heart from the chest wall improves mitral valve exposure, while not doing that sometimes makes exposure very difficult. Presence of an aortic valve prosthesis also makes exposure more difficult.

### Reconstruction of the Mitral Annulus

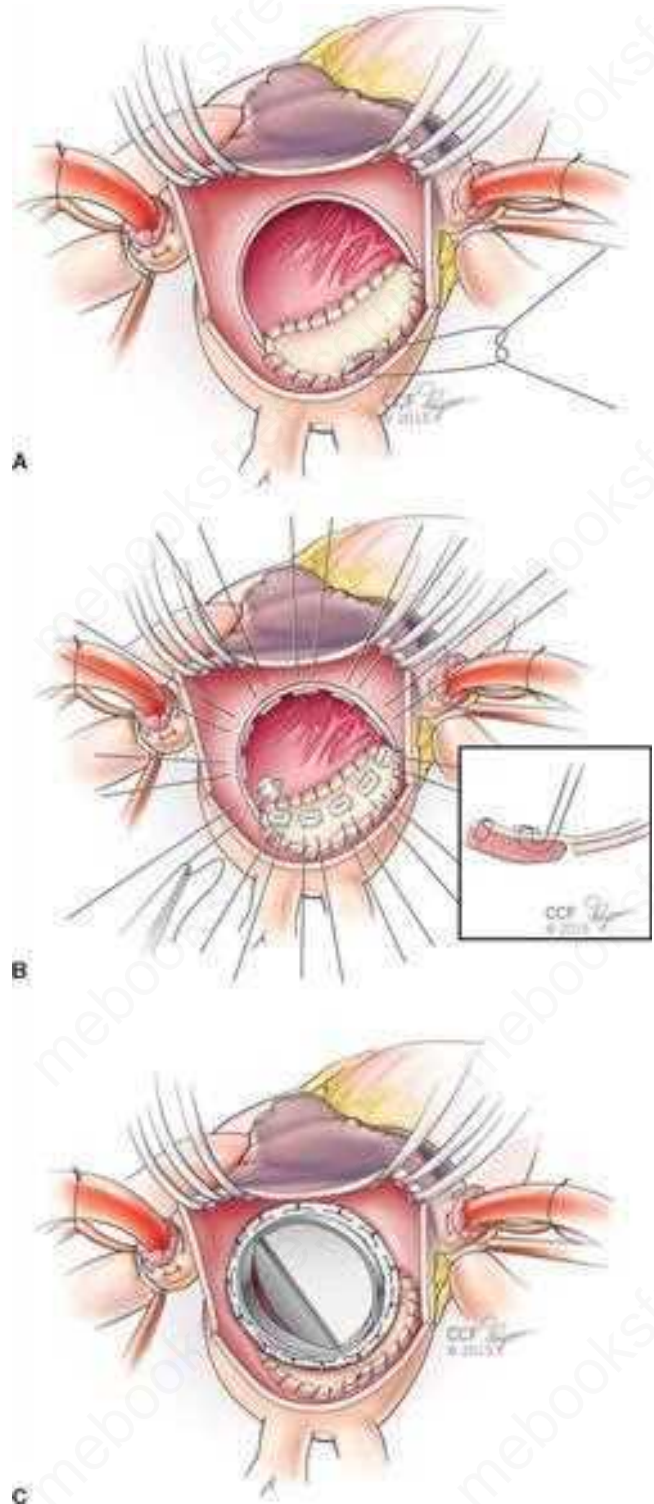

Once exposure of the mitral valve is obtained, the infected prosthesis is removed and the annulus debrided of all old

suture material and pledgets. Mitral valve PVE may produce separation of the left atrium, left ventricle, and prosthesis. In these situations, the operation includes debridement of the annulus with subsequent annulus reconstruction using autologous or possibly glutaraldehyde-fixed bovine pericardium (David technique).<sup>15,48</sup> With this technique, a semi-circular pericardial patch is used to reconstruct the annulus, with one side of the patch sutured to the endocardium of the left ventricle and the other side to the left atrium. This patch covers the cavity, which must be thoroughly debrided and sterilized before the patch is affixed. The new valve prosthesis is affixed to this reconstructed annulus (Fig. 38-4). The patch should be generous in order to minimize tension on suture lines. We look at this patch as a reinforcement of an undermined area rather than true reconstruction. The prosthesis should be implanted in such a way that there is no residual pseudo aneurysm on the ventricular side. In most situations with annular reconstruction, we use a bioprosthesis to avoid anticoagulation in the postoperative period, and have a preference for prostheses with generous soft sewing rings.

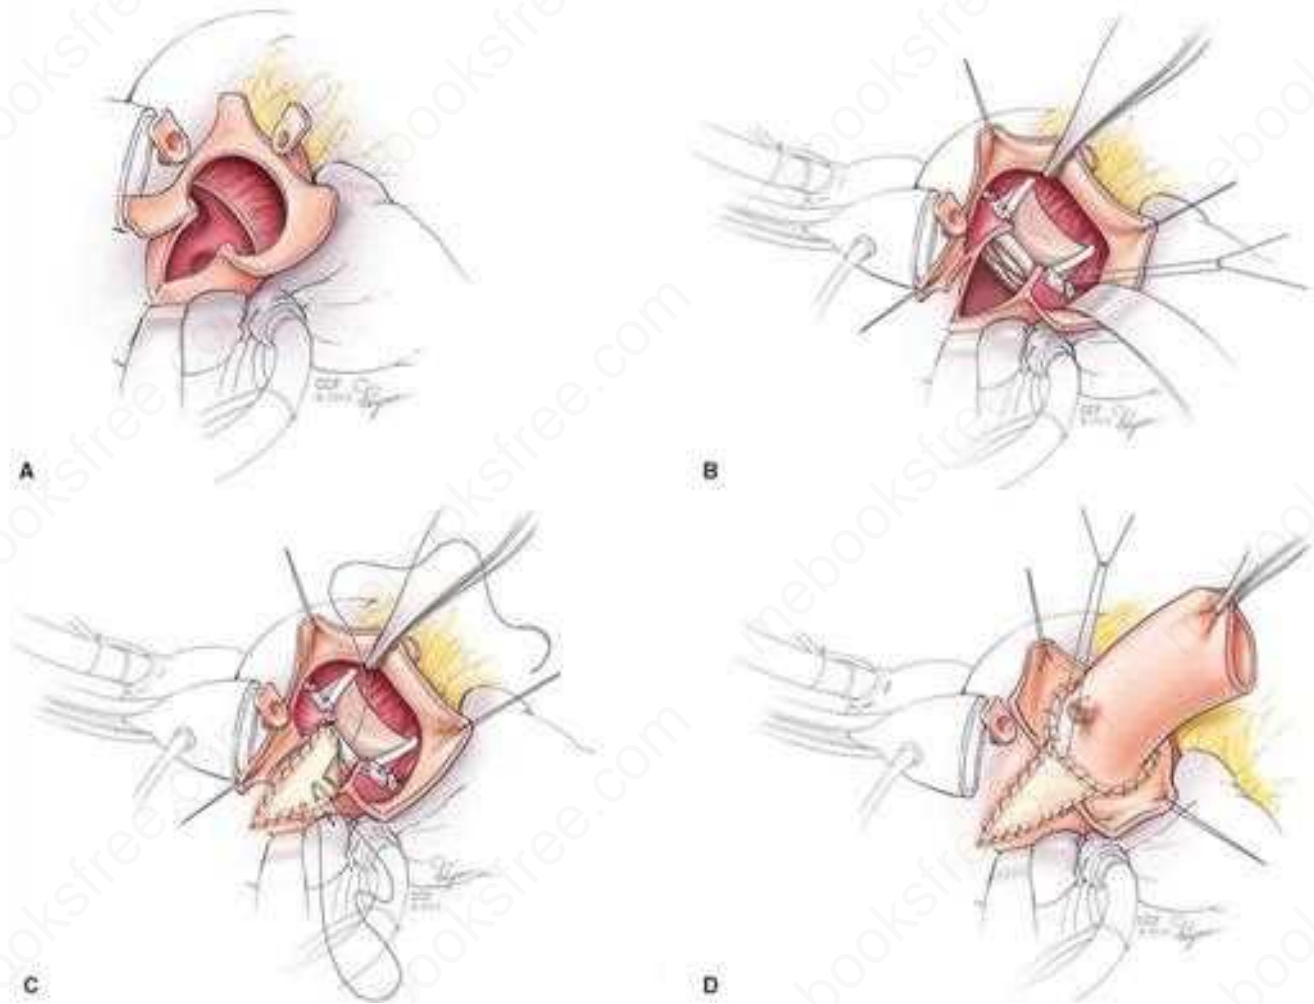

An alternative technique for mitral annular reconstruction is that described by Carpentier and colleagues.<sup>49</sup> This technique involves suture closure of the AV separation. Valve sutures are then placed with a large needle around this suture line with pledgets on the ventricular side. We have observed pseudoaneurysm formation after application of this technique, but still consider it useful in cases with shallow and fairly narrow AV separation.

### Reconstruction of the Fibrous Trigones and Interventricular Fibrosa

Extension of PVE into the intervalvular fibrosa/fibrous trigones may necessitate replacement of both the mitral and aortic valves. This usually occurs in the setting of PVE affecting both the aortic and mitral valves and seldom with isolated mitral valve endocarditis. Reconstruction of the intervalvular fibrosa as well as replacement of both the aortic and mitral valves are required (Fig. 38-5). In such circumstances the fibrous trigone may be reconstructed with autologous (or bovine) pericardium.<sup>17,49-52</sup> Perfect exposure is mandatory, whether it is provided by the extended transeptal approach or by dividing the superior vena cava and extending the left atriotomy from anterior to the right superior pulmonary vein toward the dome of the left atrium. This approach allows debridement of the aortic and mitral valves as well as the fibrous trigones. The prosthetic mitral valve is then sewn normally to the annulus posteriorly, medially, and laterally. The superior portion of the mitral valve annulus is reconstructed with a pericardial patch that supports and replaces the intervalvular fibrosa. This patch is anchored to the mitral valve annulus and the sewing ring of the prosthesis far enough back where the mitral annulus is still preserved. The patch is sandwiched between the mitral valve suture pledgets and annulus on the ventricular side. Once the mitral valve is secured in place, the aortic valve prosthesis is affixed to the aortic annulus. Posteriorly, the pericardial patch is used to

**FIGURE 38-4** Reconstruction of mitral annulus. (A) Prosthetic valve endocarditis with posterior paravalvular abscess. The valve has been removed and the abscess debrided. A generous pericardial patch sewn to the ventricle and atrium excludes the abscess cavity and reconstructs the annulus. (B) Valve sutures are placed with the pledgets on the ventricular side. (C) A new prosthesis is affixed to the pericardial patch and annulus. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography ©2015. All rights reserved.)

**FIGURE 38-5** Reconstruction of the fibrous trigones. (A) Infection involves the mitral and aortic valves. After removing both the aortic and mitral prostheses, the divided intervalvular fibrosa converts the aortic and mitral orifices into a single large opening into the left ventricle. Notice that the planes of the mitral and aortic annuli are at right angles to each other. (B) Mitral prosthesis in place, with two-thirds of the sewing ring placed along the posterior mitral annulus and a residual defect toward the aorta anteriorly. (C) A triangular autologous pericardial patch is used to reconstruct the intervalvular fibrosa and close the roof of the left atrium. The base of the patch is sewn to the anterior third of the mitral prosthesis. (D) Implantation of an aortic allograft. The base of the allograft mitral valve is sewn to the mitral valve prosthesis and patch. It is important to pay attention to the corners by the central fibrous body and the lateral trigone in order to ensure that the corners are sealed and no sutures are under tension to avoid tears and leaks. (Reproduced with permission from Pettersson GB, Hussain ST, Ramankutty RM, et al. Reconstruction of fibrous skeleton: technique, pitfalls, and results, *Multimed Man Cardiothorac Surg*. 2014 Jun 18;2014.)

cover any defect in the annulus and intervalvular fibrosa, and the lateral corners are sealed. The aortic valve is then sewn to that patch.<sup>17</sup> Another option is aortic valve and root allograft replacement with the allograft in an anatomic position and orientation, suturing the intervalvular fibrosa/mitral valve of the allograft directly to the mitral valve prosthesis.<sup>17</sup>

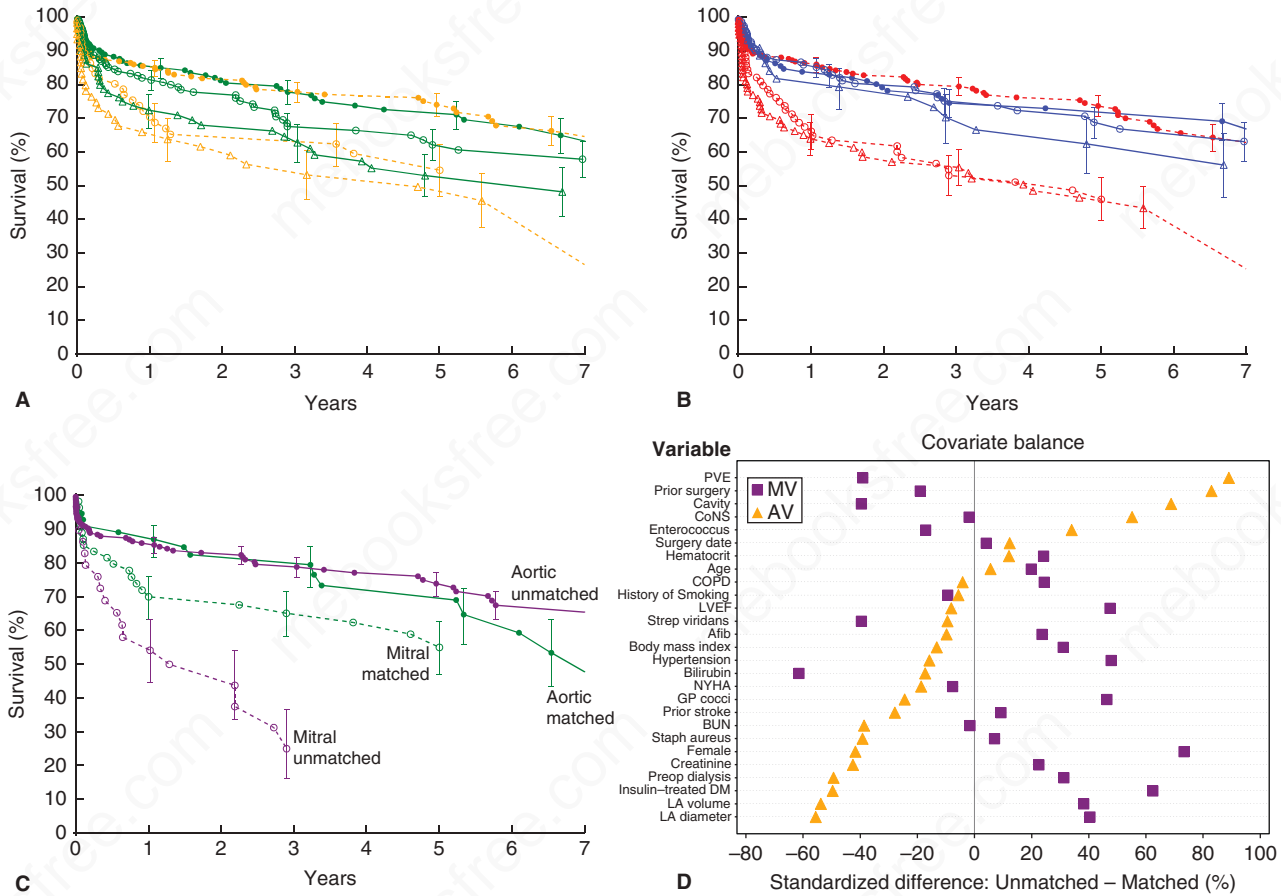

### Postoperative Antibiotic Treatment

Regardless of the mitral procedure performed, all patients with active infection receive 6 weeks of postoperative antibiotic therapy as final cure of the infection is by the antibiotics. In patients with fungal endocarditis, the intravenous treatment is followed by oral antifungal suppression for life.

## RESULTS

### Native Mitral Valve Endocarditis

Overall, the outcomes for patients requiring surgery for mitral valve IE are worse than for patients with aortic valve IE (Fig. 38-6).<sup>15</sup> This is explained by mitral IE patients being sicker as well as the fact that invasive mitral disease is surgically more difficult to deal with. Superior event-free survival, lower hospital mortality, and improved long-term survival for mitral valve repair compared with replacement have been reported (Fig. 38-7).<sup>35-43</sup> In our Cleveland Clinic series of 146 patients who had surgery for NVE, valve repair resulted in lower hospital mortality ( $p = .008$ ) and better long-term survival ( $p = .05$ ) than valve replacement.<sup>43</sup> Infection-free

**FIGURE 38-6** Survival after surgery for left-sided infective endocarditis (IE). Each symbol represents a death and vertical bars 68% confidence limits, equivalent to  $\pm 1$  standard error. **FIGURE 38-7** Event-free survival for all patients undergoing mitral valve repair or replacement. (Reproduced with permission from Muehrcke DD, Cosgrove DM 3rd, Lytle BW, et al. Is there an advantage to repairing infected mitral valves? *Ann Thorac Surg* 1997 Jun;63(6):1718-1724.)

survival was also better after valve repair than replacement, with a reinfection rate of less than 1% per year.<sup>43</sup> The most important explanations for these excellent outcomes after valve repair are (1) less advanced disease, (2) use of less prosthetic material in the infected field, (3) better preservation of left ventricular function associated with repairing mitral valves, and (4) less sick patients. Those undergoing valve replacement were the sickest patients with the most advanced and destructive disease. The choice of prosthesis, whether bioprosthetic or mechanical, does not make a difference, as they have similar survival rates and freedom from reinfection.<sup>32,53,54</sup>

### Prosthetic Valve Endocarditis

Despite improved antimicrobial regimens, outcomes of medical therapy alone are poor for PVE, particularly for patients with annular involvement or early endocarditis

after valve surgery. PVE has been associated with a much higher operative mortality than NVE.<sup>10,48,53</sup> With improved understanding of the disease and better management, both medical and surgical, the results of mitral PVE now approach those of mitral NVE (Fig. 38-6).<sup>14</sup> Outcomes are worse for invasive mitral infection than for both invasive aortic infection and infection limited to valve cusps or leaflets, and this is true for PVE and NVE (Fig. 38-6).<sup>14</sup> The reason is related to the inherent mitral valve anatomy in patients with invasive disease into the AV groove, limiting our ability to perform radical debridement, sterilization, and drainage of the infected area. In addition, we lack an alternative mitral valve prosthesis that is equally optimal for IE, simple to implant, and as good as the allograft for the aortic valve. Allograft mitral valve replacement is not simple and is still experimental.<sup>55</sup>

# Mitral Valve Repair for Congenital Mitral Valve Disease in the Adult

David P. Bichell • Bret Mettler

Isolated, non-reoperative congenital mitral valve abnormalities in adults are rare.<sup>1,2</sup> Mitral pathology concurrent with other cardiac anomalies is less rare. Atrial septal defect is the third commonest congenital cardiac lesion presenting in adulthood, occurring in an estimated 1/5700 persons, nearly 10% are ostium primum defects, and almost all primum defects have an associated mitral valve cleft.<sup>3</sup> Congenital mitral valve pathology such as arcade or parachute mitral valve very rarely present in adulthood, though the patients surviving unrepaired to adulthood may be milder forms, amenable to repair.

In contrast to the rarity of non-reoperative mitral pathology presenting in adulthood, patients needing reoperation for formerly corrected mitral pathology represent an expanding adult population. Survivors of corrective surgery in infancy and childhood add an estimated 8960 new adults cases annually to the adult congenital population in the US and there are over 1,000,000 adults living in the US today with congenital heart disease.<sup>4</sup> The prevalence of atrioventricular septal defect (AVSD) is 5.3 per 10,000 live births.<sup>5</sup> Mitral insufficiency is the principal reason for reoperation in the AVSD population. For patients undergoing an anatomic repair for complete or partial AVSD in infancy, freedom from reoperation for mitral regurgitation (MR) is 81 to 83% at 15 years, so the number of adults presenting with the need for reoperative mitral valve surgery is steadily increasing as successful infant repairs continue to accrue.<sup>6</sup>

## PATHOPHYSIOLOGY

### Normal Mitral Valve

Consideration of the normal mitral apparatus is important to the success of any repair for congenital mitral valve abnormalities. Congenital mitral valve pathology is widely variable between patients, demanding an individualized approach to each. A systematic analysis of the annular, leaflet, and

subvalvar support structures informs a surgical strategy that can be tailored to the individual.

### Annulus

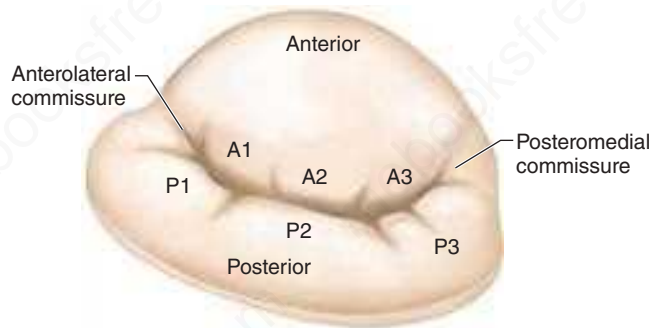

The normal mitral valve is attached to a dynamic, saddle-shaped fibrous annulus with the horn of the saddle at the anterior annulus, and the low points of the saddle at the commissures—a shape that minimizes leaflet stress through the cardiac cycle (Fig. 39-1).<sup>7</sup> The annulus is dynamic through the cardiac cycle, with apical to basilar displacement of the entire annulus, annular “folding” that changes the planar versus saddle configuration of the annulus, and a 23 to 40% contraction in annular circumference between systole and diastole.<sup>8</sup>

### Leaflets

The anterior, or aortic leaflet, occupies one-third of the annular circumference, is broader than the posterior leaflet, and is anchored in its continuity with the aortic annulus. The posterior, or mural leaflet occupies two-thirds of the annulus and is narrower than the anterior leaflet.<sup>8</sup> The leaflets are divided into named regions A1, P1, A2, P2, A3, P3, descriptive designations that are useful to consider in a systematic examination of the valve at repair (Fig. 39-1).

### Subvalvar apparatus

All chordal leaflet support radiates from the anterolateral and posteromedial papillary muscles that are anchored on the free wall of the left ventricle, and correspond to the anterolateral and posteromedial commissures of the valve. Chordal attachments are at the free edge (“primary” or “marginal” chordae), the mid leaflet, (“secondary” or “rough zone” chordae), or closer to the hinge/annulus (“tertiary” or “basal” chordae).<sup>8</sup> Papillary muscle separation is important to normal

**FIGURE 39-1** Descriptive anatomy of the mitral valve. The annulus is saddle-shaped, with commissures at the low points. Anterior and posterior leaflets and their subvalvar support structures are described as anterior and posterior components of 3 segments.

valve excursion, and fusion or close spacing produces functional valve stenosis.

The physiologic patterns that result from congenital dysplasias of the mitral valve defy clean categorization, as several conditions produce stenosis and insufficiency together, in variable combination. We organize our description of anatomic mitral malformations into (1) lesions predominantly causing stenosis, (2) those commonly associated with combined stenosis and regurgitation, and (3) those predominantly associated with regurgitation.

## Congenital Mitral Stenosis

Ruckman and Van Praagh categorized primary congenital mitral stenosis into four basic subtypes, based on autopsy data: (1) typical, (2) hypoplastic, (3) supralvalvar ring, and (4) parachute mitral valve (Fig. 39-2).<sup>9</sup> We will describe these categories, including a broader spectrum of supralvalvar entities with supralvalvar ring, and a variety of subvalvar pathologies in addition to parachute mitral valve.

**FIGURE 39-2** Papillary muscle and chordal arrangement in congenital forms of mitral stenosis. **LEFT:** The “normal” mitral valve, with well-spaced papillary muscles, chordal support radiating from papillary muscles to their respective commissures and supporting the leaflets. Leaflets separate fully in diastole to permit optimal, unobstructed left ventricular filling. **MIDDLE:** The “typical” form of mitral stenosis, with normal sized annulus, closely spaced papillary muscles with inflow restriction owing to restrictive interchordal spaces and restricted leaflet mobility. **RIGHT:** The “parachute” deformity, with a single papillary muscle, inflow restriction at tight interchordal spaces and tethered leaflets.

## Typical

In the “typical” variant of congenital valvar stenosis, the left ventricular size is normal, the mitral annulus is normal, and obstruction occurs within the valve elements themselves. The interchordal spaces are obstructed by fibrous tissue, leaflets may be thickened, chordae shortened, and papillary muscles, though distinct, are closely spaced.<sup>9</sup> In some cases, the chordal apparatus is nearly absent, and papillary muscle tissue may insert directly and rigidly onto the leaflet itself, greatly reducing leaflet mobility and options for repair.

## Hypoplastic

The hypoplastic variant is usually associated with other left-sided abnormalities such as ventricular hypoplasia, aortic stenosis, aortic arch hypoplasia, or coarctation of the aorta. The mitral annulus itself is small, and multiple valve elements are small. Hypoplastic mitral stenosis generally produces physiology that is either lethal or requires surgical palliation in infancy, and is therefore seldom found in the adult.<sup>9</sup>

## Supramitral Ring and other Supralvalvar Pathology

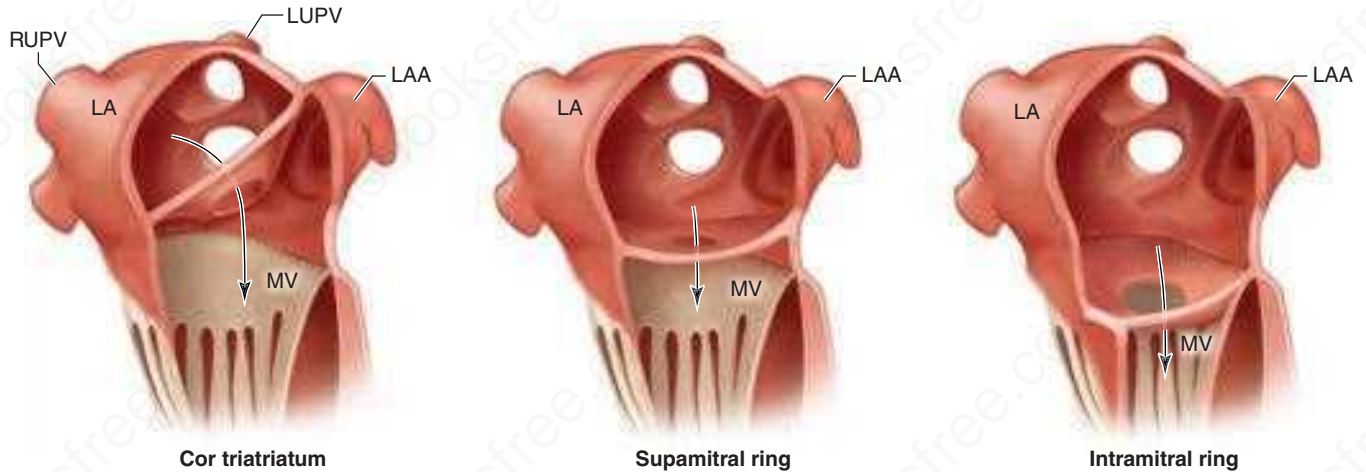

Supralvalvar obstruction to mitral inflow presenting in adulthood can take a variety of forms, causing inflow obstruction from a level remote from the valve (such as Cor Triatriatum), adjacent to the valve (supralvalvar ring), or intimately associated with the valve (intramitral ring) (Fig. 39-3).

Cor triatriatum is embryologically distinct from true mitral valve stenosis, but acts similarly, is encountered in the adult, and is therefore included. Cor Triatriatum is a membranous subdivision of the left atrium into two chambers—an upper chamber that receives the pulmonary veins, and a lower chamber that excludes pulmonary veins but includes the left atrial appendage. An “os” in the membrane is the portal through which all pulmonary venous return passes to the lower chamber and in turn through the mitral valve. Cor triatriatum can present with mild-to-severe restriction to mitral inflow, depending on the size of the os and the alternate pathways of left ventricular filling that may exist (Fig. 39-3).<sup>10,11</sup>

The true **supramitral ring** is a fibrous structure residing on the atrial side of the mitral annulus, with variable adherence to the mitral valve leaflet itself. It can produce restriction to inflow according to the size of the inflow orifice, and by restricting the movement of the leaflet itself when adherent (Fig. 39-3).

The **intramitral ring** is a thin fibrous membrane intimately associated with the leaflets and restricting leaflet excursion. The intramitral ring is always associated with subvalvar pathology (Fig. 39-3).<sup>12</sup>

A persistent left superior vena cava, present in 0.3 to 0.5% of population, courses across the floor of the left atrium in the supramitral area, and has been described to itself, uncommonly, produce a supralvalvar obstruction.<sup>13,14</sup>

**FIGURE 39-3** Congenital forms of supralvalvular mitral stenosis. **LEFT:** Cor triatriatum is a membranous subdivision of the left atrium into two chambers. The upstream chamber contains the pulmonary veins and the downstream chamber includes the left atrial appendage. **MIDDLE:** The “supramitral ring” is a membranous restriction to mitral inflow that is downstream of pulmonary veins and atrial appendage, resides in close proximity to the mitral valve, sometime fused with mitral leaflet. **RIGHT:** The “intramitral ring” is a membranous restriction to mitral inflow that is integral with the valve leaflets themselves. RUPV, right upper pulmonary vein; LUPV, left upper pulmonary vein; LAA, Left atrial appendage; LA, left atrium; MV, mitral valve.

## Parachute Mitral Valve and Other Subvalvar Pathology

There are a great variety of types of subvalvar obstruction and an understanding of the differences is important to any operative strategy to repair them.

True “*parachute mitral valve*” presenting in adulthood is very rare, with only nine published cases of isolated parachute mitral valve in adults reported over 50 years.<sup>1</sup> An embryologic failure in the separation of papillary muscles into two distinct columns results in parachute mitral valve, with a single papillary muscle from which all chordae radiate.<sup>1,15</sup> Annular and subannular restriction to mitral inflow results from thickened, shortened chordae, tethered to a single papillary origin, with tight interchordal spaces and restriction of leaflet excursion.<sup>1</sup> Mitral insufficiency may accompany mitral stenosis, possibly due to ischemic dysfunction of the single papillary muscle.<sup>1</sup> Parachute mitral valve is commonly associated with additional left heart pathology. “*Shone’s*” complex is a constellation of left sided anomalies that includes a parachute mitral valve deformity, supramitral ring, subaortic stenosis, and coarctation of the aorta. The original description by John Shone in 1963 was from autopsy data from eight cases, including one adult, noting the tendency for additional left sided pathology to accompany parachute mitral valve, and the severity of disease that accounts for its rare presentation in adulthood.<sup>15</sup> These concomitant pathologies commonly drive the need for palliative or corrective interventions in childhood, leaving rare instances of isolated parachute mitral valve to present in adulthood.<sup>17</sup> “*Parachute-like mitral asymmetry*” is a similar but distinct entity where there are two distinct papillary muscles, but the anterolateral muscle is underdeveloped, short, and imparts restriction to the valve similar to that of true parachute valve.<sup>12,17</sup>

## COMBINED MITRAL STENOSIS AND INSUFFICIENCY

Dysplasia of the mitral valve that restricts leaflet motion results in the same pathology causing both stenosis and regurgitation. Though mostly associated with stenosis, parachute mitral valve can produce regurgitation too, usually due to restricted anterior leaflet excursion. Repair may include extension of the anterior leaflet.

## MITRAL ARCADE

Mitral arcade results from an embryonic failure of the elongation of mitral valve chordae. In severe cases, there are no distinct chordae and papillary muscles insert directly onto the free edge of the leaflet. The term arcade refers to the continuous band of dysplastic chordal tissue, in continuity with the mitral valve leaflet edge, that arcs between papillary muscle bases (Fig. 39-4). Papillary muscles may be indistinct or multiple. Restricted interchordal spaces and restricted leaflet mobility produce insufficiency and stenosis, often in combination.<sup>2,12,18</sup>

## Hammock Mitral Valve

The “Hammock” mitral valve describes the appearance of a concave distortion of the posterior leaflet that results from extraneous papillary muscles and secondary chordae pulling the posterior leaflet apically and restricting its motion.<sup>19</sup>

Mitral arcade and Hammock mitral valve may present a combination of stenosis and insufficiency, usually associated

**FIGURE 39-4** Mitral arcade, characterized by undeveloped chordal structures, indistinct or multiple papillary muscles, often fusing with leaflet edge to form a rigid bridge between papillary muscle bases.

with restricted excursion of the posterior leaflet, which may require augmentation as part of its repair.

### Indications for Operative Intervention for Mitral Stenosis

Surgical indications for adults with congenital mitral stenosis are identical to those for acquired disease, and are detailed in the 2014 AHA/ACC consensus guidelines.<sup>20</sup> In brief, percutaneous balloon valvotomy is recommended for symptomatic patients with severe MS (valve inflow area of  $\leq 1.5$  cm<sup>2</sup>), if valve morphology is judged amenable to balloon palliation. Indication for surgical intervention includes severely symptomatic patients (HYHA Class III/IV) with severe mitral stenosis ( $\leq 1.5$  cm<sup>2</sup>). Patients with moderate (1.6 to 2.0 cm<sup>2</sup>) to severe mitral stenosis ( $\leq 1.5$  cm<sup>2</sup>) are considered for surgical intervention in the setting of concomitant cardiac surgery. Currently, there are no indications for surgical intervention in asymptomatic patients. Additional considerations at operation include resection of the left atrial appendage for patients with embolic events on anticoagulation for atrial fibrillation.<sup>20</sup>

### REPAIR TECHNIQUES FOR CONGENITAL MITRAL STENOSIS

Fundamental to success in repair of mitral stenosis or insufficiency with restricted leaflet excursion is to create freely

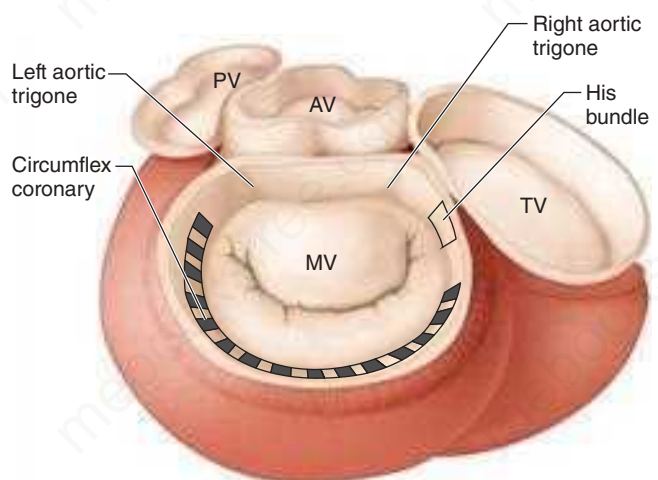

mobile leaflets that permit unobstructed ventricular filling in diastole, and are sufficient in surface area and support to form a large surface area of coaptation in systole.

### Supravalvar Mitral Stenosis Repair

The repair for supravalvar restriction to mitral inflow consists of a complete resection of the obstructive Cor triatriatum membrane or supravalvar mitral ring. The true supravalvar mitral ring or intramitral ring can be densely adherent to the leaflets and care must be taken to perform a complete resection of the fibroelastic membrane. Careful blunt dissection techniques establish a plane between true leaflet and membrane. Careful intraoperative assessment of additional associated mitral abnormalities must be made in addition to membrane resection.

### Annular Mitral Stenosis Repair

Annular hypoplasia requires annular enlargement. Adjacent vital structures considerably limit the options to enlarge the mitral annulus. The adjacent aortic valve limits annular enlargement anteriorly, between the trigones. The His bundle limits annular enlargement rightward of the aorta, and the circumflex coronary artery lies subjacent to the posterior and leftward annular perimeter. Extensive annular resection may preclude valve repair, obligating valve replacement into the enlarged annular area or in the supra-annular position (Fig. 39-5).

**FIGURE 39-5** Surgical landmarks of the mitral valve annulus, and anatomic limitations to annular enlargement. The mitral annulus between right and left aortic trigones is tissue shared with the aortic valve annulus. Rightward of the right trigone is an area adjacent to the His bundle. Subjacent to the posterior and leftward aspect of the mitral annulus is the circumflex coronary artery.

**FIGURE 39-6** Parachute mitral valve, viewed en face (upper panel) and in cut-away view (lower panel). (A) Poorly developed commissures, fused chordae, leaflets tethered to a single papillary muscle. (B) After valvuloplasty consisting of the creation of commissural leaflet separation, interchordal fenestration, and the splitting of the single papillary muscle.

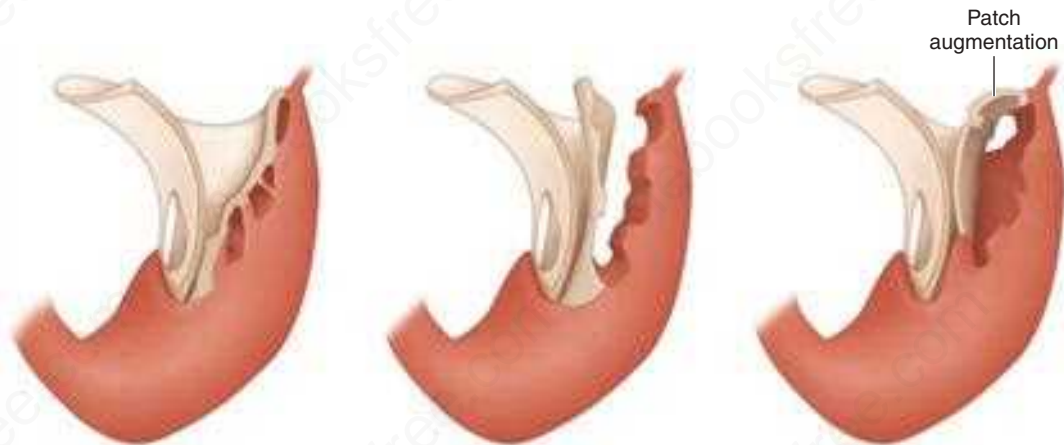

### Subvalvar Mitral Stenosis Repair

The variant of congenital mitral stenosis classified as “typical” shares many features of parachute mitral valve, parachute-like mitral valve, hammock, and arcade. All are principally defined by subannular pathology, with normal or even dilated true annulus. The overlap between parachute mitral valve, parachute-like, arcade, and hammock has prompted the suggestion that they lie on a continuum and are not discrete entities.<sup>21</sup> We will describe a systematic operative approach applicable to all these lesions, with reference to specific lesions where special attention is warranted. The approach aims sequentially at all levels of restrictive valve architecture. A fibroelastic layer adherent to the leaflet is carefully dissected from the true leaflet, starting from the atrial side at the annulus and working toward the free edge, in a manner similar to that of supra-valvar ring resection. Orificial restriction is relieved by commissurotomy. In the case of true parachute mitral valve, the leaflets act as a single funnel-shaped structure, and commissures are designed in “assumed” locations that radiate from the papillary muscle tip toward each trigone.<sup>22</sup> Restrictive interchordal spaces are opened by chordal thinning and chordal fenestration. Papillary muscles are split

where fused or closely spaced. In true parachute mitral valve, the single papillary muscle requires aggressive and complete splitting, and possibly thinning, to permit optimal separation in diastole (Fig. 39-6). Particularly referable to Hammock mitral valve, posterior leaflet restriction can be alleviated by detaching the leaflet from the annulus, reflecting it away from the annulus to expose the subvalvar pathology. This exposure permits the division of any secondary chordae or papillary attachments, and the alleviation of leaflet tethering by the separation of fused papillary muscle from the ventricular free wall (Fig. 39-7).<sup>19</sup> Where shortened chordae insert directly into ventricular free wall without a distinct papillary muscle, papillary-like structures can be sculpted by splitting muscle tissue away from true ventricular free wall.<sup>22</sup> With optimal mobilization of the leaflets, anterior and posterior leaflet height can be assessed and patch augmentation carried out as necessary to produce full leaflet mobility. Artificial chordae can be constructed to support prolapsing or unsupported portions of the rehabilitated valve.<sup>19</sup>

Intraoperative valve testing is performed by infusing saline into the ventricle. Intraoperative echocardiography is an essential adjunct to assure the integrity of any valve repair.

**FIGURE 39-7** Repair for Hammock deformity of the mitral valve. The concave and tethered posterior leaflet (left) is detached, reflected anteriorly, and muscular attachments are divided (middle). Patch augmentation (right) further mobilizes the leaflet to permit coaptation with the anterior leaflet.

## CONGENITAL MITRAL INSUFFICIENCY

Levy and Edwards classified congenital mitral insufficiency into four categories: (1) cleft leaflet (anterior or posterior), (2) anterior leaflet tissue deficiency, (3) double orifice mitral valve, and (4) anomalous mitral chordae.<sup>23</sup> We will organize our description of primary congenital mitral valve pathology around these major categoric headings, and further describe the growing spectrum of reoperative mitral valve pathology.

### Cleft Leaflet

Mitral valve cleft can occur in isolation, but is more commonly associated with primum atrial septal defect, partial or complete AVSD. The cleft is centrally situated on the anterior leaflet, and is an inverted “V”-shaped separation of the halves of the leaflet toward the papillary muscles. While the central portion of the normal anterior leaflet has chordal support from both papillary muscles and ample leaflet surface to form a stable zone of apposition with the posterior leaflet, the cleft leaflet may suffer from insufficient leaflet material and insufficient chordal support in the central zone of apposition, producing a central regurgitant jet, and challenging the integrity of repair (Fig. 39-8).<sup>24</sup>

### Double Orifice Mitral Valve

**Double orifice mitral valve** is defined as a single annulus with two complete orifices, as distinct from **duplicate mitral valve**, where there are two complete and distinct valves with complete annuli. In double orifice mitral valve, the smaller orifice is typically posteromedial, and the bridging tissue between orifices can be complete or partial.<sup>12</sup> though stenosis can be present, the physiologic consequence of double orifice mitral valve is predominantly insufficiency. There is frequent association with additional cardiac defects, most typically

some form of AVSD, or in combination with obstructive pathologies of the left heart.<sup>12</sup>

### Ebstein’s Malformation of the Mitral Valve

This exceedingly rare entity is characterized by MR from a posterior leaflet that is flattened against the ventricular wall and with apical annular displacement.<sup>12</sup>

## INDICATIONS FOR OPERATIVE INTERVENTION FOR MITRAL INSUFFICIENCY

Indications for operative intervention for congenital mitral insufficiency are also identical to those for acquired disease, and are outlined in the 2014 AHA/ACC consensus guidelines.<sup>20</sup> In brief, mitral surgery is recommended for symptomatic patients with chronic severe MR and left

**FIGURE 39-8** Leaflet and chordal arrangement of the normal mitral valve (left panel), and cleft mitral valve (right panel). With mitral cleft, leaflet tissue and chordal support may be deficient at the central zone of apposition.

**FIGURE 39-9** Strategies for repair of mitral cleft. Direct closure alone (left) may result in leaflet restriction and reduced area of apposition with the posterior leaflet. Patch augmentation of the deficient central leaflet lacks chordal support, and artificial chordae may be necessary (middle). Cleft closure with leaflet detachment near the annulus and patch augmentation (right) can improve leaflet mobility and surface area of coaptation with the posterior leaflet.

ventricular ejection fraction (LVEF) >30%, or for asymptomatic patients with chronic severe MR and LV dysfunction (LVEF 30 to 60% or LV end-systolic dimension, LVESD  $\geq$  40 mm). Asymptomatic patients with chronic severe MR and preserved LV function (LVEF >60%, LVESD < 40 mm) are considered for repair if judged a high likelihood of durable success, or in the setting of new onset AF, resting pulmonary hypertension (pulmonary artery pressure >50 mm Hg), or in the setting of concomitant cardiac surgery.<sup>20</sup>

## REPAIR TECHNIQUES FOR MITRAL INSUFFICIENCY

Repair of an isolated cleft may be performed with direct closure if adequate anterior leaflet is present (Fig. 39-9). When found in association with double orifice mitral valve, complete cleft closure can result in stenosis, and valve replacement may be an only option when insufficiency persists.<sup>12</sup> At repair of mitral valve cleft, it is important to study the leaflet morphology to treat any deficiencies in the surface area. In those cases, simple cleft closure alone is ineffective, and leaflet augmentation should be considered in conjunction with cleft closure. The simplest augmentation for mitral cleft fills the primary inverted “V” deficiency that is central and at the zone of apposition. A wedge-shaped patch of glutaraldehyde-fixed pericardium can be used to augment the deficit directly. To prevent prolapse of the augmented central segment, chordal transfer or chordal construction can be added to the repair strategy (Fig. 39-9).<sup>25</sup>

In more complicated, often reoperative cases, leaflet dysplasia with deficient surface area may extend beyond the central portion of the leaflet, precluding effective repair by direct closure or central leaflet augmentation alone. Generalized deficient, dysplastic leaflet may require a radial leaflet detachment from the annulus with patch augmentation to produce or restore adequate leaflet height and mobility, and to effect competent coaptation (Fig. 39-9).<sup>26</sup>

Further maneuvers to improve coaptation surface at repair include posterior leaflet quadrangular resection and eccentric posterior annular reduction.<sup>27</sup> Posterior leaflet quadrangular resection with reduction posterior annuloplasty, chordal shortening, lengthening, and replacement techniques is discussed in detail in previous chapters.

# Minimally Invasive and Robotic Mitral and Tricuspid Valve Surgery

W. Randolph Chitwood, Jr. • Barbara Robinson • L. Wiley Nifong

*Minimally invasive mitral valve surgery* (MIS) refers to a collection of techniques and operation-specific technologies, all of which are designed to lessen surgical trauma and improve clinical outcomes. In the last 20 years, enhanced visualization and instrumentation as well as modified perfusion and aortic occlusion methods have propelled the development of MIS operations. Cohn and Cosgrove (1996) first modified cardiopulmonary bypass techniques to enable safe, effective, minimally invasive aortic and mitral valve surgery.<sup>1-3</sup> Concurrently, innovative port-access methods, using endo-aortic balloon occlusion, were proven to be effective.<sup>4,5</sup> Thereafter, video-assisted and robotic methods were developed and applied effectively by several surgical groups.

Despite acceptance today, many surgeons initially were very critical of performing any complex valve operations through small incisions, owing to safety risks and the possibility of inferior results.<sup>6,7</sup> Since then many institutions worldwide have published excellent MIS comparative outcomes with traditional surgery. These showed definite clinical advantages, which included decreased blood loss and less transfusions as well as minimal postoperative care and pain. Collectively, these translated into shorter hospital stays, faster return to normal activities, less use of rehabilitation resources, and overall healthcare cost savings. Each of these advantages has been a driver for the continued development and expansion of MIS operations.

Today, replacing and repairing cardiac valves through small incisions is a standard practice. The combination of alternative sternal and thoracotomy approaches, new aortic clamping techniques, modified cardiopulmonary bypass circuits and cannulas, shafted-instruments, and three previous generations of robotic systems, all have set the stage for current minimally invasive and robotic mitral surgery, which has gained acceptance at many centers worldwide. Large institutional series as well as several meta-analyses have confirmed that MIS mitral valve surgery is safe and effective for most patients.<sup>8-14</sup> Although overall mitral repair rates in the United States have increased from 51% in 2000 to 62% in

2010, adoption of minimally invasive operations lags behind at less than 30% of repair cases.<sup>15-17</sup> In comparison, in 2015 nearly 50% of over 5000 mitral valve repairs in Germany were done minimally invasively.<sup>18</sup> At our center, mitral repair rates approach 100% for both MIS and robotic operations in selected patients with degenerative mitral disease.

With better understanding of the natural history of degenerative mitral valve disease, more *asymptomatic patients* now are being referred for repairs. Recent 2014 ACC/AHA (United States) and/or 2012 ESC/EACTS (European) Heart Valve Guidelines suggested that these patients should be referred only to high volume centers, having a heart team approach with a 95% chance of a repair and less than 1% operative mortality.<sup>19,20</sup> These same “high bar” standards now have been set for minimally invasive repairs. To this end, surgeons who plan to embark on this trek should have significant experience in repairing valves through a sternotomy as well as have a significant patient volume, a unified heart team, and full support from the operating room and hospital administration.<sup>16</sup>

Hopefully, this chapter will serve both as an educational tool and helpful guide for those who plan to do, or currently are doing, minimally invasive mitral and tricuspid valve surgery. Today, most surgeons have reserved the hemisternotomy for aortic valve surgery. The majority of minimally invasive mitral and tricuspid repairs are done either through a right minithoracotomy or even less invasive port access methods. Thus, this chapter will relate only to direct-vision, video-assisted (endoscopic), and robot-assisted MIS mitral/tricuspid operations performed via right thorax access.

## EVOLUTION OF MITRAL VALVE REPAIR SURGERY

### The First Operations

T. Lauder Brunton first suggested that the mitral valve stenosis could be treated surgically.<sup>21</sup> In May of 1923, Elliott Cutler performed a mitral valvulotomy in an 11-year-old girl

using a tenotomy knife. Thereafter, she lived for 4.5 years. His next six patients died, and he abandoned the procedure.<sup>22</sup> Sir Henry Souttar performed a successful digital commissurotomy in May of 1925. His patient recovered uneventfully but he was never referred another patient for this operation.<sup>23</sup> Despite these early repair attempts, mitral surgery remained dormant until 1948 to 1949 when Horace Smithy, Charles Bailey Dwight Harken, and Russell Brock independently revitalized the technique of commissurotomy.<sup>24–27</sup> There were early successes by Lillehei and McGoon to repair degenerative mitral valves.<sup>28,29</sup> Other surgeons developed various annuloplasty techniques.<sup>30,31</sup> Some of these operations were quite successful but the development of a mitral valve replacement prosthesis eclipsed further development of repair techniques.<sup>32,33</sup>

### Traditional Repair Success

The concept of repairing mitral valves was revived and developed by Carpentier and Duran.<sup>34,35</sup> Carpentier's landmark address entitled *The French Correction (1983)* made surgeons realize that most insufficient degenerative valves could be repaired and that the benefits exceeded those of a replacement.<sup>36</sup> His techniques were proven to yield excellent results when done through a median sternotomy. Many subsequent clinical series confirmed these benefits and repair became a standard of care in Europe and the United States, albeit slowly adopted.<sup>37–40</sup> The perfection of mitral repair operations done through a sternotomy laid the foundation for minimally invasive techniques to be the next wave of advancement.

### Minimally Invasive Mitral Valve Surgery

The idea of MIS mitral surgery emanated during the “Heartport Era” with the development of balloon aortic occlusion devices, long-shafted instruments, and port cardiac access.<sup>4,5</sup> These innovations facilitated MIS greatly and encouraged surgeons to expand the development of even less invasive operations. Cohn and Cosgrove among others showed modified less invasive sternal incisions safe and efficacious when replacing and repairing mitral valves.<sup>1–3</sup> Later, propensity matched patient series confirmed that repair results were similar to sternotomy-based operations.<sup>12</sup>

The concept of operating inside the heart using *video-assisted or endoscopic vision* is not new. In November of 1923, Duff Allen and Evarts Graham planned to use a cardioscope to visualize a commissurotomy in a 31-year-old woman but were unsuccessful.<sup>41</sup> Harken experimented with intracardiac visualization techniques in 1943.<sup>42</sup> In 1958, Sakakibara predicted that valve operations could be done using endoscopic secondary vision.<sup>43,44</sup> Kaneko (1995) used video assistance through a sternotomy to aid in mitral repairs and commissurotomies.<sup>45</sup>

In February of 1996, Carpentier performed the first video-scopic minimally invasive mitral repair, which was done via a right minithoracotomy.<sup>46</sup> Our group performed the first camera-directed minimally invasive mitral replacement 2 months

later.<sup>47–49</sup> Mohr, Reichenspurner, Vanermen, Hargrove, and Chitwood expanded the influence of video-directed minimally invasive mitral surgery by publishing large mitral repair series with excellent results.<sup>8–10,14</sup>

### Robot-Assisted Mitral Valve Surgery

In 1998, Carpentier accomplished the first robotic mitral repair using a daVinci robot prototype.<sup>50</sup> A week later, Mohr completed seven successful robot-assisted mitral repairs with this system.<sup>51</sup> These operations proved that mitral repairs could be done safely using robotic telepresence alone. In 2000, Grossi performed a mitral valve leaflet repair using the Zeus robot.<sup>52</sup> In 1999, our group purchased the first commercial daVinci Surgical System (Intuitive Surgical, Inc., Sunnyvale, CA) in the United States and then developed additional instruments and repair techniques in our robotic laboratory. In May of 2002, under an FDA safety and efficacy clinical trial, we performed the first complete robotic mitral repair with leaflet resection and a band annuloplasty using the daVinci system.<sup>53</sup> This device was FDA approved for intracardiac surgery in 2002 after two clinical trials.<sup>54</sup> Our inaugural series of 300 patients confirmed the safety and efficacy of robot-assisted mitral valve repair.<sup>55</sup>

Dedicated robotic mitral valve repair referral programs have shown outcomes similar to operations done either through a sternotomy, hemisternotomy, minithoracotomy, or port only access.<sup>56–60</sup> The device, instrument, and maintenance costs have been challenged; however, surgeons at the Mayo and Cleveland Clinics have shown that optimized robotic care paths can render economic parity with other incisional approaches.<sup>61,62</sup>

### ACCLIMATIZATION AND PROGRESSION

In previous book chapters, we have compared a surgeon's progression in minimally invasive valve surgery skills akin to a “Mount Everest trek.” Although this analogy may be less apropos today, it does bespeak the advantages of an advancing pathway on which one can accommodate anywhere along this surgical escarpment. Embarking from a conventional median sternotomy-based operation or “base camp,” surgeons can advance progressively toward less invasiveness through experience and methodological acclimatization. In this schema, entry levels of technical complexity are mastered before advancing past small-incision, direct-vision approaches (Level 1) toward more complex video-assisted/directed procedures (Level 2 or 3), and finally to completely robot-assisted operations (Level 4). With the evolution of technology and advancing surgical expertise, most established mitral repair surgeons are able to attain “comfort zones” along this trek.

This chapter shows that patient selection, preoperative screening, patient positioning, the operative setup, perfusion, and operative management are generally the *same for all of our MIS and robot-assisted operations*. This standardization

should help surgeons move more rapidly through the progression of MIS operations. Major differences between direct vision and video-assisted MIS operations relate mainly to the size of the minithoracotomy. In robot-assisted operations, changes relate to instrument arm placement, instruments, and telemanipulation methods. Mitral and tricuspid valve repair techniques have been standardized for all three operative approaches.

## PATIENT SELECTION

Table 40-1 shows what we consider to be an ideal mitral valve operation. Today, we have been able to achieve most of these factors: however, others remain for the future. Clearly, the die has been cast (*alea iacta est*) regarding the absolute requirement for patient safety and optimal long-lasting repairs, no matter what technique is employed. Patients who are selected for minimally invasive mitral surgery should have the same indications as outlined in either the 2014 ACC/AHA (United States) or 2012 ESC/EACTS (European) Guidelines.<sup>19,20</sup> At our institution, all patients with either degenerative or functional mitral insufficiency are considered for a videoscopic or robotic MIS. Asymptomatic patients are selected based on the IIa recommendations in the recent ACC/AHA guidelines.<sup>19</sup> Patients with significant comorbidities, and those requiring multivessel coronary revascularization, an aortic valve replacement or have a significantly dilated ascending aorta should be operated upon through a sternotomy. Operative risks, age, fragility, and mitral pathology complexity all should be considered when selecting these patients. All patients should be informed of alternative approaches, including a traditional sternotomy, and they should understand that there is a small possibility of requiring a sternal conversion. Absolute and relative *contraindications* to robotic and MIS mitral surgery

**TABLE 40-1: The Ideal Mitral Valve Repair**

- Small nonrib spreading working incision
- Central antegrade cardiopulmonary perfusion
- High-definition magnified 3D vision
- Ergonomic intracardiac instrument access
- Tactile feedback
- Facile prosthesis attachment devices
- Minimal
  - Cardiopulmonary perfusion times
  - Cardiac arrest times
  - Blood product usage
  - Ventilation times
  - Intensive care requirements
  - Incision pain
  - Hospitalization
- High-quality repairs
  - Greater than 95% repairs
  - Few reoperations (<2%)
  - Operative mortality (<1%)
  - No SAM or residual leak

**TABLE 40-2: Contraindications to Minimally Invasive and Robotic Mitral Valve Surgery**

Absolute	Relative
Previous right thoracotomy	Previous sternotomy
Severe pulmonary dysfunction	Moderate pulmonary dysfunction
Myocardial infarction or ischemia < 30 days	Asymptomatic coronary artery disease
Coronary artery disease—requiring coronary surgery	Coronary artery disease—requiring *PCI
Severe generalized vascular disease	Limited peripheral vascular disease
Symptomatic cerebrovascular disease or stroke < 30 days	Asymptomatic cerebrovascular disease
Right ventricular dysfunction	Poor left ventricular function (*EF < 50%)
Pulmonary hypertension (fixed > 60 torr)	Pulmonary hypertension (variable > 50 mm Hg)
Significant aortic stenosis or insufficiency	Mild to moderate aortic stenosis or insufficiency
Severe mitral annular calcification	Moderate annular calcification
Severe liver dysfunction	Chest deformity (pectus or scoliosis)
Significant bleeding disorders	
Significantly dilated aortic root	

\*PCI, percutaneous catheter intervention; EF, left ventricular ejection fraction

are listed in Table 40-2. Some relative contraindications can be managed by selecting alternate methods for perfusion and myocardial protection (eg, axillary artery cannulation and hypothermic ventricular fibrillation). For single vessel coronary disease, preoperative coronary stenting has obviated the need to avoid consideration for a mitral/tricuspid MIS repair.

## PREOPERATIVE SCREENING

Candidates for any MIS or robot-assisted mitral operation should be screened carefully for peripheral vascular and coronary artery disease as well as pulmonary maladies. In most patients, either a computed tomographic angiogram and/or contrast coronary angiogram should be performed. Suspect patients should undergo tomographic and/or ultrasound screening for aortoiliac, carotid, and general aortic disease. Peripheral perfusion and aortic endoballoon occlusion should be avoided in patients with severe aortic atherosclerosis or a dilated ascending aorta. Pulmonary function tests should be done in heavy smokers and those having symptoms of obstructive disease. A detailed transthoracic echocardiogram should be done to define general valve pathology, ventricular function, and the presence of pulmonary hypertension. If the latter is present, a right heart catheterization may be

indicated. In patients with complex disease, we perform a preoperative 3D transesophageal echocardiogram (TEE).

## REPAIR PLANNING: 3D TEE STUDIES

We always develop an intraoperative “blueprint” to plan mitral and tricuspid repairs Table 40-3. After patients are anesthetized, the direction of each jet (leak) is mapped with both 2D and 3D TEE studies. The mobility and prolapse level is determined for each restricted or prolapsing segment. Leaflet segments ( $P_1$ - $P_3$ ,  $A_1$ - $A_3$ ) are measured. Next, the planar angle between the aortic and mitral valve annulus is determined. Finally, the annular diameter, outflow tract septal thickness, and coaptation point to septal (C Sept) distances are measured. Operative planning includes the avoidance of *systolic anterior motion of the anterior leaflet* (SAM). Thus, we pay special attention to the length of  $A_2$  and  $P_1$ - $P_3$  heights (annulus to coapting edge). Table 40-4 shows the anatomic, operative, and dynamic features that can contribute to postoperative SAM. Preventative *structural repair measures* that may avoid this complication include: (1) implantation of a large enough ring/band, (2) reduction of the posterior leaflet height to 15 mm or less, and (3) achievement of an optimal leaflet coaptation surface (8–10 mm). The length of  $A_2$  guides us for annuloplasty band size selection. Finally, a 3D valve model is constructed from these measurements (Fig. 40-1A–C). During the valve reconstruction, this model as well as other imaging studies can be visualized in the daVinci operating console using the Tile Pro software (Intuitive Surgical, Inc., Sunnyvale, CA). To determine the need for an adjunctive tricuspid valve repair, we quantitate the regurgitant volume and measure the annular size. We now include a tricuspid annuloplasty repair in all patients that have even moderate insufficiency with annular dilatation of more than 4 cm.

## OPERATIVE MANAGEMENT: GENERAL

As mentioned before, the operative organization and management are very similar for minithoracotomy or port access

**TABLE 40-3: Transesophageal Echocardiography: “Blueprint Planning”**

- Degree of valve leakage
- Direction of individual leakage jets
- Lengths (mm) of  $A_2$ , and  $P_1$ ,  $P_2$ , and  $P_3$
- Annular diameter and geometry—mitral and tricuspid
- Definition of posterior leaflet clefts and interdependence
- Planar angle between mitral and aortic annulus
- Degree (mm) of leaflet segmental prolapse or restriction
- “Septal knob” thickness (mm)
- Aortic outflow tract size (mm)—coaptation to septal distance
- Reconstructed topographic mitral valve model

**TABLE 40-4: Anterior Leaflet Systolic Motion (SAM) Contributing Factors: Anatomic, Operative, and Functional**

- $P_1$ - $P_3$  leaflet length > 2 cm (annulus to edge)
- $A_2$  leaflet length > 3 cm
- Aortomitral plane angle < 120°
- Narrow aortic outflow tract
- Thick septal “knob”
- Small annuloplasty prosthesis
- Inotropic drug support
- Under filled left ventricular

(MIS) video-assisted, direct vision, and robot-assisted mitral repairs (RMVP) and replacements. *The Atlas of Robotic Cardiac Surgery* details anesthesia management, instrument setup, and conduct of these and other operations at several well-known centers.<sup>63</sup> Moreover, *Cardiopulmonary Bypass and Mechanical Support: Principles and Practice* provides precise details of our method of cardiopulmonary perfusion (CPB) for all of these operations.<sup>64</sup> The use of endo-balloon aortic occlusion requires special attention and is detailed in these texts.

## Patient Position

To help widen the right intercostal spaces (ICs), which helps to prevent rib spreading, the right chest should be elevated by 30° using a midthorax towel roll. The right arm should be “sling” positioned inferior to the posterior axillary line. Some surgeons prefer to position the flexed right arm above the head using different forms of stabilization. At this time, anterior and posterior Zoll defibrillator pads should be placed to subtend the heart. To monitor adequate limb perfusion during CPB, we place Invos System (Somanetics, Inc., Troy, MI) oxygen saturation monitoring patches on each thigh. Standard skin preparation and draping must provide wide access to the right chest, sternum, and both groins. To facilitate transthoracic aortic clamp placement, the right chest should be prepared sterilely as far as the posterior axillary line.

## Anesthesia Management

Although some surgeons prefer not to isolate the right lung, we believe that unilateral ventilation can be done safely and facilitates inspection for bleeding at the end of the operation. In the past, we deflated the lung first and then opened the pericardium with long instruments before establishing CPB. However, we now begin CPB before deflating the right lung and avoid manipulating it while heparinized. To isolate the right lung, either a double-lumen endotracheal tube or a right endobronchial blocker is used. In all of our minimally invasive cardiac surgery operations, we monitor closely cardiac dynamics and function as well as leg and brain perfusion.

**FIGURE 40-1** Preoperative transesophageal echo studies. (A) Long-axis 2D view of prolapsing  $P_2$  leaflet segment;  $A_2$ , anterior leaflet; Av, aortic valve; VS, ventricular septum. (B) 3D view with prolapsing posterior leaflet  $P_2$  segment;  $P_1$  and  $P_2$ —other posterior leaflet segments; LFT, left fibrous trigone; RFT, right fibrous trigone. (C) Topographic 3D model showing prolapsing  $P_2$  segment;  $A_2$ , anterior leaflet; AL, anterior-lateral; PM, posterior-medial; Ao, aortic valve; A, anterior; P, posterior.

Forehead patches are applied to monitor *bispectral index* (BIS, Covidien, Inc., Boulder, CO), which provides an index of cerebral perfusion and anesthetic levels.

A left radial artery catheter is placed for systemic blood pressure monitoring. If intra-aortic balloon occlusion (clamping) is planned, arterial pressures should be measured continuously in both arms. This is done to ensure that the endoballoon has not inadvertently occluded the innominate artery. Thereafter, a right internal jugular vein catheter is inserted for drug infusions and placement of a flow directed Swan–Ganz pulmonary artery catheter (Edwards Lifesciences, Irvine, CA). Using the “double stick” technique, a thin-walled (15-Fr or 17-Fr) Bio-Medicus (Medtronic, Inc., St. Paul, MN) right internal jugular venous drainage cannula is inserted under echocardiographic guidance (Fig. 40-2). Some surgeons use a single femoral venous return cannula that is passed through the right atrium into

**FIGURE 40-2** Anesthesia preparation. TEE, transesophageal echo probe; DLET, double lumen endotracheal tube; IJ SVC, internal jugular vein to superior vena cava venous drainage cannula; IP, internal jugular vein drug infusion port; SG, internal jugular vein Swan Ganz pulmonary artery catheter.

the superior vena cava (SVC). However, to assure a dry surgical field throughout these operations, we have found that dual cannulation is more reliable. Lastly, the 3D transesophageal echo probe is positioned and detailed studies are done.

### Working Incision

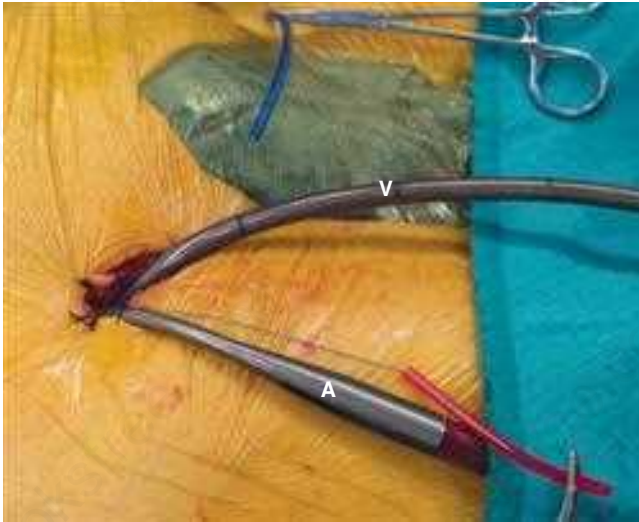

Today, most minimally invasive and robotic mitral/tricuspid valve operations are performed through a right fourth ICS minithoracotomy. Current visualization choices include a direct view through the incision, 2D endoscopic, or 3D robotic. However, the new Aesculap 3D EinsteinVision system (E Braun, Inc., Tuttlingen, Germany) has been compared favorably to daVinci robotic 3D visualization.<sup>65</sup> The *size of the working incision* usually depends on the visualization and operative methods chosen by the surgeon.

For both direct vision and 2D endoscopic MIS, a 4 to 5 cm minithoracotomy is made in the fourth ICS near the anterior axillary line. We suggest a slightly larger incision for surgeons just beginning MIS mitral surgery. For robotic operations, a smaller working incision (2 to 3 cm) is placed in the same topographic chest region. In preference to using a rib-spreading retractor, we now prefer a flexible Alexis soft tissue wound protector (Applied Medical, Inc., Rancho Santa Margarita, CA). In the past, we used the Perivue Soft Tissue retractor (Edwards Lifesciences, Inc., Irvine, CA) for nonrib spreading access. We have found that this minimizes postoperative pain and provides good working-incision exposure for either direct vision, video-assisted, or robotic minimally invasive mitral/tricuspid valve surgery. Other robotic surgeons have found that true port-access (1 to 2 cm) can be used without compromising either the operation or safety.<sup>57–60</sup>

### Cannulation and Cardiopulmonary Perfusion

All perfusion cannulas are placed under echocardiographic guidance using the Seldinger guide-wire technique. Through a 2-cm oblique groin incision adventitial 4-0 polypropylene

**FIGURE 40-3** Cardiopulmonary bypass cannulas. Groin incision with arterial (A) and venous (V) cannulas in place for cardiopulmonary perfusion (see text for details).

oval (longitudinal) purse-string sutures are placed in both femoral vessels near the inguinal ligament. The right femoral artery is cannulated with either a 17 or 19-Fr Bio-Medicus cannula (Medtronic, Inc., Minneapolis, MN). For inferior vena caval drainage, either a 22-Fr (single stage) or a 23/25-Fr (dual stage) RAP femoral venous cannula (LivaNova, Inc., Arvada, CO) is passed into the right atrium (Fig. 40-3). In corpulent patients, we tunnel cannulas through the upper thigh subcutaneous tissue. This allows coaxial dilators and cannulas to have safer passage into vessels at a 30° to 45° angle. Vacuum-assisted venous drainage is used in all of our operations. Presently, we use Sorin S5® heart-lung machine, modified for use with a venous bag reservoir or V-Bag (Circulatory Technology, Inc., Oyster Bay, NY) and equipped with magnetic drive for Revolution centrifugal pump suction (LivaNova USA, Inc., Arvada, CO) (Fig. 40-4). Figure 40-5 illustrates our current perfusion circuit for MIS and robotic heart surgery.

### Cardiac Air Removal

Meticulous cardiac air removal is particularly important in minimally invasive valve operations. Difficulty exists in manipulating and deairing the cardiac apex, as it cannot be elevated. Also, with a right anterolateral minithoracotomy, air tends to be retained along the dorsally oriented ventricular septum and in the right pulmonary veins. Moreover, this position places the right coronary ostium in the most vulnerable position to entrap air. Continuous carbon-dioxide (CO<sub>2</sub>) insufflation has been particularly helpful in minimizing intracardiac air and should be begun before cardiac chambers are opened. Carbon dioxide is much more soluble in blood than air and displaces it very effectively. We infuse CO<sub>2</sub> continuously (4-5 L/min) into the thorax, and prior to cross clamp release, ventilate both lungs vigorously to draw the gas deep

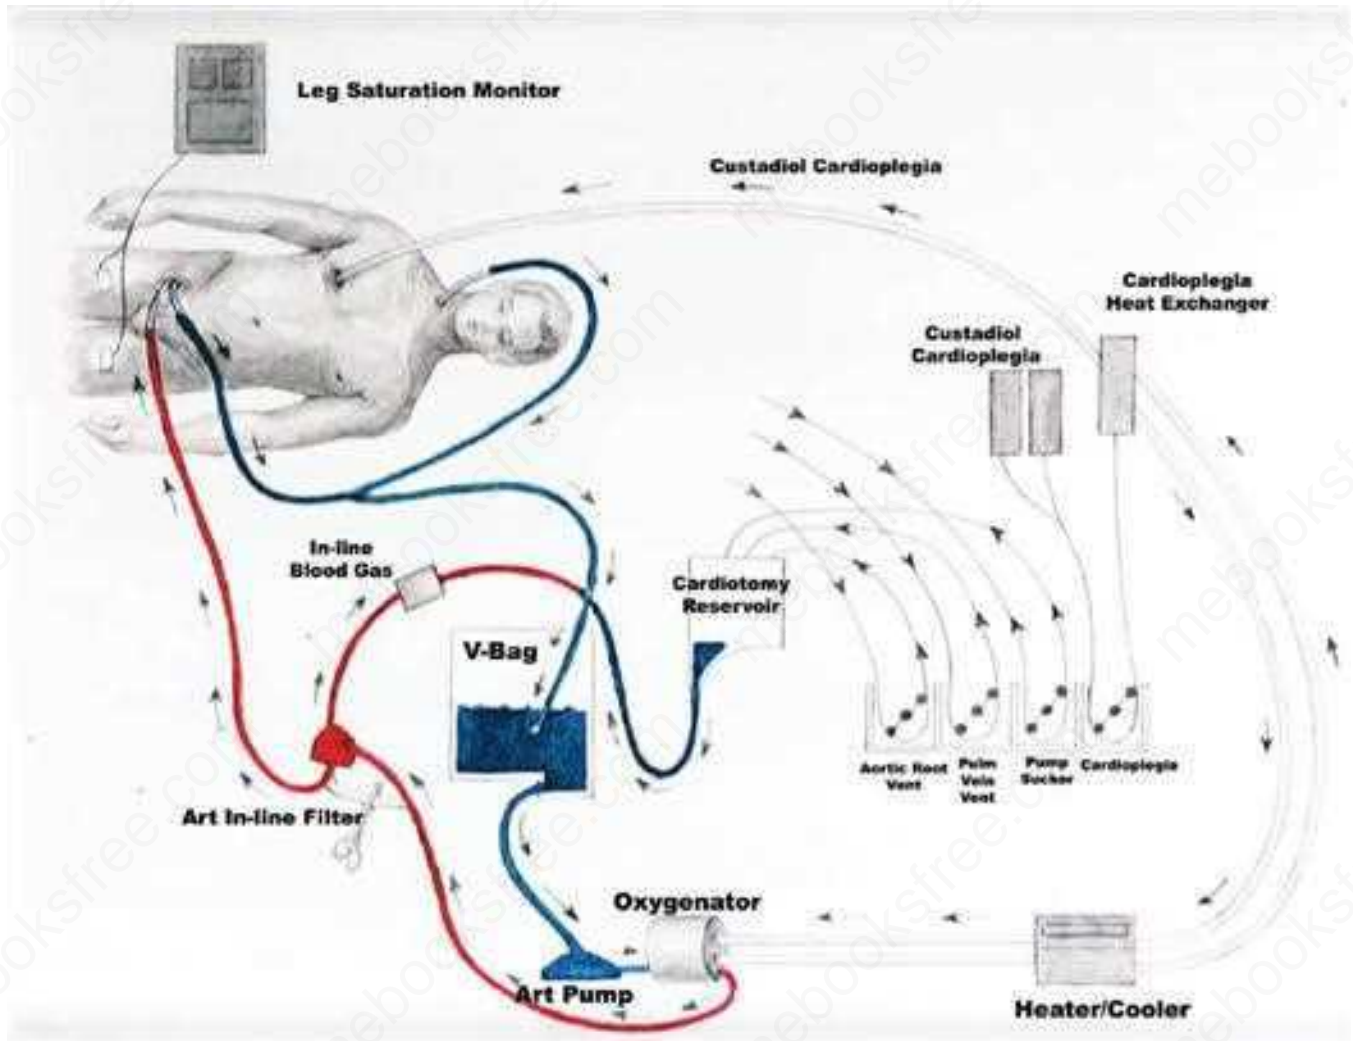

**FIGURE 40-4** Cardiopulmonary bypass circuit. Venous bag reservoir or V-Bag (Circulatory Technology, Inc., Oyster Bay, NY) attached to a magnetic drive to propel the Revolution centrifugal pump suction head (LivaNova USA, Inc., Arvada, CO).

into all pulmonary veins. After atriotomy closure and following cross-clamp release, suction is applied to the aortic root vent. One can compress the right coronary artery origin during early ejection. Constant transesophageal echocardiographic monitoring is essential to assure adequate air removal before weaning from cardiopulmonary bypass.

### Alternate Arterial Cannulation Techniques

Ileo-femoral and/or aortic atherosclerosis may preclude safe retrograde perfusion. To cannulate the ascending aorta directly, it is important to place two concentric pledgeted purse strings near the innominate artery origin. We use either a Biomedicus (Medtronic, Inc., Minneapolis, MN) guide-wire directed cannula or a 23-Fr Straight Shot device (Edwards Lifesciences, Irvine, CA), which is passed through the chest wall via a 10-mm trocar. If it is not feasible to cannulate the ascending aorta directly, we use the right axillary artery for

**FIGURE 40-5** Cardiopulmonary bypass perfusion circuit for minimally invasive mitral surgery. Our circuit employs the venous bag reservoir pictured in Fig. 40-4. Femoral arterial and venous cannulas are inserted through a small groin incision. An internal jugular venous cannula augments return to the V-Bag reservoir. Cold Custadiol antegrade cardioplegia is delivered via an ascending aorta cannula. (Reproduced with permission from Gravlee GP, Davis RF, Hammon J, et al: *Cardiopulmonary Bypass and Mechanical Support: Principles and Practice*, 4th ed. Philadelphia: Wolter Kluwer; 2015.)

antegrade perfusion. The artery is exposed through an infraclavicular incision. An 8-mm GelSoft knitted graft (Vascutek, Terumo, Ann Arbor, MI) is sewn end-to-side to the axillary artery with 5-0 polypropylene suture. Thereafter, the graft is connected to the bypass circuit using either an appropriate size arterial cannula or a three-eighth inch pump tubing connector. Terumo also makes a PTFE graft that is annealed directly to a perfusion cannula (Fig. 40-6A and B). Alternatively, the axillary artery can be cannulated directly; however, distal arm perfusion should be monitored while the cannula is in place.

### Aortic Occlusion

For aortic occlusion, we use a transthoracic cross clamp Scanlan International, Inc., St. Paul, MN as it has been proven to

be safe, reliable, economic, and simple to apply (Fig. 40-7A and B). However, a number of surgeons use the IntraClude endoballoon (Edwards Lifesciences, Irvine, CA) for aortic occlusion (Fig. 40-8). This technique has a steeper learning curve than using the clamp. The balloon position must be precise and remain stable in the ascending aorta. There is a potential for either innominate artery occlusion or intraventricular displacement. Therefore, it is essential echo monitor the balloon position throughout the operation. Also, introduction through the specialized femoral arterial cannula can limit limb perfusion. In this circumstance, the endoballoon catheter should be reinserted through the other femoral artery. Despite these concerns, this method can provide effective aortic occlusion with a simultaneous route for delivering antegrade cardioplegia and venting air.

**FIGURE 40-6** Axillary arterial alternate cannulation. Two methods of axillary arterial cannulation are shown. (A) An 8-mm GelSoft knitted graft (Vascutek, Terumo, Ann Arbor, MI) is sewn to the right axillary artery; a similar size arterial perfusion cannula is inserted into the graft and tied tightly in place. (B) Terumo PTFE graft that is annealed to the arterial perfusion circuit.

When applying the transthoracic aortic clamp, the posterior arm should be passed through the transverse sinus under either *direct or videoscopic vision* (Fig. 40-9A and B). The shaft of the clamp should be passed just in front of the SVC near the pericardial junction. The anterior clamp arm (tine) portion should be positioned across the aorta until it reaches the main pulmonary artery. Care must be taken not to injure the right or main pulmonary artery, left atrial appendage, left

main coronary artery, or aorta. We prefer to place the clamp with the tip directed toward the transverse aortic arch.

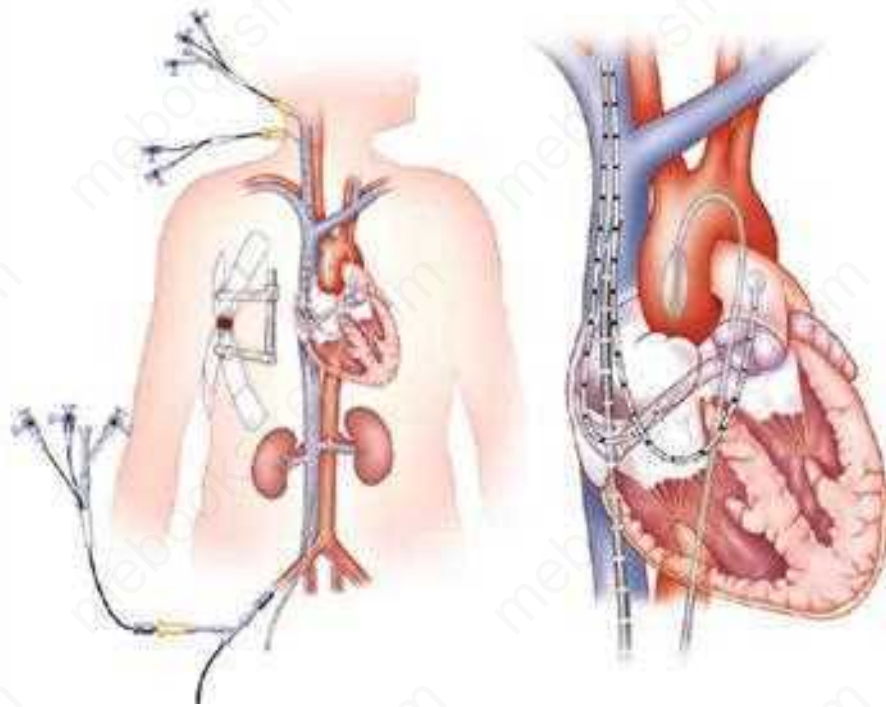

### Myocardial Protection

As mentioned earlier, we have always used the transthoracic aortic clamp method for both minimally invasive and robot-assisted mitral valve surgery. For antegrade cardioplegia administration, a long cardioplegia-vent catheter (Medtronic, Inc., St Paul, MN) is inserted through an ascending aortic purse-string, secured, and passed either through a chest wall trocar or the working incision. We prefer a pledgeted diamond shape 4-0 PTFE purse-string suture placed distal to the right coronary artery origin near the fatty Fold of Rindfleisch (Fig. 40-10). This catheter should be inserted either under robotic, endoscopic, or direct vision.

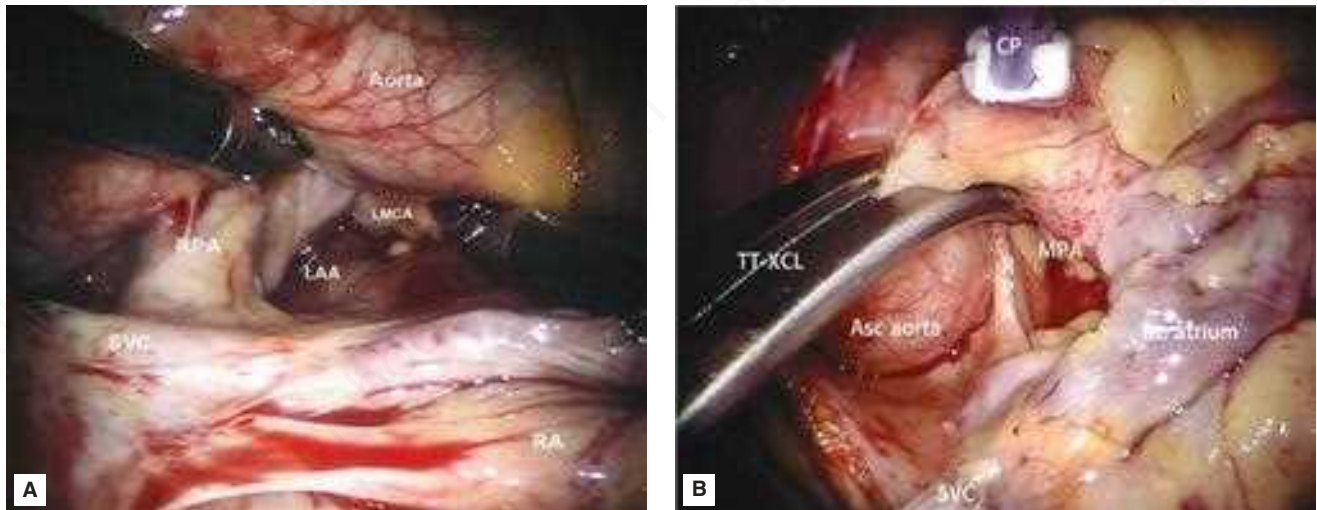

We now use Custodiol—Bretschneider's HTK solution (Franz Köhler Chemie Bensheim GMBH, Germany) for cardioplegia as it provides much longer myocardial protection without requiring frequent reinfusions. We start with single large infusion (20 to 25 mL/kg) at 4 to 6°C, and after 1 hour give a half dose. For maximal myocardial protection, we combine antegrade cardioplegia with a systemic blood inflow temperature of 28°C. If blood cardioplegia is used, repeat administrations should be given at 15- to 30-minute intervals. Multiple cardioplegia infusions, requiring atrial retractor relaxation and repositioning, can entrain air into the aortic root. For patients having had a *previous sternotomy*, we cool systemically to 26°C and induce ventricular fibrillation by rapid pacing with a custom Swan-Ganz catheter. In patients with mild aortic insufficiency, additional intracardiac suction can be combined with dropping perfusion flow briefly for difficult suture placement.

**FIGURE 40-7** Transthoracic aortic clamp. For minimally invasive mitral valve operations, the transthoracic aortic clamp (Scanlan International, Inc., St. Paul, MN) should be passed through the 3D intercostal space. (A) Transthoracic aortic clamp and (B) clamp tines with DeBakey-type teeth. (Used with permission from Scanlan International Inc., St. Paul, MN.)

**FIGURE 40-8** Endo-balloon aortic occlusion. Femoral arterial and venous perfusion cannulas have been inserted. An IntraClude endo-balloon (Edwards Lifesciences, Irvine, CA) has been passed through the femoral arterial perfusion cannula and echo-guided retrograde to the ascending aorta. A pulmonary artery vent catheter has been placed. A retrograde cardioplegia coronary sinus cannula has been inserted through the right internal jugular vein. (Reproduced with permission from Chitwood WR: Atlas of Robotic Cardiac Surgery. London: Springer-Verlag; 2014.)

**FIGURE 40-9** Transsternal aortic clamp placement. (A) The transverse sinus is shown with the following structures: RPA, right pulmonary artery; LAA, left atrial appendage; LMCA, left main coronary artery; SVC, superior vena cava; aorta and right atrium are also shown. The correct trajectory for clamp placement from the 3D interspace, across the pericardial-SVC junction with the tip residing superior to the LAA and inferior to the RPA. (B) The transverse sinus is shown after transsternal cross clamp (TT-XCL) placement. The clamp tip has been directed cephalically across the ascending aorta (Asc Aorta). The right pulmonary artery (RPA) and main pulmonary artery (MPA) are shown, as are the SVC and right atrium. CP denotes the cardioplegia cannula.

**FIGURE 40-10** Cardioplegia/vent catheter insertion. (A) The cardioplegia/vent catheter (CP) has been inserted into the ascending aorta (Ao) through a 4-0 pledgeted PTFE “purse string” suture placed just distal to the right coronary artery origin in the fatty fold. (B) The cardioplegia catheter (red) has been secured in the ascending aorta with a Rummel tourniquet (blue). (Reproduced with permission from Grover FL, Mack MJ: *Master Techniques in Surgery: Cardiac Surgery*. Philadelphia: Lippincott Williams & Wilkins; 2016.)

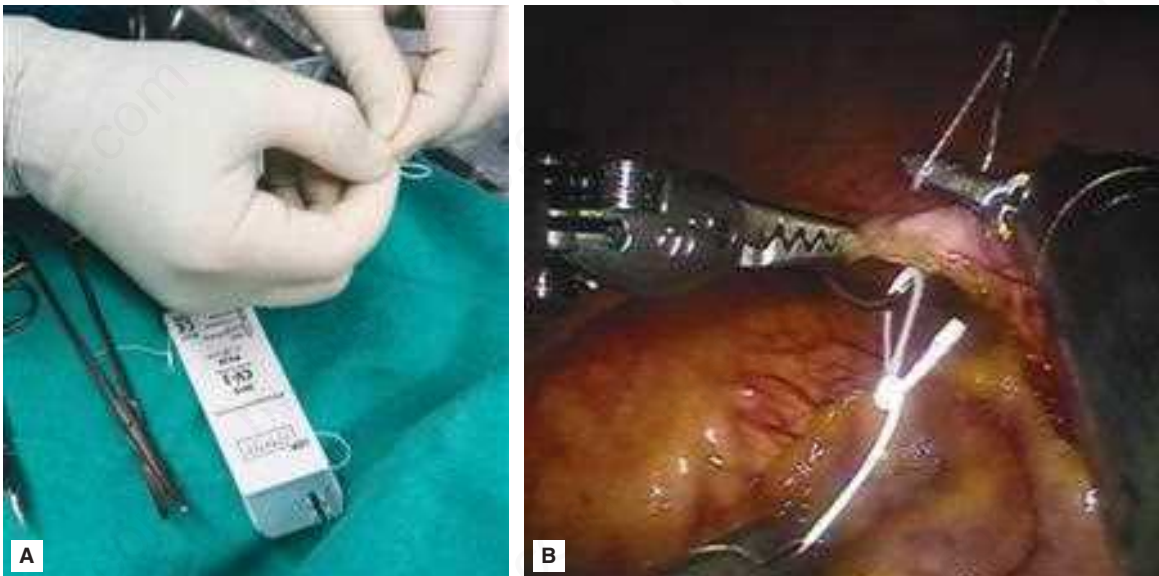

## Cardiac Exposure

After going on CPB, the pericardium is opened longitudinally 3-cm anterior to the phrenic nerve with either long shafted endoscopic or robotic instruments. Two to three well-spaced pericardial retraction sutures are placed along the inferior (dorsal) pericardial edge (Fig. 40-11A and B). We then pass the needle back through a pretied end-loop. Using a crochet hook instrument, the single suture is withdrawn laterally through the chest wall to provide cardiac exposure. Care should be taken not to stretch or directly injure the phrenic nerve.

The anterior (ventral) pericardial edge is distracted through the working incision with two sutures.

## OPERATIVE MANAGEMENT: 2D VIDEO-ASSISTED MINIMALLY INVASIVE MITRAL SURGERY

Figure 40-12 shows our table arrangement for 2D video-assisted MIS mitral operations. After establishing cardiac arrest, we pass a 5-mm high-definition 2D endoscope

**FIGURE 40-11** Suture loops: pericardial retraction/atriotomy closure. (A) Tiny PTFE loops are hand tied. These 3-0 PTFE loops are used to close the left atrium. After the suture is passed through the atriotomy tissue, the needle is passed through the loop, and the suture is tightened. This obviates the need for extracorporeal knot tying. (B) For pericardial retraction sutures, 2-0 braided suture loops are tied as in A. After the loop-suture pericardial edge fixation, the suture is passed through the lateral chest wall using a “crochet hook” instrument.

**FIGURE 40-12** Video-assisted minimally invasive mitral surgery: operative setup. A 5-mm Storz videoscopic camera (2D—Camera) has been placed through a trocar inserted in the 3D intercostal space and is then attached to a table-mounted holder. The transthoracic cross clamp is shown placed through the 3D or fourth intercostal space. A nonrib spreading soft tissue retractor is shown. The CO<sub>2</sub> insufflation and left atrial sump suction catheters are shown. (Reproduced with permission from Grover FL, Mack MJ: *Master Techniques in Surgery: Cardiac Surgery*. Philadelphia: Lippincott Williams & Wilkins; 2016.)

(Karl Storz GmbH & Co. KG, Tuttlingen, Germany) through a third ICS trocar and attach it to a hand-positioned holder. A transthoracic atrial retractor arm (Atrial Lift System, Atricure, Inc., Cincinnati, OH) is passed through the chest wall, just medial to the sternum in the fourth interspace (Fig. 40-13). The arm is then coupled to the appropriate size blade, which is inserted into the left atrium. After minimal interatrial groove dissection, the left atriotomy should be made just medial to the right superior and inferior pulmonary veins. To lift interatrial septum and expose the mitral valve, the retractor arm is attached to a table-mounted support. This device is also used to facilitate tricuspid valve repairs.

Long-shafted instruments are used for endoscopic and direct vision MIS and provide rotational ergonomics but lack the advantage of full articulation (Fig. 40-14). Specialized knot pushers and suture cutters (Scanlan International, Inc., St. Paul, MN) greatly facilitate MIS mitral operations (Fig. 40-15). It is incumbent that needle holders have a strong grip as many positioning angles confer increased torque compared with traditional suturing methods. For suture organization, we often use Gabby-Frater suture guides (Teleflex Medical, Research Triangle, NC), placed around the working incision.

**OPERATIVE MANAGEMENT: 3D ROBOT-ASSISTED MITRAL SURGERY**

**Heart Team Robotic Program Development**

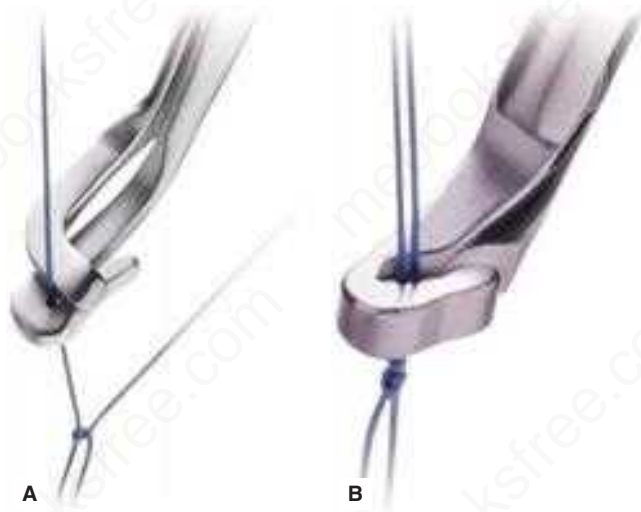

We recently published a consensus statement from the combined STS/AATS New Technology Committee entitled “Pathway

**FIGURE 40-13** Video-assisted minimally invasive mitral surgery: endoscope and retractor. A table-mounted camera holder is shown with a 2D endoscope in position. For mitral valve surgery, the atrial lift retractor is inserted through the chest wall and into the atriotomy. (Atrial Lift System, Atricure, Inc., Cincinnati, OH). Thereafter, it is supported by a fixed retractor table mount. (Reproduced with permission from Chitwood WR: *Atlas of Robotic Cardiac Surgery*. London: Springer-Verlag; 2014.)

for surgeons and programs to establish and maintain a successful robot-assisted adult cardiac surgery program.<sup>66</sup> It emphasizes that an organized heart team is mandatory to develop and maintain a successful cardiac robotic surgical program. Also, our editorial entitled “Mitral valve repair using robotic technology: Safe, effective, and durable” provides additional helpful information and guidance for developing programs.<sup>67</sup>

Before beginning robot-assisted mitral and tricuspid surgery, surgeons should be accomplished at mitral repairs and preferably other minimally invasive approaches.<sup>16</sup> Cardiologists should fully support program development and champion participation in combined valve clinics. This cooperation encourages cardiologist and surgeons to agree upon

which patients are appropriate for a robot-assisted operation. It is important that anesthesiologists, surgeons, tableside assistants, scrub personnel, circulating nurses, and perfusionists train and work together as a unit.

Procedure training at an experience robotic valve center has been important to launch successful programs and greatly shortens the learning curve. We suggest that even skilled mitral valve referral surgeons should engage a proctor for the first operations. There are a number of experienced centers that can offer training in robotic mitral valve surgery. Our Robotic Training Center has been a mainstay for mitral valve robotic surgical training. To date, we have held 634 robotic surgery courses in all specialties. Of these, 160 were training general cardiac surgery teams with an additional 104 that were specific for robotic mitral valve repair.

### The daVinci Surgical System

The daVinci surgical system (Intuitive Surgical, Inc., Sunnyvale, CA) provides operative field access with superb visualization and enhanced ergonomics, which allows surgeons to perform complex operations through small port-like incisions. Long hand-held instruments placed through a small working port have a fulcrum effect that can reverse instrument direction from that of the surgeon’s hand. This factor, coupled with innate human tremor, may limit accurate suture placement and valve leaflet reconstruction. Accuracy achieved with daVinci instruments emanates from the wide freedom of instrument tip motion at the operative plane. The surgeon always has the same operating console instrument control as if they were activated directly by his or her hands.

Currently, this device is the only robotic system FDA approved to perform intracardiac surgical procedures. We have used three system generations, including the daVinci SI HD (high-definition) dual console device, which was first commercialized in 2009 (Fig. 40-16). The current daVinci XI System

**FIGURE 40-16** daVinci SI Surgical System. (A) daVinci SI dual surgeon consoles (foreground) with instrument cart in place (background) and (B) daVinci instrument cart showing with two instrument arms, a retractor arm and the 3D high-definition camera.

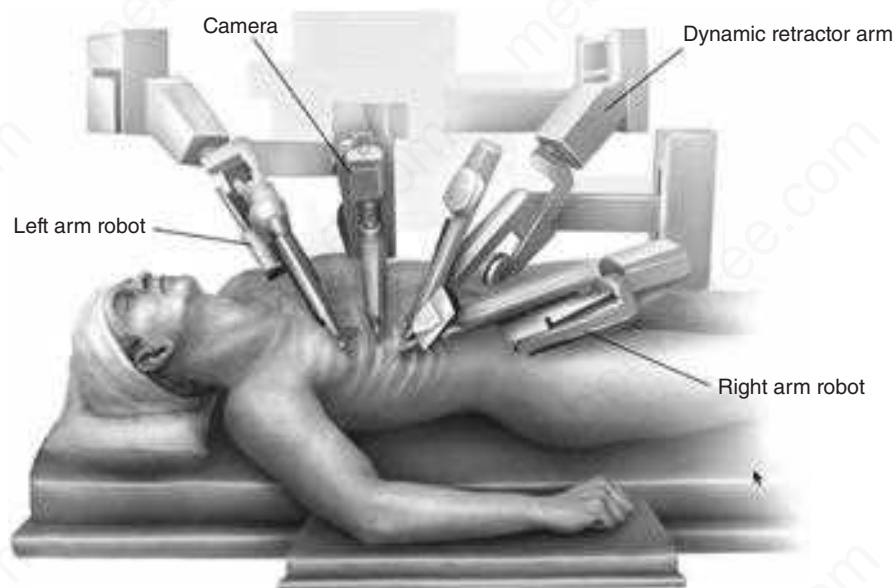

**FIGURE 40-17** daVinci XI Surgical System. (A) Surgeon console and (B) instrument cart. (Used with permission from Intuitive Surgical Inc., Sunnyvale CA.)

(2014) (Fig. 40-17) has a laser targeting system that facilitates docking and instrument engagement. Moreover, 3D visualization has been improved, and the device has robotic tissue stapler capabilities.

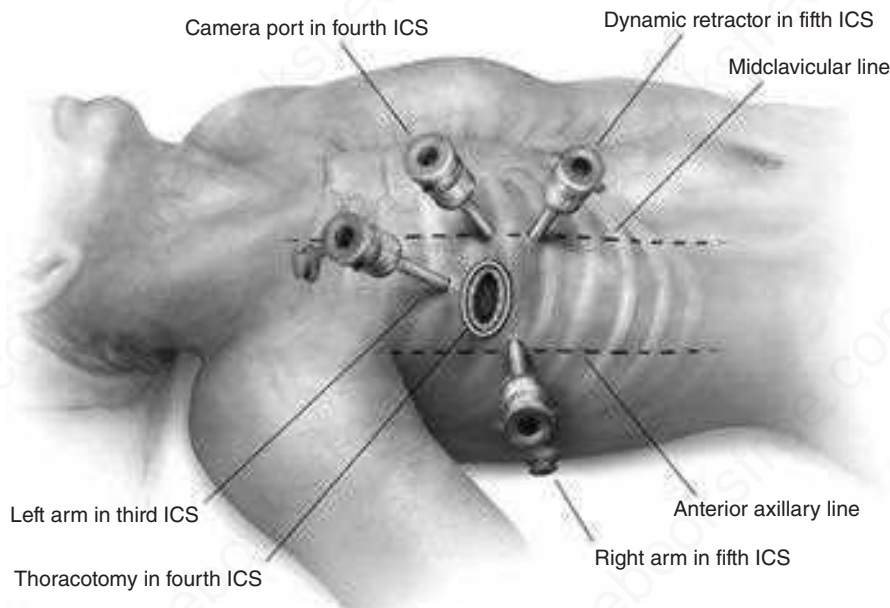

All da Vinci systems are comprised of an operating console, an electronic vision cart, and a surgical instrument cart. For

mitral/tricuspid valve surgery, the instrument cart should be positioned along the left side of the patient (Fig. 40-18). Activator arms are mobilized to gain access to right chest instrument trocars, which have been inserted through specific ICSs (Fig. 40-19). The two instrument arms, the 3D camera, and dynamic retractor are then inserted through these preplaced

**FIGURE 40-18** Robot-assisted mitral valve surgery: patient and instrument positions. The patient is positioned with a 30° lift or towel roll placed under the right shoulder with the right arm distracted to behind the chest. The robotic instrument cart should be positioned along the left side of the operating table. Activator arms are shown to be overarching the patient to gain access to pre-position instrument trocars. (Reproduced with permission from Chitwood Jr WR. Idiopathic Hypertrophic Subaortic Septal Obstruction: Robotic Trans-atrial Resection, Oper Tech Thorac Cardiovasc Surg 2012; Winter 17(4):251-260.)

**FIGURE 40-19** Robot-assisted mitral valve surgery: instrument trocar placement. Trocars have been placed in the designated intercostal spaces (ICS). (Reproduced with permission from Chitwood Jr WR. Idiopathic Hypertrophic Subaortic Septal Obstruction: Robotic Trans-atrial Resection, *Oper Tech Thorac Cardiovasc Surg* 2012;Winter 17(4):251-260.)

trocars. Instrument end effectors translate accurately the surgeon's hand and finger motions. A clutching mechanism enables frequent hand-position readjustments to maintain an optimal ergonomic orientation to the visual field.

Both the daVinci SI and XI have dual-console capabilities, which enable surgeon collaboration during complex cases and facilitates training. The robotic EndoWrist instruments (Intuitive Surgical, Inc., Sunnyvale, CA) have seven degrees of ergonomic freedom, and allow tremor free dexterity with both dominant and nondominant hands. This tremor filtration instills a sense of ambidexterity in the operating surgeon.

### Simulation Training for Robot-Assisted Surgery

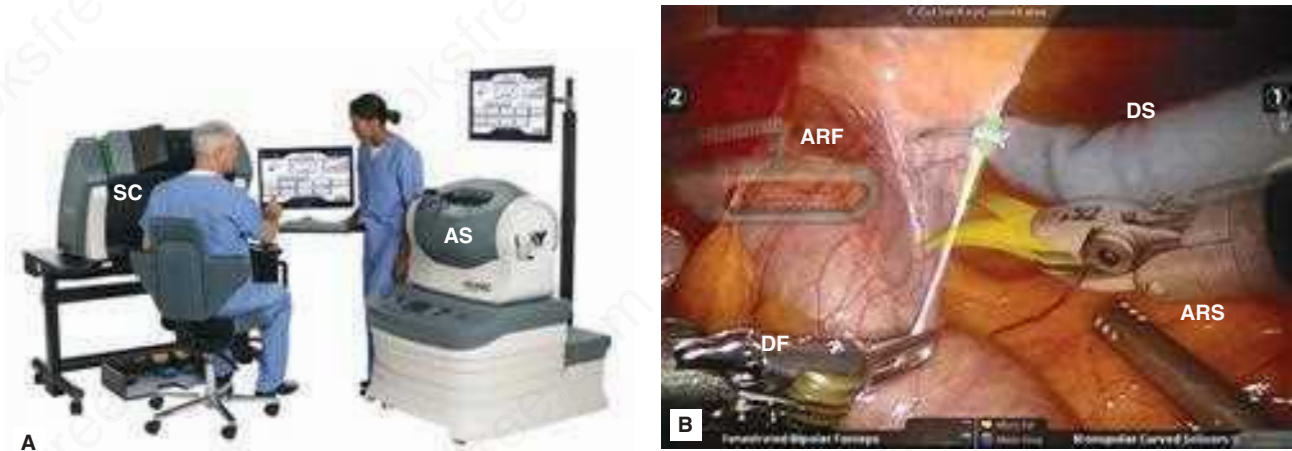

Robotic mitral repair would seem to be the ideal operation to simulate because of: (1) a single working-incision entry point, (2) instrument convergence in a limited operative environment, (3) a 3D digital mitral valve image, (4) topographic echo modeling, (5) end-effector motion freedom, and (6) a motionless arrested heart. However, simulation of actual mitral repair operations today has not been possible. Think of a future when a surgical learner could emulate the exact hand motions and instrument interactions in a simulated landscape that was an actual mitral valve repair done by an experienced surgeon. An entire digital library could be cataloged with specific pathologies. Moreover, through image fusion pathology, specific topographic "blue prints" could be transported into the simulated operative field.

Current robotic simulators have evolved to where they can be advantageous to surgeons learning robot-assisted surgery.

Figure 40-20A shows the current Mimic dV-Trainer along with the assistant surgeon simulator console, the Xperience Team Trainer (XTT). The surgeon's simulator console recapitulates realistically the telemanipulation capabilities of the daVinci SI and XI systems. The assistant trainer (Xperience Team Trainer) allows a tableside surgeon to interact with the surgical field in which the console surgeon is operating. Multiple training protocols can be developed to challenge the console and assistant surgeon to perform synchronous tasks customized for a specific operation. As seen in Fig. 40-20B, the Mimic dV-trainer now has augmented reality functionality called Maestro AR that allows trainer instruments either to follow or repeat an actual recorded surgical maneuver. Figure 40-21 shows the da Vinci backpack simulator, which attached directly to either a current daVinci SI or XI console and is integrated with the robotic software. The console surgeon performs specific training tasks using the daVinci hand controls. The daVinci backpack system and the Mimic dV-Trainer record task metrics and generate a skill report for execution accuracy, speed, and ergonomic motions. More difficult surgical tasks are provided iteratively as the surgeon gains increasing simulation experience.

### Instrument Trocar Placement

Instrument trocars (see Figs. 40-19 and 40-22) are positioned as follows: (1) *left robotic arm*—3D interspace (just anterior to anterior axillary line), (2) *right robotic arm*—fifth interspace (anterior to midaxillary line), and (3) *dynamic retractor arm*—fifth interspace (midclavicular line). After tableside docking the instrument cart, the 30° endoscopic camera is passed

**FIGURE 40-20** Robotic simulation: Mimic dV-Trainer. (A) This illustration shows the surgeon console (SC) and the assistant surgeon trainer (Xperience Team Trainer) (AS) for the Mimic dV-Trainer System. After procedure specific simulation exercises have been performed, a skill metric report is generated. (B) Augmented reality (Maestro AR function) that allows the (virtual) instruments in surgeon console trainer to either follow or repeat an actual recorded surgical maneuver. **FIGURE 40-21** Robotic simulation: da Vinci Skills Simulator. The “Backpack” (BP) Skills Simulator attaches directly to either a daVinci SI or XI surgeon console. Various surgical simulated tasks challenge the surgeon and a report is generated. With advancing skills more difficult tasks are provided. (Used with permission from Intuitive Surgical Inc., Sunnyvale CA.)

**FIGURE 40-22** Robot-assisted mitral valve surgery: inserted instruments. LAR, dynamic left atrial retractor; C, 3D high-definition camera; LA, left instrument arm; RA, right instrument arm; CO<sub>2</sub>, carbon dioxide insufflation port in the right arm trocar.

“up-looking” either through the working incision or a fourth interspace trocar, placed along the midclavicular axillary line. The camera trocar is inserted just anterior to and in the same interspace as the working incision. Robotic instruments used for mitral and tricuspid valve surgery include: Resano (8-mm) Endowrist forceps, which are deployed through the left trocar. The curved Endowrist scissors and needle holders (Suture-cut and Large) are inserted through the right port (Fig. 40-23A–D). Lastly, the dual-blade dynamic retractor is positioned in the chest before initiating CPB (Fig. 40-24).

### MIS AND ROBOT-ASSISTED MITRAL/TRICUSPID VALVE REPAIR TECHNIQUES

After the da Vinci system instruments are “trocar-docked” at the operating table, CPB is begun, and the pericardium is opened and distracted laterally. We place the aortic purse-string suture and cardioplegia cannula using robotic instruments. To establish a structurally sound repair, we generally follow the operative philosophy and techniques prescribed by Carpentier.<sup>31</sup> However, modifications and simplifications

A

B

C

D

**FIGURE 40-23** Robot-assisted mitral valve surgery: end-effector instruments. (A) Suture-cut needle holder; (B) large needle holder; (C) curved scissors; and (D) Resano forceps.

**FIGURE 40-24** Robot-assisted mitral valve surgery: dynamic atrial retractor. (A) Closed position for trocar insertion and (B) open position for atrial retraction.

of these methods remain the mainstay of our repair strategy for both robot-assisted and videoscopic mitral surgery.<sup>63</sup> Table 40-5 shows our “Technique Toolbox” that we use for both RMVP and MIS videoscopic mitral valve repairs.

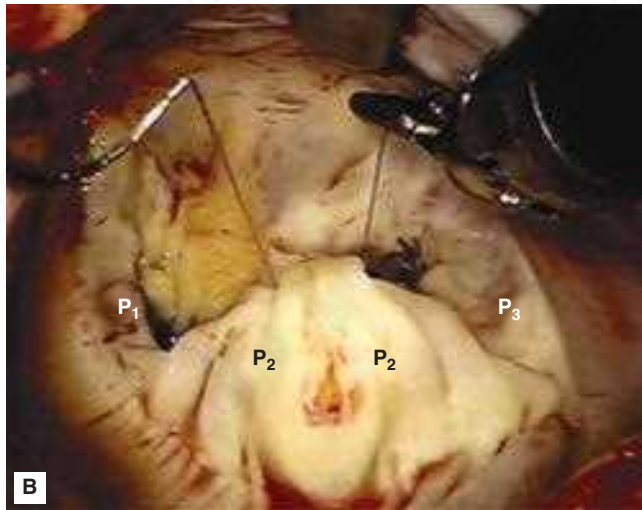

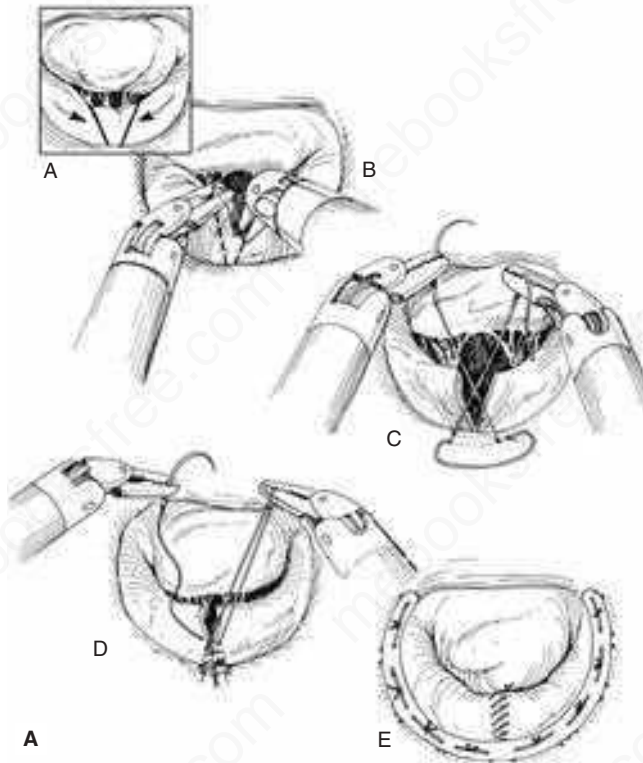

### Posterior Mitral Leaflet Repair

All of our leaflet repairs are based on the preoperative echocardiographic measurements shown in Table 40-3, and from these we apply the repair techniques listed in Table 40-5. Of degenerative mitral with significant insufficiency, 80% of pathologies relate to posterior leaflet defects. Thus, a simple triangular resection often will correct isolated segmental prolapse (Fig. 40-25 A (A-E) and B).<sup>68</sup> We suggest first using

this method to correct isolated scallops having mid-prolapse or ruptured chords. Leaflet segments remaining longer than 2-cm can be reduced in height either using a folding plasty (Fig. 40-26A–D) or additional triangular resections.<sup>69</sup> In the presence of diminutive P<sub>1</sub> and P<sub>2</sub> scallops with a very large P<sub>2</sub>, either the “haircut” resection technique (Fig. 40-27) or insertion of several PTFE neochords can be effective.<sup>70–72</sup> For multiple prolapsing scallops longer than 2 cm, several folding plasties can be used to create the best coaptation line. Final scallop height adjustments should be made after the annuloplasty band has been implanted. An alternative to triangular resections or folding-plasties is using multiple PTFE neochord replacements (Fig. 40-28A–D, plus insets). Native chord replacements, using either individual neochords or

**TABLE 40-5: Minimally Invasive and Robotic Mitral Valve Repair “Technique Toolbox”**

(A) Trapezoidal  $P_2$  leaflet resection; (B) triangular leaflet resection; (C and D) running suture closure; and (E) completed repair with annuloplasty band in place; (inset) after a triangular resection, reapproximated  $P_2$  segments for interrupted suture closure.

the “Leipzig-loop” method, have been adopted widely. In severely prolapsing Barlow’s valves with very elongated scallops and a great deal of redundant tissue, we still defer to a classic mid scallop ( $P_2$ ) quadrangular resection with a posterior leaflet sliding-plasty (Figs. 40-29A–D and 40-30A–D). However, multiple triangular resections, folding-plasties and/

or multiple neochords may be used to repair moderately diseased Barlow’s valves. All of our mitral leaflet repairs have been supported by a trigone to trigone Cosgrove annuloplasty band (Edwards Lifesciences, Inc., Irvine, CA).

### Anterior Leaflet Repair

With isolated uniform anterior leaflet prolapse of less than 2 to 3 mm, we place the annuloplasty band first and then perform a saline test. Usually, this corrects a minor prolapse. When significant anterior prolapse exist, individual areas can be addressed with a local triangular resection, a secondary chord transfer or PTFE neochord replacement, or a combination of these techniques. For a large segment, anterior leaflet prolapse multiple neochords are effective as is a “flip over” chord segment transfer (Fig. 40-31A–E) from the posterior leaflet. Advancement of a chord-bearing anterior leaflet strip can be done if there is a uniform prolapse of  $A_2$  (Fig. 40-32A–D). In elderly patients, especially with significant comorbid conditions, we may perform an (“Alfieri”) edge-to-edge mid-leaflet repair, combined with an annuloplasty. We only use this repair either when reduced operative time is important or there is a significant chance of residual SAM. When a large anterior leaflet prolapsing segment is related to *multiple chords from an elongated papillary muscle*, correction can be accomplished either by muscle shortening (folding) (Fig. 40-33A–D) or insertion of several PTFE chords. We perform a saline test after each individual repair maneuver.

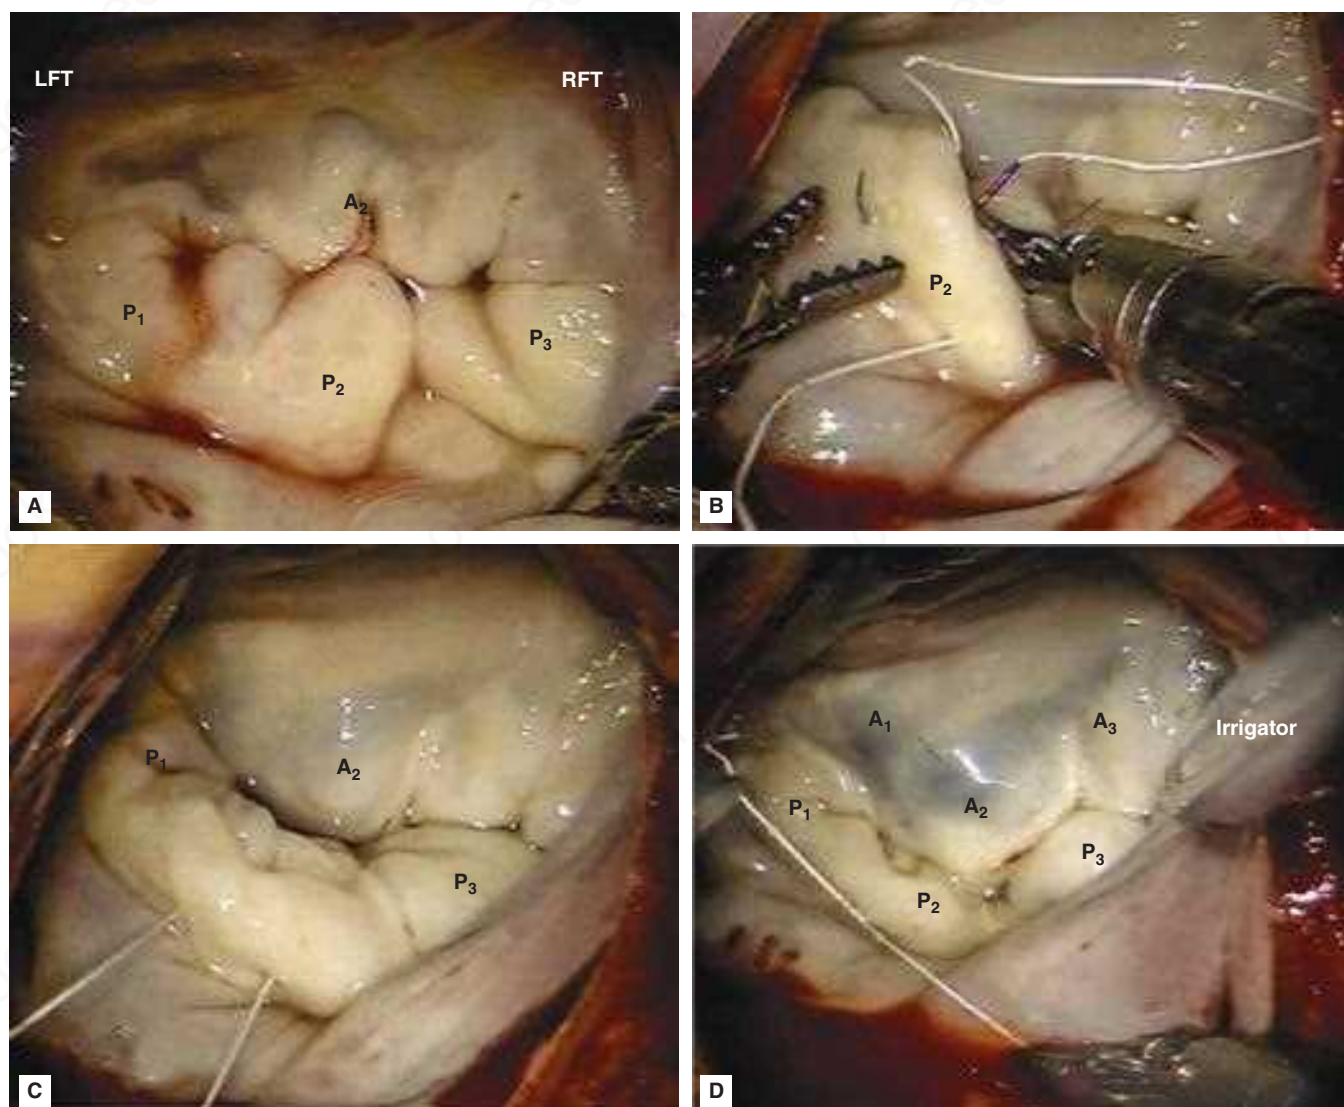

### Commissure Repairs

In most circumstances, commissure prolapse can be corrected by: (1) closure with a Carpentier “magic” stitch (Lembert edge to edge suture) or figure of eight “Alfieri” stitch, (2) insertion of commissural PTFE chords, or (3) papillary muscle folding. The latter can shorten an elongated papillary muscle that has “seemingly” redundant chords, which are attached to both anterior and posterior leaflet edges. This should symmetrically return the prolapsing commissure to an anatomic position.

### Annuloplasty Methods

Annular dilatation is present in most patients with degenerative mitral valve disease. We perform an adjunctive annuloplasty in all repairs to restore the native geometry, reduce the annular size, reinforce the repair and prevent further dilatation. Reducing the anterior-posterior annular diameter increases the leaflet coaptation surface. As mentioned before, annuloplasty band size selection is guided by our intraoperative echocardiographic derived nomogram Table 40-3. For consistency and ease of implantation, we use the Edwards Cosgrove Annuloplasty Band System (Edwards Lifesciences, Irvine Calif.) in most robotic and minimally invasive mitral repairs. Generally, a “trigone to trigone” posterior band provides optimal coaptation, while preserving a “saddle-shaped” systolic configuration.

We first place sutures through the right fibrous trigone, and continue in a clockwise direction. Previously, to

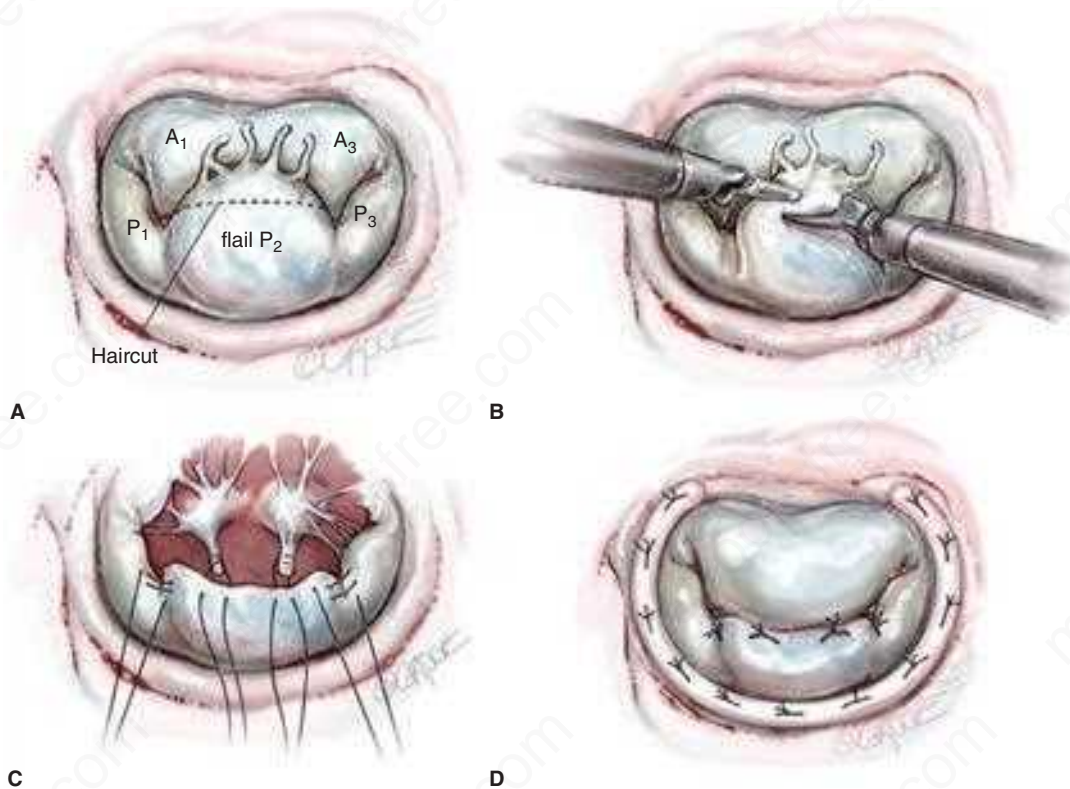

**FIGURE 40-26** Mitral repair technique: posterior leaflet folding plasty. (A) Prolapsing long  $P_2$  leaflet segment; LFT, left fibrous trigone; RFT, right fibrous trigone. (B) PTFE suture passed through the leaflet at the annulus, then “matted” back through the  $P_2$  tip toward the annulus. (C) Both sutures are tightened to render an even coating surface with the anterior leaflet ( $A_2$ ). (D) During a saline pressure test, the PTFE suture is adjusted and tied, rendering a competent valve.

secure annuloplasty bands, we instrument tied interrupted 2-0 Ticron (Covidien, Mansfield, MA) or 2-0 Cardioflon (Peters Surgical, Paris France) sutures. The Cleveland Clinic group has shown great success in using a continuous annuloplasty band suturing technique.<sup>73</sup> We now prefer to use multipoint band fixation, using deep annular braded sutures (2-0 Cardioflon, Peters, Inc., Paris, France), which are secured by Cor-Knot (LSI Solutions, Inc., Victor, NY) titanium clips (Fig. 40-34A–C). After passing both suture ends through the band, they are brought through a wire loop in the applier. The suture-bearing wire loop then is withdrawn through both the applier and a titanium shim. After applying countertraction at the annuloplasty band, the device simultaneously crimps the shim and cuts the suture. The Cor-Knot device has been

very effective at both speeding the operative time and providing very secure band attachment.

### Tricuspid Valve Repair

Generally, we perform tricuspid repairs on the beating heart. For cardiac bicaval venous drainage, we isolate the SVC with a double-looped (Potts) umbilical tape and withdraw the IVC cannula below the liver. Alternately, the IVC can be isolated as described for the SVC. After the right atriotomy has been made, the tricuspid valve is exposed with either the stationary lift or dynamic robotic retractor. At the 2 o'clock anterior annular position, a 2-0 braded suture is placed and then passed extra corporeally through a Tri-Ad semi-rigid tricuspid

**FIGURE 40-27** Mitral repair technique: “haircut” posterior leaflet plasty. (A) An extremely large flail  $P_2$  segment is shown with many ruptured chords. Diminutive  $P_1$  and  $P_3$  segments preclude using a resection strategy. (B) The  $P_2$  tip is resected horizontally to match the lengths of adjacent  $P_1$  and  $P_3$  segments. Remaining good  $P_2$  chords are preserved. (C)  $P_1$ - $P_2$  and  $P_2$ - $P_3$  clefts are suture closed. Preserved chords then are reattached along the resected edge of  $P_2$ . An alternate technique is to resuspend  $P_2$  using PTFE neochords. (D) The completed repair with a band annuloplasty. (Reproduced with permission from Chitwood WR: Haircut mitral valve repair: posterior leaflet-plasty, *Ann Cardiothorac Surg* 2015 Jul;4(4):387-392.)

annuloplasty band (Medtronic, Inc., St. Paul, MN). Then, the band is lowered to the native annulus and secured with a Core Knot titanium clip. We then continue with interrupted sutures from this first stitch, continuing clockwise along the anterior annulus and thereafter counter clockwise.

## ROBOT-ASSISTED MITRAL VALVE REPLACEMENTS

Although tissue excision and suturing methods are similar in robotic mitral valve replacement operations, there are differences in the operative conduct.<sup>74</sup> In some rheumatic valves, leaflet and chordal excision can be difficult using the robotic technique. Current articulated instruments do not have the necessary force to cut very thick or calcified tissue. In this circumstance, we make a larger 5 to 6 cm working incision and excise the thick leaflet and chordal tissue using long manual instruments. We then place all subvalvular valve pledgeted sutures and neochords using daVinci System. Chord sparing replacements are done either by excising the anterior leaflet midportion and leaving natural chords intact or by removing them to increase the prosthesis valve size and replacing them with PTFE neochords. We attempt to preserve all native posterior leaflet chords by passing sutures through the leaflet edge and back through the annulus. In patients with a

severely calcified rheumatic valve or annulus, we may defer to either the 2D endoscopic or direct vision method for a replacement.

To organize sutures securely, guides are placed around the working incision as they are placed serially. Valve sizers are passed through the working incision, and the appropriate prosthetic valve is selected. Thereafter, extra-corporeally suture needles are passed through the prosthetic valve sewing-ring. After positioning the valve in the annulus and confirming seating, sutures are secured using the Core-Knot technique. A ventricular vent is placed and to remove residual air before closing the left atrium. Currently, for all endoscopic and robotic mitral valve operations, we use 4-0 PTFE sutures with pretied end loops to close the left atrium (see Fig. 40-11A). This technique provides a secure closure and saves operative time.

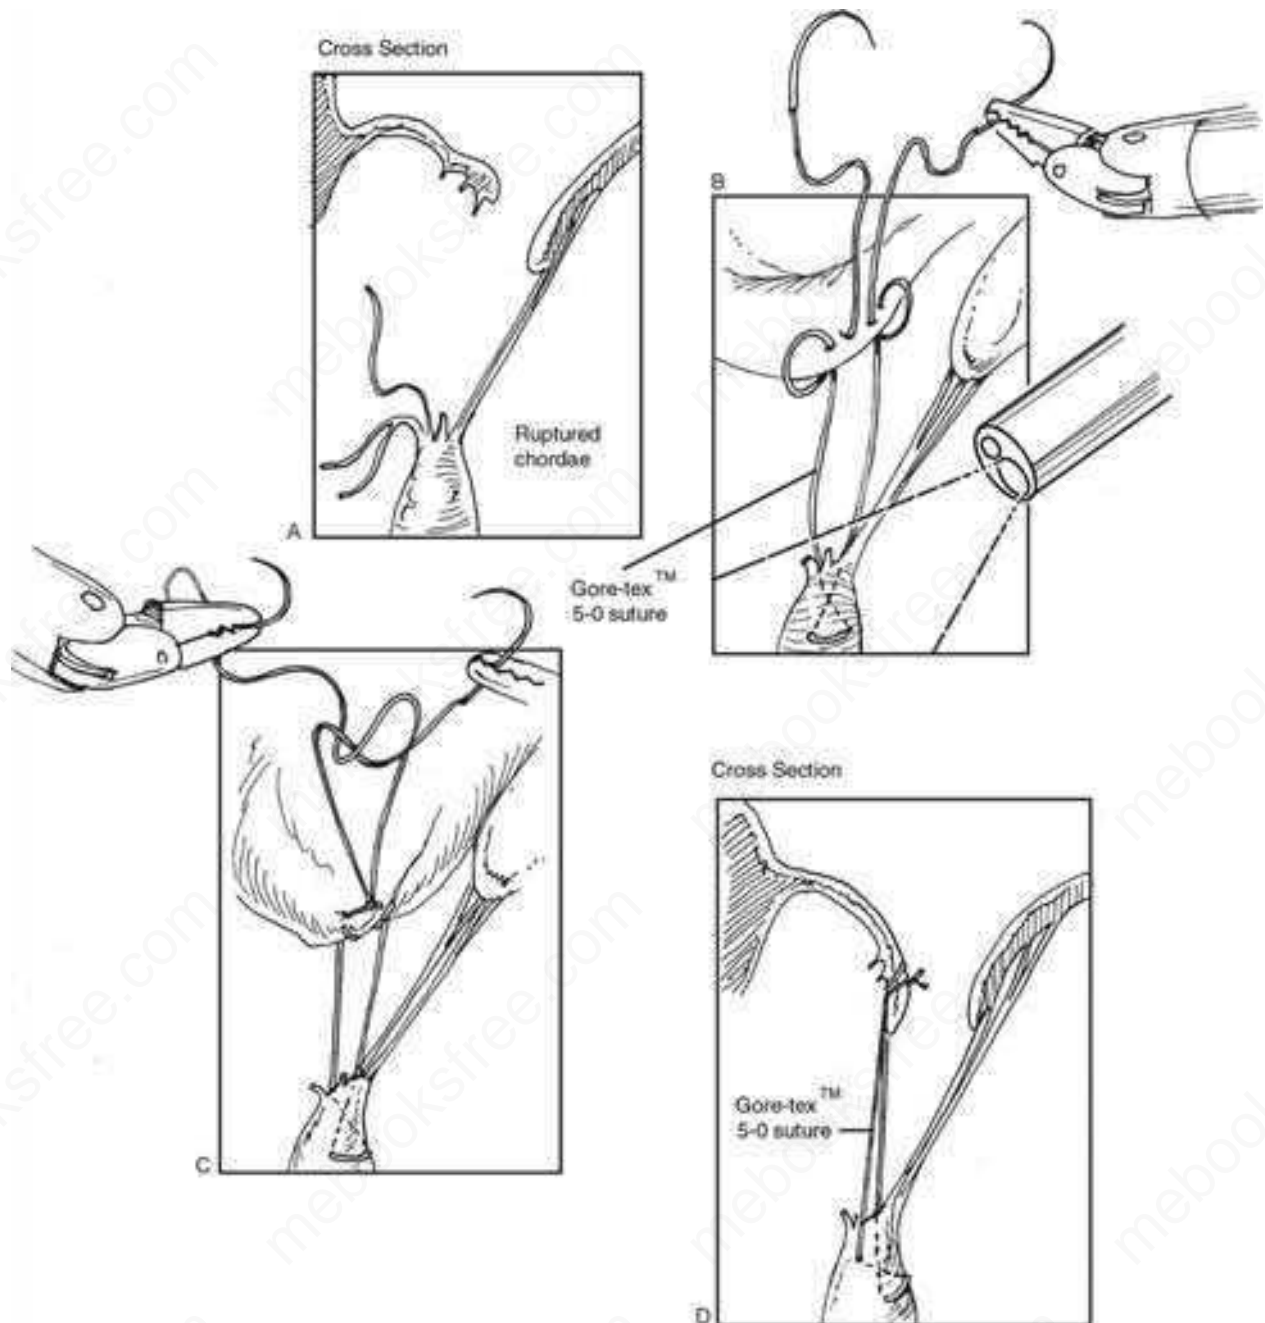

## COMPLICATIONS AND PREVENTION

Patients undergoing any minimally invasive mitral/tricuspid valve operation risk the same complications that can occur with a traditional sternotomy-based procedure. Nevertheless, there are other complications that are inherent in perfusion and ventilation methods used for both MIS and robotic operations. In over 1000 robotic cardiac operations, we have

never had a complication that was related directly either to the daVinci System or the robotic instruments. Our back-up plan for a system failure has always been conversion to either a direct-vision, videoscopic, or sternotomy approach.

Possible major complications with tips to prevention are listed as follows:

- *Retrograde cardiopulmonary perfusion* techniques always induce a risk of atheroembolic strokes, vena caval injury, femoral arterial complications, and retrograde aortic dissections. Careful preoperative vascular screening can minimize these problems. All cannulas should be inserted using the Seldinger technique under echocardiographic

**FIGURE 40-28** Mitral repair technique: neochord replacement. (A) Flail anterior leaflet from multiple ruptured chords. (B) 5-0 Gore-tex PTFE sutures are passed through the fibrous head of the corresponding papillary muscle using a tendon repair “cross stitch” configuration (W. L. Gore & Associates, Inc., Flagstaff, AZ). This precludes the need for a pledget and prevents muscle ischemia. Each suture is then passed twice through the flail leaflet edge, forming a loop hitch. (C) During saline pressure testing these loops are adjusted to provide an optimal coaptation surface. Thereafter they are tied. We suggest that final suture adjustment and tying be done after annuloplasty prosthesis placement. (D) The leaflet prolapse has been reduced to an ideal level of coaptation.

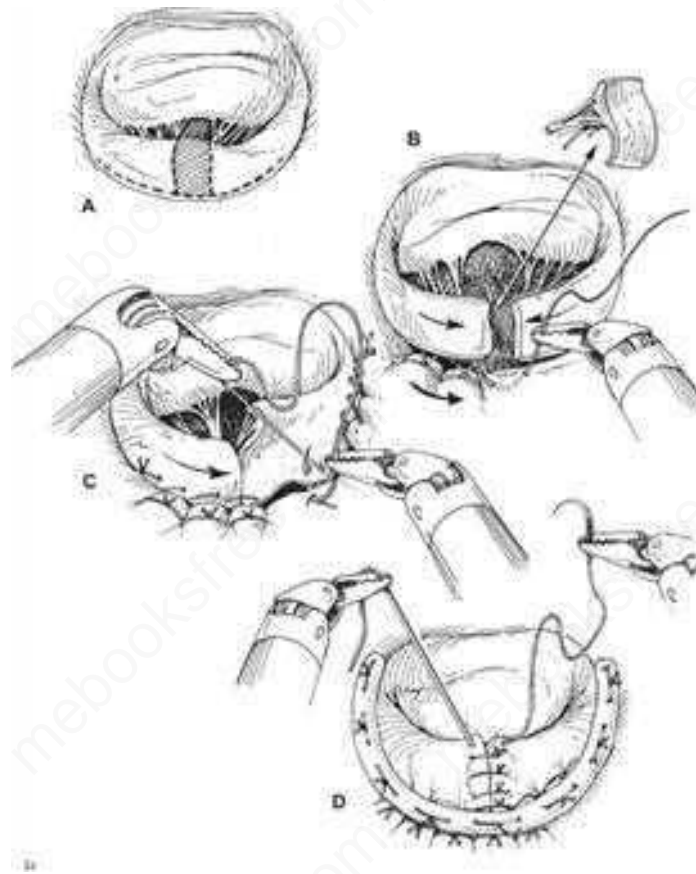

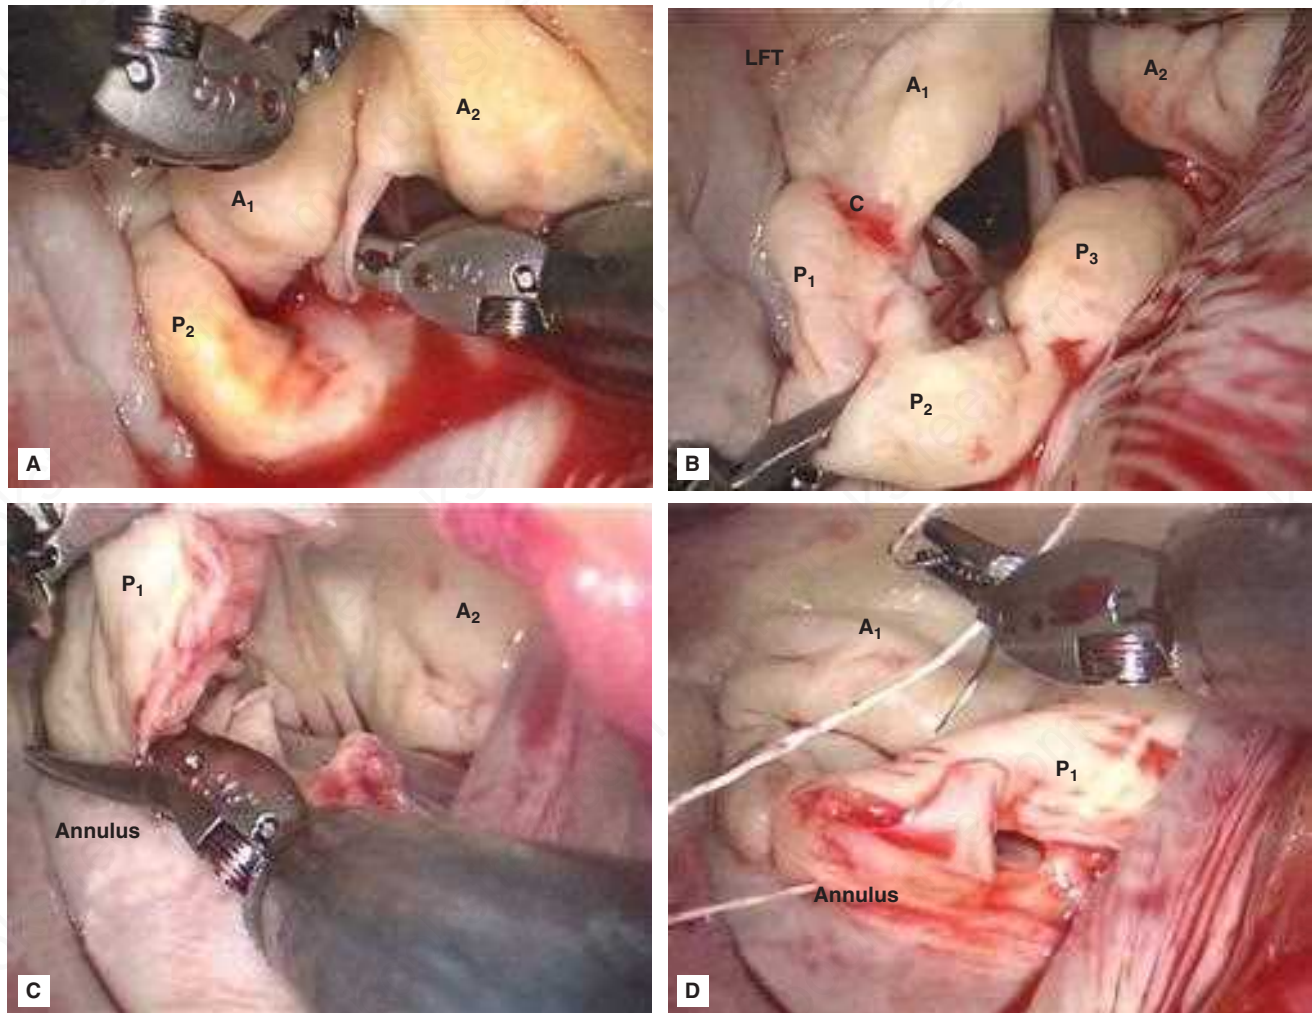

E

**FIGURE 40-28** (Continued)

**FIGURE 40-29** Mitral repair technique: posterior leaflet sliding plasty. (A) In a globally prolapsing redundant posterior leaflet, a large quadrangular resection has been performed. Thereafter, a radial periannular leaflet incision has been made on each side of the resection. (B) A number of mattress plication sutures are placed along the radial incision to reduce the annular length symmetrically. (C) Residual medial and lateral posterior leaflet tissue is advanced or “slid” centrally with a polypropylene or PTFE suture. (D) The defect between each newly approximated leaflet segment then is closed using either a running or interrupted suture technique. Finally, an annuloplasty prosthesis is implanted.

**FIGURE 40-30** Mitral repair technique: posterior leaflet sliding plasty. (A and B) The entire posterior leaflet has redundant prolapsing tissue. LFT, left fibrous trigone; C, anterior commissure. (C) A large  $P_2$  quadrangular resection has been performed. A radial periannulus incision has freed  $P_1$  to near the anterior commissure. (D) A PTFE suture is shown “advancing/sliding” residual  $P_1$  tissue centrally along the annulus to meet with the opposing  $P_3$  flap. visualization. The endo-balloon should not be used in patients with mobile atheroma or diffuse aortic disease.

- *Leg ischemia during retrograde perfusion* can be avoided. We place oxygen saturation monitoring patches on both legs. With a significant decrease in cannulated leg oxygen saturation, we place a shunt from the CPB arterial cannula into the distal femoral artery.
- *Phrenic nerve injury* can be caused by over stretching the pericardium, cautery thermal injury, cryoablation, and/or direct instrument injury. This is a major problem in patients with compromised pulmonary function. Injury can be avoided by visualization of the nerve during instrument insertion and cautery usage. Overstretching can be avoided by making the pericardial incision at least 3-cm ventral to the nerve.
- *Unilateral pulmonary edema* is a serious complication. Short perfusion times, systemic cooling, avoiding

barotrauma, limiting blood product transfusions, and minimizing lung deflation times can reduce this risk. We also believe that low-level positive pressure and frequent alveolar recruitment, while on cardiopulmonary bypass, is beneficial.<sup>75,76</sup>

- *Transthoracic clamp injuries* can occur as the posterior element passes near the right pulmonary artery, left main coronary artery, and left atrial appendage. Visualization of the clamp pathway during application minimizes the chance of these complications. Pump arterial flow should be decreased during clamping. We have had no clamp related aortic dissections in any of our robot-assisted or videoscopic MIS mitral operations.
- *Right ventricular dysfunction* can be minimized. Meticulous cardiac deairing before weaning from cardiopulmonary bypass is essential. Right 30° chest elevation places the right coronary artery ostium in a perfect position

**FIGURE 40-31** Mitral repair technique: native chord segment transfer. (A) A localized prolapsing portion of  $A_2$  is shown. A small chord-bearing donor: section of posterior leaflet is selected. (B) The select area is resected and translocated while protecting intrinsic chords. This segment is “flipped over” to the prolapsing region of  $A_2$ . (C and D) The donor segment is then suture approximated to  $A_2$ ; (inset) in this instance, it is attached to the posterior rough zone of  $A_2$ ; and (E) the residual  $P_2$  defect is closed, and annuloplasty prosthesis is implanted.

**FIGURE 40-32** Mitral repair technique: anterior leaflet/chord advancement. (A) The entire  $A_2$  is prolapsing to the same uniform level. (B) A strip of chord-bearing  $A_2$  is transected horizontally along the coapting edge, being careful not to disrupt any chords. (C) This chord-bearing strip is advanced along the anterior surface of  $A_2$  to the level that the prolapse is reduced to create good coaptation with  $P_2$ . (D) Using mattress sutures, the strip is attached to  $A_2$  and annuloplasty prosthesis is implanted.

for air embolism from residual left ventricular air and/or aortic entrainment during cardioplegia infusions.

- *Left ventricular dysfunction* is a serious problem and can be avoided or minimized by selecting patients with ejection fractions of no less than 40 to 50%. If blood cardioplegia is used it must be given at 15- to 20-minute intervals. Systemic cooling (28°C) and meticulous de-airing are mandatory to maximize myocardial protection. Ventricular distention is a serious problem and can be prevented by leaving a ventricular vent after a repair or replacement.

## CLINICAL OUTCOMES

### Nonrobotic Minimally Invasive Mitral Valve Surgery

Many earlier observational and/or propensity-matched series have shown that direct-vision and video-assisted MIS mitral

surgery is safe with clinical results similar to operations done through a sternotomy. Four recent studies, that are cited herein, each reported over 1000 MIS mitral operations.<sup>77–80</sup> Nearly all of the 6179 patients were operated through a right minithoracotomy and approximately 75% underwent retrograde femoral CPB perfusion. Of these patients, the operative mortality was 0.75% and stroke rate was 1.2% (mean). Mohr et al reported the largest of these series with 2829 MIS mitral repairs.<sup>78</sup> Their freedom from a reoperation was 97 and 93% at 5 years and 10 years, respectively. The long-term survival was 87 and 74% at 5 and 10 years, respectively.

A recent meta-analysis from the *International Society of Minimally Invasive Cardiac Surgery* showed that versus a conventional (C) sternotomy, MIS mitral operations had less postoperative atrial fibrillation, chest tube drainage, transfusions, and infections.<sup>13</sup> There was no difference in the repair quality or freedom from reoperation. Moreover, operative mortality was not statistically different (1.5% C vs 1.2% MIS). Other benefits included reduced intensive care times and length of hospitalization as well as faster return to normal activity. These advantages were despite significantly longer perfusion and aortic cross clamp times. Conversely, they found more strokes (1.2% C vs 2.0% MIS), aortic dissections (0.0% C vs 0.2% MIS), and phrenic nerve injuries (0% C vs 3.0% MIS) in the MIS group. In contradistinction, the meta-analyses of Modi, Cao, and Sundermann have shown similar benefits and clinical outcomes as with traditional sternotomy operations, including strokes and operative mortality.<sup>81–83</sup>

The presumptive increased stroke risk with MIS has been attributed to retrograde CPB perfusion.<sup>84–86</sup> Most studies that impugned retrograde perfusion as the etiology of MIS strokes also included large numbers of patients who underwent endo-balloon aortic clamping. Retrograde endo-balloon catheter passage through the aorta seemingly risks cerebral atheroembolism, especially in nonscreened patients. This confounds any study that is considering the absolute relationship between retrograde perfusion and strokes. Moreover, these series did not report a vascular screening strategy and subtended the early days of MIS mitral surgery. Grossi found that there were no differences in perioperative strokes between antegrade and retrograde perfusion, if screened high-risk vascular patients were not included.<sup>86</sup> Atluri and Hargrove determined that in *screened patients* with retrograde CPB perfusion both endoballoon and direct aortic clamping had similar neurological events.<sup>87</sup> Also, Modi and Chitwood (meta-analysis) showed retrograde perfusion to be safe when patients were screened for aortic and peripheral vascular disease.<sup>88</sup>

### Robot-Assisted Mitral Valve Surgery

Our early series (years 2000–2010) reported 540 RMVPs of which 454 patients underwent a lone mitral procedure, and 86 had a concomitant atrial fibrillation ablation.<sup>56</sup> In the lone repair cohort, cross clamp and CPB times averaged 116 and 153 minutes, respectively, and the operative mortality was 0.2%. Of those treated for preoperative atrial fibrillation, 96.5% were atrial fibrillation and drug free at 351 days

**FIGURE 40-33** Mitral repair technique: papillary muscle shortening. (A) Redundant chords from the posterior papillary muscle have allowed  $A_3$  and  $P_3$  to create wide prolapse of the posterior commissure (C). (B) A PTFE suture has been passed through the fibrous tip of the posterior papillary muscle and then through the base. The suture should be tightened to reduce the muscle length before tying and the valve saline tested. (C and D) Thereafter, the suture is tied at the papillary muscle base.

(15–946 days). During patient follow-up, 2.9% required a re-operation for a failed repair. This study included the original FDA clinical trials and was the inaugural United States robotic mitral valve repair series.

Overall, we have performed over 1000 RMVP operations at our institution. Our single surgeon's (Dr. Chitwood) experience of 944 RMVPs (years 2000–2014) included the earlier series. For these operations, the original daVinci, the daVinci S, and the daVinci SI devices were used serially. Trento showed improving results with every device iteration, as did our group.<sup>58</sup> Of these patients, 675 had RMVPs alone, 321 had a concurrent maze procedure (M-RMVP) and 38 were reoperations in patients that had a prior sternotomy (Re-RMVP). For the entire series, the in-hospital mortality was 1.4%; however, for

an isolated RMVP was 0.15%. Of the entire series, 2.5% had reoperations for a failed repair, which was 1.7% for a lone RMVP. For each of these cohorts, mean CPB times were 148, 187, and 176 minutes, respectively. For RMVP and M-RMVP groups, mean aortic cross-clamp times were 108 and 128 minutes, respectively. Re-RMVP operations were done under hypothermic ventricular fibrillation (113 minutes, mean). In the RMVP patients, *major complications* included myocardial infarctions (0.9%) and strokes (0.9%). Reexplorations for bleeding were required in 2.7% of patients. There were two incidences of residual phrenic nerve palsy. Packed red cell transfusions were required in 28% of patients and 38% with any blood product. Of the RMVP patients, 56.9% were discharged within 4 days with 75.0% within 5 days. When

**FIGURE 40-34** Mitral repair technique: Cor-Knot annuloplasty band anchoring. (A) After loading the Cor-Knot applicator (CKA), a previously placed annuloplasty band (B) suture is withdrawn through a loop wire. When the wire is withdrawn, the suture transits titanium “shim,” which is then crimped and the suture cut in one motion. (B) A titanium shim is shown after band approximation. (C) A completed annuloplasty band implantation using multipoint fixation Cor-Knot shims.

leaving the operating room, 97.1% of patients had no or trivial mitral regurgitation. Table 40-6 shows the complete post repair transesophageal echocardiographic data. Other large RMVP series have shown similar clinical outcomes.<sup>57-60</sup>

### The Future

As the singer Bob Dylan said in 1964 “*The Times They Are a Changin’*” and indeed they are changing .... and fast.<sup>89,90</sup> Long-term clinical data have established the expectation that mitral repair is the “gold” standard. Cardiology guidelines now

suggest that asymptomatic patients should be referred for surgery earlier, before atrial fibrillation, ventricular dysfunction, annular dilatation, and/or advanced valve pathology develops. Echocardiographic imaging continues to advance every year, and providing improved operative guidance. In experienced hands, minimally invasive and robotic derived repair results now parallel those of sternotomy operations. Although minimally invasive mitral surgery in the United States lags behind European centers, our younger surgeons know that the future favors even less invasive operations. Finally, the Internet and social media have given patients many more clinical choices

**TABLE 40-6: Robot-Assisted Mitral Valve Repairs: N = 944 Postoperative Transesophageal Echocardiographic Studies**

Residual mitral insufficiency	All patients N = 944 (%)	RMVP N = 675 (%)	C-RMVP N = 231 (%)	Re-RMVP N = 38 (%)
None	81.8	82.4	80.1	60
Trivial	15.3	15.1	16.0	36.8
Mild	2.8	2.4	3.9	2.6
Moderate	0.7	0.0	0.9	0.0
Severe	0.1	0.0	0.0	0.0

and empowerment than in the past. They are more knowledgeable about their health care and demand to participate. Collectively, these facts seem like the “Sword of Damocles” for surgeons who scoff at the evolving mitral technology.

Advent and application of the Mitra-Clip (Abbott Vascular, Santa Clara, CA) and completion of the first Everest Trial proved that in high-risk patients, mitral regurgitation could be reduced to the point where symptoms abated. Even when some residual regurgitation remained, patients were better. This set the stage for off-pump neochord chord replacements to reduce leaflet prolapse in patients with a nondilated annulus. Transcatheter annuloplasty prostheses have been developed to reduce dilatation. The story regarding treatment of ischemic mitral regurgitation is not completed, but we do know that transcatheter replacements may stabilize patients more than a repair. Heretofore, less attention was paid to the leaking “lonely” tricuspid valve. The natural history of this malady is better understood and transcatheter remedies are evolving.

Where does that leave surgeons? We are in the enviable position of being able to surgically repair mitral valves while simultaneously coopting transcatheter therapy. Owing to proven long-lasting results, surgical repair in younger patients will continue for a number of years. To be sure, if we can provide the least invasive complete repairs, based on sound engineering principles, we will prevail. Hopefully, principles set forth in this chapter comprise the entry portal to the future of mitral valve therapy.

# Percutaneous Catheter-based Mitral Valve Repair

Mani Arsalan • J. Michael DiMaio • Michael Mack

Mitral valve repair (MVR) remains the standard of care for patients with severe valve incompetence. MVR is usually accomplished by either an open surgical (sternotomy) approach or by minimally invasive (right lateral minithoracotomy) access techniques. Recently there has been an intense interest in developing percutaneous catheter-based techniques, especially for high-risk patients.<sup>1-4</sup>

Although the success of transcatheter aortic valve replacement (TAVR) has been rapid, progress toward percutaneous correction of mitral regurgitation (MR) has been much more modest.<sup>5</sup> The success of catheter-based treatment of aortic stenosis can be attributed to a number of factors: the singular pathophysiology of the diseased valve, the aortic valve's anatomical location that allows for precise valve stent implantations at the annular level, and the successful development of delivery systems using conventional imaging techniques. The field of percutaneous MVR, however, has not progressed so rapidly for a host of reasons including the complex pathophysiology of MR with a diversity of etiologies, as well as challenges in imaging and delivery and secure anchoring of the valve without impingement on surrounding cardiac structures. These obstacles have led to slower than anticipated clinical adoption of catheter-based approaches for the treatment of MR. To understand the potential for successful therapy, it is first instructive to examine the pathophysiology of the various mechanisms of the disease.

## PATHOPHYSIOLOGY OF MITRAL REGURGITATION

The mitral valve (MV) is a complex structure composed of two leaflets, a fibrous annulus with varying degrees of continuity and integrity, and a subvalvular apparatus consisting of chordae tendineae and papillary muscles attached to the wall of the left ventricle (LV). The etiology of MR can be categorized into two ways: primary also called degenerative or organic, and secondary or functional MR.

In primary MR (Carpentier Type II), the intrinsic disease is a result of leaflet degeneration, ranging from fibroelastic deficiency to an excess of connective tissue called Barlow's disease, in patients with MV prolapse. Although MR of intrinsic

disease occurs initially as isolated leaflet disease, secondary annular dilatation occurs in the majority of patients by the time that they present for treatment.

The largest proportion of patients who present with MR, however, are those with secondary MR (Carpentier Type IIIB), in which the valve is anatomically normal but has been stretched by tethering and ventricular dilatation.<sup>6</sup> Secondary MR is not a primary valvular pathology but is a result of a cascade of events initiated by this ventricular dilation. Ventricular dilation leads to apical and lateral distraction of the papillary muscles, which results in tethering of the mitral leaflets. This tethering causes central regurgitation secondary to failure of coaptation of the anatomically normal leaflets during systole.<sup>7</sup> The causes and prognosis of secondary MR are inherently different from intrinsic disease. Although annular dilatation also occurs in this disease, it is a secondary phenomenon. The principle utilized during surgical repair of secondary MR is based upon overcorrection of the annular dilatation component by performing an undersized annuloplasty to restore leaflet coaptation. To date, it is still unknown whether correcting secondary MR has any impact on the underlying pathology or affects long-term survival.<sup>8-11</sup>

## CURRENT TRANSCATHETER APPROACHES TO THE TREATMENT OF MITRAL REGURGITATION

There is a wide spectrum of devices and approaches to manage MR from a percutaneous or transcatheter approach (Table 41-1).<sup>12</sup> Most catheter-based repair techniques are based on techniques that have been proven to be effective in open surgical MVR. Examples include the edge-to-edge technique, placement of artificial chords, and annular remodeling. However, the challenges in adapting these techniques to catheter-based treatment are significant and center mainly on device delivery and imaging. In contrast to open surgical therapy which employs a combination of techniques, transcatheter approaches have not yet successfully combined these different techniques, and, thus, complex pathologies are hard to correct.

**TABLE 41-1: Concepts of Transcatheter Techniques for the Management of Mitral Regurgitation**

- Mitral “spacer”
- Mitral valve replacement

Although many different strategies and devices have been developed, only three have received European (CE Mark) approval to date. These are the MitraClip (Abbott Vascular, Irvine, CA), NeoChord DS 1000 (NeoChord, Inc., Louis Park, MN), and Carillon Mitral Contour System (Cardiac Dimensions, Inc., Kirkland, WA). MitraClip has also received US Food and Drug Administration (FDA) approval for commercial sale in the United States, but only for patients with primary MR who are at high risk for surgical repair. Other devices are in various stages of development.

Some devices such as the MitraClip have been employed to treat both primary and secondary MR. Most, however, have been designed to treat only one etiology or the other, with the majority devoted to secondary MR because of the larger clinical need and the existence of excellent surgical repair techniques for primary disease. We will first review the procedures and devices for the management of primary mitral disease.

## Primary Mitral Regurgitation

### PERCUTANEOUS EDGE-TO-EDGE REPAIR

The MitraClip system is the only device with extensive clinical application, now with over 19,000 implantations worldwide. The MitraClip mimics the surgical edge-to-edge repair technique of Alfieri (Fig. 41-1).<sup>13</sup> The device received CE approval in 2008, and FDA approval in 2013. However, the FDA approved the MitraClip only for primary MR in high surgical risk patients and not for patients with secondary MR.

The MitraClip system is designed to allow off-pump endovascular reconstruction of the regurgitant MV. It includes a clip device (MitraClip) and a steerable guiding catheter that enables placement of the clip on the free edges of the MV leaflets. The clip ensures permanent leaflet approximation and creates a double orifice MV (Fig. 41-2). The procedure is performed percutaneously via the femoral vein with transseptal puncture in a cardiac catheterization laboratory or in a hybrid suite with echocardiographic guidance under general

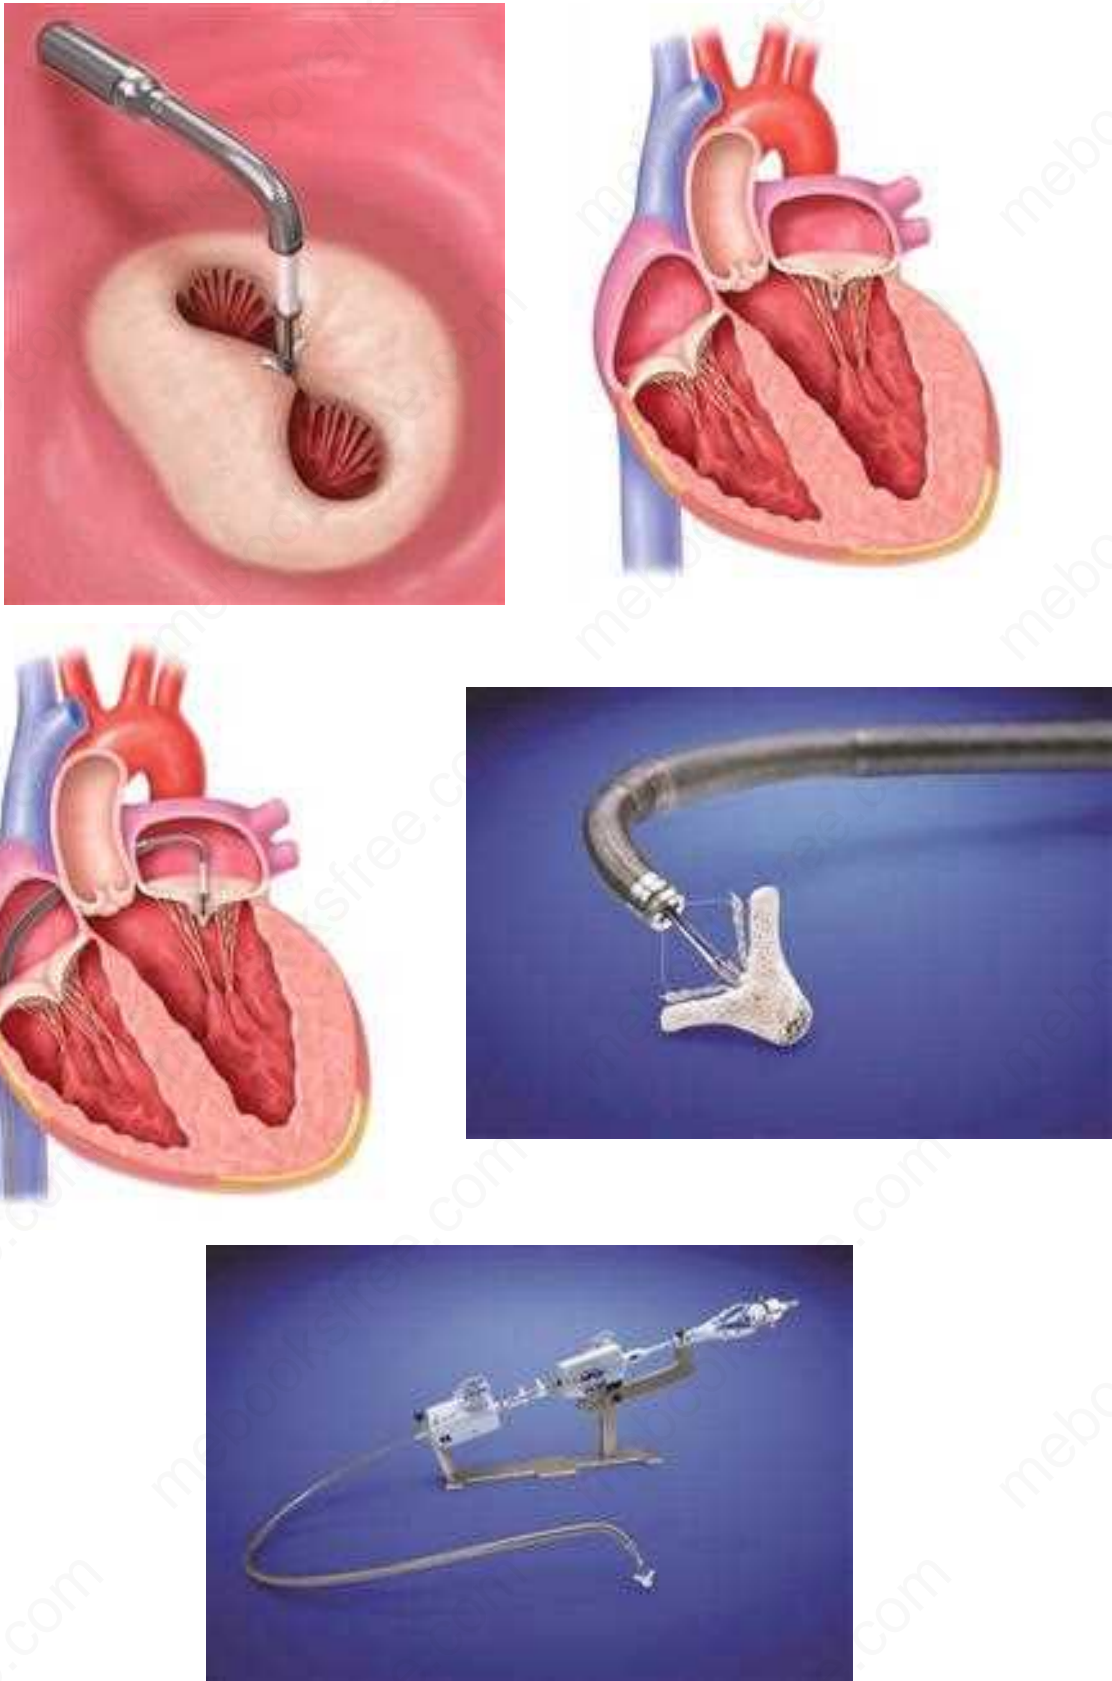

**FIGURE 41-1** Concept of surgical correction of mitral regurgitation by attaching the free edges of the mitral leaflets, creating a double orifice valve.

anesthesia. The addition of three-dimensional and X-plane echocardiography has significantly facilitated the procedure, as the improved visualization allows for more accurate MitraClip positioning (Fig. 41-3).

Without any strict recommendations from the manufacturer on type or duration of postoperative antiplatelet therapy, several anticoagulation regimens have been proposed. In the Everest I and II trials, aspirin 325 mg daily for 6 months to 1 year was implemented with 75 mg of clopidogrel daily for 1 month.<sup>14-16</sup> In Europe 100 mg of aspirin daily for 3 months and 75 mg of clopidogrel daily without a loading dose for 4 weeks are more commonly used.<sup>14,17</sup>

The primary benefit associated with the use of the MitraClip is reduction of MR with elimination of the needs for open chest surgery, cardiopulmonary bypass, and cardiac arrest. The potential risks include those associated with cardiac catheterization and transseptal puncture. The major concern regarding this technique is uncertainty regarding the efficacy of a procedure that results in a less complete correction of MR than is usually accomplished surgically. This concern is based on the knowledge that surgical edge-to-edge repair without annuloplasty is associated with a higher rate of recurrent severe regurgitation if the residual MR is greater than 1+ postoperatively.<sup>18</sup> Whether partial reduction of MR is sufficient to translate into ventricular reverse remodeling and, more importantly, any clinical benefit remains to be determined.<sup>9,11</sup> Additional concerns have been raised regarding the potential impairment of the ability to perform a subsequent surgical valve repair should this become necessary.<sup>19-21</sup>

There is a recent trend to implant multiple clips during a single procedure to achieve better coaptation and, thus, improved outcomes.<sup>22</sup> Of note, there have been very few reports of mitral stenosis necessitating intervention following MitraClip repair.<sup>23,24</sup> Even after multiple clip implantations in the same patient, mitral stenosis has rarely occurred.

**FIGURE 41-3** Three-dimensional echocardiogram demonstrating the MitraClip in position. (© 2013 Abbott. All rights reserved. MitraClip is a trademark of the Abbott Group of Companies.)

MitraClip has undergone significant clinical testing. In the initial clinical feasibility trial (Everest I: Endovascular Valve Edge-to-Edge REpair Study), 55 patients were enrolled, and both the safety and efficacy of the device were demonstrated. The pivotal Everest II trial was a multicenter randomized controlled trial to evaluate the benefits and risks of MVR using the MitraClip device compared with open MV surgery in 279 relatively low-risk patients with moderate or severe MR. It was conducted as a per-protocol analysis on a noninferiority hypothesis. Although transfusion was the major component of the composite safety endpoint in the surgical arm, the device met the safety noninferiority hypothesis criteria even if transfusion was eliminated. The primary effectiveness endpoint was determined as freedom from the combined outcome of death, MV surgery or reoperation, and MR greater than 2+ at 12 months. The trial also met the clinical success noninferiority hypothesis, which set a pre-specified margin of 31%, at 12 months. The clinical success rate in the device group was 72.4% compared with 87.8% in the control group, an absolute observed difference margin of 15.4%. However, most likely due to the early learning curve with this device, acute procedural success (MR  $\leq$  2+ at discharge) was achieved in only 77% of patients, and 21% required subsequent open MV surgery. Ultimately, the Everest II trial showed that the MitraClip is safer, particularly by reducing the frequency of postoperative transfusions, but not as effective in reducing MR as compared to conventional MV surgery.<sup>25</sup>

The EVEREST II High-Risk Registry and REALISM Continued Access Study High-Risk Arm investigated the outcome of MitraClip therapy in 351 high-risk patient with 3 to 4+ MR. MR was reduced to  $\leq$ 2+ in 86% of patients at discharge.<sup>26</sup> Despite a mean STS-predicted operative mortality risk of  $11.3 \pm 7.7\%$  for mitral replacement, the Kaplan-Meier freedom from death was 77.2% at 12 months. Freedom from MV surgery was 97.8% over this interval, even though 16.4% of patients had MR > 2+ at 12 months. This result

may have been inflated, however, by the high operative risk in these patients.

Since MitraClip was approved in Europe, several registries have demonstrated high rates of procedural success and favorable short-term outcomes. The Transcatheter Mitral Valve Interventions (TRAMI) Registry with 1064 patients (71% with secondary MR) showed that the procedure can be performed at a high success rate (95% device success) with no procedural deaths in a high-risk patient cohort (median STS mortality score 10; 69% of the patients with LVEF <50%).<sup>27</sup> In the ACCESS-EU registry, the MitraClip was implanted in 567 patients at 14 sites.<sup>28</sup> The mean logistic EuroSCORE was 23%, and 77% of patients had secondary MR. Multiple clips were used in 40% of patients. MR was reduced to  $\leq$ 2+ in 91% of patients without any procedural deaths. NYHA class and 6-minute walk distance had both improved at 1-year follow-up. The European Sentinel Pilot Registry, with a similar rate of secondary MR patients (71% of 628), confirms these results while maintaining high procedural success (95.4%) and low mortality rates (in-hospital mortality 2.9%). Although the rehospitalization for heart failure was more common in the secondary MR group (25.8 vs 12.0%,  $p = .009$ ), recurrence of severe MR was present only in 6% of patients at 1 year following the procedure.<sup>29</sup>

The current guidelines are largely influenced by the encouraging results of these clinical trials. The 2012 ESC/EACTS Valve and HF guidelines provide a class IIb (LOE C) recommendation to consider MitraClip use in symptomatic patients with both severe primary and secondary MR.<sup>30</sup> The patients need to be judged inoperable or at high surgical risk by a “heart team” and should have a life expectancy greater than 1 year. Patients with secondary MR additionally need to be under optimal medical therapy and cardiac resynchronization therapy, if indicated.

Despite the fact that MitraClip has CE mark approval in secondary MR and has achieved good results in the large European registries for this disease category, the FDA has approved MitraClip only for the treatment of patients with primary MR in high surgical risk patients. Thus, in the 2014 ACCF/AHA Valve guidelines, MitraClip is recommended with class IIb (LOE b) guidance for severe primary MR in symptomatic patients at prohibitive risk for MV surgery.<sup>31</sup>

The future role of MitraClip in the management of both primary and secondary MR remains unclear.<sup>32</sup> Particularly, high-risk patients with secondary MR may benefit from MitraClip therapy. Three large ongoing randomized trials (COAPT, RESHAPE-HF, and Mitra-Fr) comparing MitraClip plus guideline-directed medical therapy (GDMT) versus GDMT alone in secondary MR may further elucidate the optimal role for MitraClip. The results of these trials should be available by 2017. However, even in the healthiest subgroup of patients—those with primary MR, no annular calcification, and optimal initial medical MR reduction—freedom from recurrent MR is only 60% after 9 years if annuloplasty is not performed.<sup>33</sup> This might be acceptable for

older or high-risk patients, but not for patients who are suitable for surgery.

### Leaflet Repair Using Artificial Chords

The NeoChord DS1000 device allows off-pump implantation of artificial neochordae to repair prolapsing or flail mitral leaflets. The access for this procedure is a left minithoracotomy through which a purse-string is placed at the apex of the beating heart. A delivery device that contains an infrared sensor to detect tissue supports optimal grasping of the free edge of the prolapsing leaflet. Via indirect visualization with 3D echo, a suture is passed through the grasped free edge of the leaflet. The two ends of this suture are then brought through the apex of the heart and tied on the epicardial surface (Fig. 41-4). Proper chordal length is determined by adjustment under direct transesophageal echocardiographic guidance. The chords can be appropriately lengthened or shortened based on the color jet seen on echo.

Current experience with the NeoChord DS1000 is limited to slightly more than 100 patients. The Transapical Artificial Chordae Tendinae feasibility trial showed acute procedural success in 26 out of 30 patients (86.7%), deemed as overall reduction of MR from  $\geq 3+$  to  $\leq 2+$ . Four patients (13.3%) had to be converted to conventional MV repair.<sup>34</sup> At 30-day follow-up, only 17 patients maintained MR grade  $\leq 2+$ , and four patients with recurrent MR had surgical MV repair during the 30-day follow-up. Results improved with experience: durable reduction in MR to  $\leq 2+$  at 30 days was achieved in 5 (33.3%) of the first 15 patients and 12 (85.7%) of the last

14 patients. Furthermore, the implantation of two or three chords led to an improved MR reduction, which has been similarly demonstrated in the surgical loop technique. Larger studies are needed to prove efficacy and durability of this technique. Of note, a technique to perform edge-to-edge repair with this device may be under development.

### Secondary Mitral Regurgitation

#### MITRAL ANNULAR REMODELING TECHNIQUES

Although there is dilatation of the entire mitral annulus in patients with secondary MR, the greatest degree of dilation is in the posterior annulus and the greatest increase in dimension is in the septal-lateral (or anterior-posterior) diameter.<sup>8,35</sup> Therefore, secondary MR is most commonly surgically managed by reduction in the septal lateral diameter of the dilated mitral annulus by an undersized, complete, and rigid annuloplasty ring. A key element of this surgical repair includes anchoring a complete ring to the central fibrous skeleton of the heart at the fibrous trigones because anchoring the ring away from the mitral annulus in the atrial wall or in the leaflet tissue leads to less effective reduction in annular dimensions. Similarly, it has been well proven in the surgical arena that a partial posterior annuloplasty is less effective in annular reduction to treat MR.<sup>36-38</sup> On the other hand, correction of the septal lateral diameter by as little as 5 to 8 mm has been demonstrated to reconstitute leaflet coaptation and improve MR. Transcatheter approaches to secondary MR are based on this concept of mitral annulus remodeling to decrease the septal lateral diameter. There is no shortage of novel strategies to accomplish this goal (see Table 41-1). Some devices take advantage of the anatomical relationship between the coronary sinus and posterior mitral annulus; other devices take a more direct approach by plicating the posterior annulus; still others rely on distraction of the LV or left atrial walls to decrease the septal lateral diameter.

### Coronary Sinus Annuloplasty

Its proximity to the posterior mitral annulus makes the coronary sinus an attractive access point for placement of devices to remodel the mitral annulus (Fig. 41-5).<sup>39-43</sup> The ease of transvenous access led to early optimism. However, variability in the anatomic relationship of the coronary sinus to the mitral annulus has made it a challenge to obtain consistent decreases in annular dimensions. Although the coronary sinus is most commonly located adjacent to the posterior annulus, it is frequently located along the free wall of the left atrium, superior to the mitral annulus therefore relying on traction on the left atrial free wall for annular remodeling.<sup>44,45</sup> The smallest distance between the coronary sinus and the mitral annulus is usually at the entry to the sinus. Separation of the coronary sinus from the mitral annulus is maximal at the posterolateral commissure, as demonstrated in an anatomical study by Miselli of coronary sinus anatomy in 61 human cadaver hearts.<sup>46</sup> In this cohort, the distance between the inferior border of the coronary sinus and the mitral annulus at the P2 and

**FIGURE 41-4** Placement of artificial chords from the left ventricular apex under echocardiographic guidance.

**FIGURE 41-5** Concept of a posterior mitral annulus plication performed by a device placed through the coronary sinus.

P3 mitral segments averaged 9.7 mm. It is important to note that in patients with severe MR, the distance between the coronary sinus and the mitral annulus is usually much greater than in patients without severe regurgitation. In addition, the path of the circumflex coronary artery and/or its branches between the coronary sinus and mitral annulus is of significant concern. The left circumflex artery or major branches have been reported to course between the coronary sinus and the mitral annulus in up to 80% of patients (Fig. 41-6).<sup>46</sup> Due to all of these concerns, the Carillon Mitral Contour System, a fixed-length device designed for plication of the coronary sinus between deployable anchors placed via internal jugular access, is the only remaining device employing the coronary sinus approach. Its proximal anchor is released near the coronary sinus ostium, and its distal one is deployed near the anterior commissure, deep on the coronary sinus. In case of insufficient MR reduction, the device can be repositioned.

In the AMADEUS feasibility study, the device was successfully implanted in 30 of the 48 enrolled patients (62.5%).<sup>47</sup> In these patients the mitral annular diameter was significantly reduced, leading to MR reduction by at least 1 grade and improvement in functional class at 2-year follow-up. In the TITAN trial, which investigated a second-generation device, 36 of 53 patients underwent successful device implantation (67%).<sup>48</sup> In both studies a high number of patients (17% in the AMADEUS, 15% in the Titan trial) did not receive the device due to unwanted interaction with the left circumflex artery. In the remaining patients with unsuccessful intervention, the Carillon device was retrieved, as it did not reduce MR by at least one grade. The major adverse events rate in the two studies decreased from 13 to 1.9%, but, due to low success rates, limited reversal in LV remodeling, and lack of control groups, the results of the initial Carillon Mitral Contour System trials remain controversial.<sup>49</sup>

**FIGURE 41-6** Example demonstrating by computerized tomography the relationships between the coronary sinus and the mitral annulus. Note the intervening circumflex coronary artery. (Reproduced with permission from Choure AJ, Garcia MJ, Hesse B, et al: In vivo analysis of the anatomical relationship of coronary sinus to mitral annulus and left circumflex coronary artery using cardiac multidetector computed tomography: implications for percutaneous coronary sinus mitral annuloplasty, *J Am Coll Cardiol*. 2006 Nov 21;48(10):1938-1945.)

## Direct Mitral Annular Remodeling

There are a number of devices designed to remodel the mitral annulus by direct plication. The Mitralign system (Mitralign, Inc., Tewksbury, MA) consists of polyester pledgets, a suture, and a stainless steel lock. A suture-based plication of the posterior annulus is placed retrograde through the aortic valve on the ventricular side of the mitral annulus. Two sutures are placed to plicate P1-P2 and P2-P3 (Fig. 41-7).<sup>50</sup> Sixty-one patients were enrolled in the EU study for CE mark approval which was completed in 2014. In 45 patients (73.8%), the device was implanted with improvement in MR, quality of life, and NYHA classification at 30-day follow-up.<sup>51</sup> A larger implant with a 50% increase in cinching distance, which may result in a stronger annulus diameter reduction and enhanced outcome, is now available, but CE mark approval is pending.

Another device, the Valtech Cardioband (Valtech, Inc., Tel Aviv, Israel), places a tensioning band with anchoring screws placed into the mitral annulus via a transeptal atrial access.<sup>52</sup> The tensioning band is then adjusted under echocardiographic

**FIGURE 41-7** Plication of the posterior mitral annulus by a percutaneous transventricular approach. (© 2015 Mitralign. All rights reserved.)

guidance until the regurgitant jet disappears as leaflet coaptation is restored. Early results of a multicenter study involving 29 symptomatic patients with moderate-to-severe secondary MR showed a 100% successful implant rate and 93% acute MR reduction postoperatively with sustained results over 6 months (91% MR  $\leq$  2+).<sup>53</sup> Both 6-minute walk test and NYHA classification improved in 11 patients (37.9%) at 6-month follow-up, but improvement did not reach statistical significance. CE mark approval is still pending for the Valtech Cardioband.

### Transcatheter Mitral Valve Replacement

Perhaps the most intriguing concept currently for the percutaneous treatment of secondary MR is transcatheter MV replacement (TMVR). One of the disadvantages of surgical annuloplasty for secondary MR is the recurrence of regurgitation in approximately one third of patients by one year. Even if the annuloplasty performed by a surgical or percutaneous approach leads to complete correction of MR at the time of the index procedure, the ongoing ventricular disease process may eventually cause further dilation of the ventricle. This leads to further tethering of the papillary muscles and free edges of the leaflets, resulting in return of MR some time after repair. In fact, the recurrence rate at 12 months after MVR is reported to be higher as compared to MV replacement (32.6 vs 2.3%).<sup>54</sup> MV replacement, instead of repair, could theoretically prevent recurrence of MR even if further left ventricular dilation occurs after the procedure because LV dilatation should not affect an implanted prosthesis.

After the TAVR evolution, rapid adoption of TMVR was anticipated. However, the development of TMVR has been delayed by the complex structure of the MV, composed of the left ventricular outflow tract, ventricular myocardium, papillary muscles, chordae, and native MV leaflets. Because the MV is a much more complex structure than the AV, many different variables must be considered during TMVR in comparison to the relatively straightforward TAVR technique. Most importantly, unlike the aortic annulus in aortic

stenosis, the mitral annulus is not calcified in MR, so there is no good anchoring zone for the implanted valve. However, the solid ring structure of a biological MV prosthesis or complete annuloplasty ring can be an ideal anchoring zone for a TAVR valve to be placed in the mitral location. Thus, in recent years, valve-in-valve (VinV) and valve-in-ring (VinR) procedures have become routine in many centers worldwide for high-risk patients. Both, VinV and VinR can be performed safely with transapical or transfemoral access.<sup>55-59</sup> But, without prior surgical MV or annuloplasty ring implantation, fixation of a TMVR is difficult.

Several devices have been developed to perform TMVR, of which some have recently initiated compassionate and early feasibility human trials and others have yet to initiate trials. These include the CardiAQ device (CardiAQ Valve Technologies, Inc., Winchester, MA), the Tiara device (Neovasc, Inc., Richmond, BC, Canada), the Tendyne device (Tendyne Medical, Inc., Roseville, MN), and the Fortis transapical device (Edwards Lifesciences, Irvine, CA).

The CardiAQ is a self-expanding, stent-based, bovine pericardial bioprosthesis. The device self-anchors without radial force and grabs the native MV leaflets (Fig. 41-8a). In 2012, it was the first TMVR device to reach human implantation using a transfemoral/transseptal access. After redesign, the second-generation CardiAQ device was implanted transapically in three patients 2014. The CE mark trial with 100 patients at 10 sites is anticipated to start in early 2015.<sup>60</sup>

The Tiara device is a self-expanding, nitinol-based, bovine pericardial bioprosthesis (Fig. 41-8b). It can be implanted transapically, facilitated by a 32F sheathless system. The device captures the native mitral leaflets and has a full atrial skirt to minimize paravalvular leak. The D shape of the valve could help to prevent LV outflow obstruction. After three successful implantations in the first-in-man (FIM) trial, the TIARA-I feasibility study started in late 2014.<sup>61,62</sup>

The Tendyne device is an apical, self-expanding, nitinol-based, porcine pericardial bioprosthesis with a ventricular tethering fixation system anchoring the valve to the left ventricular apex (Fig. 41-8c). It is fully retrievable and repositionable, and it is available in multiple sizes. After three patients

**FIGURE 41-8** Transcatheter Mitral Valve Replacement devices in clinical trials. (A. Used with permission from Tiara, Neovasc Inc, Richmond, BC, Canada. B. Used with permission from Tendyne Medical, Inc., Roseville, MN. C. Used with permission from Intrepid, Medtronic Inc, Minneapolis, MN. D. Used with permission from Edwards Lifesciences LLC, Irvine, CA.)

were successfully treated under a compassionate use protocol, the device was implanted in the first patient of an early feasibility study in November 2014. The patient recovered quickly and was released from the hospital on day 5.<sup>63</sup>

The Fortis transapical device is composed of a cloth-covered nitinol stent with three anticalcification-treated bovine pericardial leaflets. At present, only the 29 mm size valve is available, suitable for patients with a native annular diameter (A2-P2) between 30 and 44 mm. Valve fixation is performed by two paddles that capture the mitral leaflets. An atrial flange is designed to prevent paravalvular leaks. Rapid pacing is not necessary because normal blood flow is maintained throughout the entire procedure. All seven reported implantations of the Fortis device have led to a MR Grade  $\leq 1+$ . One of the patients died after a partial displacement of the valve because the posterior paddle failed to capture the posterior mitral leaflet. Enrollment for a clinical feasibility study started in August 2014.<sup>64,65</sup>

## CONCLUSION

There are a host of unique and intriguing concepts for transcatheter treatment of MR. Although progress in the transcatheter treatment of aortic stenosis was rapid and promising,

progress with MR has been much slower due to the complex MV anatomy, the variable MR pathologies, the necessity for complex delivery systems, the limited early success in clinical trials, and the existence of an effective, established therapy (open surgery). In addition, proper trial design has proven to be challenging, with the demonstration of clinical benefit remaining particularly difficult. However, the clinical unmet need is sizable, and with a host of unique concepts under early investigation, significant progress can be expected in the near future. The MV will be one of the most interesting targets for therapeutic cardiac device innovations in the coming years.

# Mitral Valve Replacement

Tsuyoshi Kaneko • Maroun Yammine • Dan Loberman  
• Sary Aranki

This chapter discusses the surgical indications, operative techniques, and early and late follow-up after implantation of mechanical and bioprosthetic mitral valve devices. The valves that are discussed are those that are currently (2015) approved by the Food and Drug Administration (FDA). Figure 42-1 shows the former and current FDA-approved prosthetic mechanical mitral valve devices, including the Starr-Edwards ball-and-cage valve (historical relevance only), the Omnicarbon tilting-disk valve, the Medtronic Hall tilting-disk valve, the St. Jude Medical bileaflet valve, the Carbomedics bileaflet valve, the ATS bileaflet valve, and the On-X bileaflet valve. The FDA-approved bioprosthetic valve devices are shown in Fig. 42-2 and include the Hancock II porcine valve, the Carpentier-Edwards porcine valve, the Carpentier-Edwards pericardial valve, the Mosaic porcine valve, and the Biocor porcine valve.

Heart valve prostheses are continually undergoing iterative advancement by the manufacturers; however, the ideal valve has yet to be developed. This ideal replacement prosthesis would have longevity of a mechanical prosthesis combined with the superior hemodynamic function of the native biologic tissue valve. As a result, this hypothetical ideal replacement device would not require lifetime anticoagulation and carries no risk of either thromboembolic events or valve thrombosis. Achieving this goal will require major advancements to currently available designs.

## INDICATIONS FOR MITRAL VALVE REPLACEMENT

The indications for mitral valve replacement (MVR) are variable and undergoing evolution. Because of increasing use of reparative techniques, particularly for mitral regurgitation (MR), replacement or repair of a mitral valve often depends on the experience of the operating surgeon. Current indications for valve replacement pertain to the types of valve problems that are unlikely to be repaired by most surgeons or which have been shown to have poor long-term success after reconstruction. Indications are discussed according to (1) pathophysiologic states and (2) type of valve required (ie, mechanical or bioprosthetic).

## MITRAL STENOSIS

Mitral stenosis (MS) is almost exclusively caused by rheumatic fever even though a definite clinical history can be obtained in only about 50% of patients. The incidence of MS has decreased substantially in the United States in the last several decades because of effective prophylaxis of rheumatic fever; nevertheless, in certain developing countries MS is still very common. Two-thirds of patients with rheumatic MS are females.

The pathologic changes associated with rheumatic valvulitis are mainly fusion of the valve leaflets at the commissures, shortening and fusion of the cordae tendineae, and thickening of the leaflets owing to fibrosis with subsequent stiffening, contraction, and calcification. Approximately 25% of patients have pure MS, but an additional 40% have combined MS and MR.<sup>1</sup>

Stenosis usually develops one or two decades after the acute illness of rheumatic fever with no or slow onset of symptoms until the stenosis becomes more severe. Limitation of exercise tolerance usually is the first symptom, followed by dyspnea that can progress to pulmonary edema. New-onset atrial fibrillation and the risk for thromboembolism, hemoptysis, and pulmonary hypertension are other common symptoms in patients with MS.

Besides echocardiographic imaging, the diagnostic workup of the symptomatic patient with MS should include a complete cardiac catheterization, including coronary angiography in any patient older than 40 years old. In younger patients, echocardiographic assessment of the mitral valve suffices in most symptomatic patients unless there is a history of chest pain or coronary artery disease. Typically echocardiogram establishes the extent of MS by determining valve gradients and valve area, but in complex cases cardiac catheterization with direct measurement might be more beneficial.

Recently published 2014 American Heart Association/American College of Cardiology guideline has a new staging system for MS.<sup>2</sup> The criteria for severe MS has changed from mitral valve area of 1.0 cm<sup>2</sup> or less to a mitral valve area of 1.5 cm<sup>2</sup>, the normal native mitral valve area being 4 to 6 cm<sup>2</sup>, and/or a diastolic half pressure time more than

150 ms. Symptomatic severe MS is considered stage D while asymptomatic severe MS is stage C. Finally, a mitral valve area of less than  $1.0 \text{ cm}^2$  or diastolic half pressure time more than 220 ms is considered "very severe MS."

Currently, the first option for MS is percutaneous balloon valvuloplasty and certain anatomic characteristics allow a more successful valvuloplasty (Table 42-1).<sup>2</sup> The Wilkins score is used to predict the success rates of this procedure by taking into consideration valve thickness, valvular calcification, leaflet mobility, and subvalvular thickening. Each category has a score of 1 to 4 and a total score of 8 or less predicts higher success rate with balloon valvuloplasty. If the score is higher than 8, MVR is recommended.<sup>3</sup> Subsequently, the 2014 ACC/AHA guidelines gave class I recommendation for

mitral valve surgery in severely symptomatic patients (NYHA class III/IV) with severe MS (stage D) who are not high risk for surgery and who are not candidates for previous balloon valvuloplasty or have failed a previous balloon valvuloplasty and in patients with severe MS (stage C or D) undergoing other cardiac surgery. Class IIa recommendation is given for severely symptomatic patients (NYHA class III/IV) with severe MS (stage D) provided there are other operative indications and Class IIb recommendation for patients with moderate MS (MVA  $1.6\text{-}2.0 \text{ cm}^2$ ) undergoing other cardiac surgery and patients with severe MS (stages C and D) who have had recurrent embolic events while receiving adequate anticoagulation. We must also mention that the degree of pulmonary artery pressure elevation secondary to MS continues to be

**FIGURE 42-1** FDA-approved mechanical mitral valves. (A) Starr-Edwards ball-and-cage. (B) Medtronic Hall tilting-disk. (C) Omnicarbon tilting-disk. (D) St. Jude Medical bifleaflet.

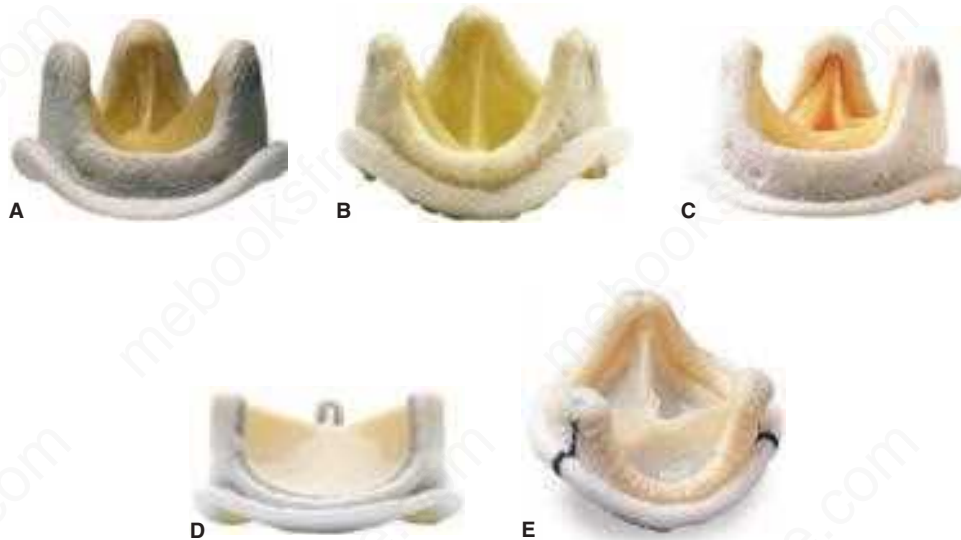

**FIGURE 42-1** (Continued) (E) Carbomedics bileaflet. (F) ATS bileaflet. (G) On-X bileaflet.

an area of concern for the mitral valve surgeon but it has been known for more than 40 years that after MVR for MS, pulmonary artery pressure decreases within hours in most patients and decreases more gradually over weeks to months in others.<sup>4-6</sup>

Historically, the success with closed commissurotomy after World War II and the development of the Starr-Edwards

valve in the early 1960s led to an enormous increase in operations for rheumatic mitral valve disease. It was until the 1990s that the balloon dilation of fibrotic stenotic mitral valves became increasingly common.<sup>6-8</sup> Open mitral commissurotomy and valvuloplasty also became an alternative for MS patients,<sup>9,10</sup> but some studies have shown better long-term

 **TABLE 42-1: Summary of Recommendations for MS Intervention**

Recommendations	COR	LOE
PMBC is recommended for symptomatic patients with severe MS (MVA $\leq$ 1.5 cm <sup>2</sup> , stage D) and favorable valve morphology in the absence of contraindications	I	A
Mitral valve surgery is indicated in severely symptomatic patients (NYHA class III/IV) with severe MS (MVA $\leq$ 1.5 cm <sup>2</sup> , stage D) who are not high risk for surgery and who are not candidates for or failed previous PMBC	I	B
Concomitant mitral valve surgery is indicated for patients with severe MS (MVA $\leq$ 1.5 cm <sup>2</sup> , stage C or D) undergoing other cardiac surgery	I	C
PMBC is reasonable for asymptomatic patients with very severe MS (MVA $\leq$ 1.0 cm <sup>2</sup> , stage C) and favorable valve morphology in the absence of contraindications	IIa	C
Mitral valve surgery is reasonable for severely symptomatic patients (NYHA class III/IV) with severe MS (MVA $\leq$ 1.5 cm <sup>2</sup> , stage D), provided there are other operative indications	IIa	C
PMBC may be considered for asymptomatic patients with severe MS (MVA $\leq$ 1.5 cm <sup>2</sup> , stage C) and favorable valve morphology who have new onset of AF in the absence of contraindications	IIb	C
PMBC may be considered for symptomatic patients with MVA $>$ 1.5 cm <sup>2</sup> if there is evidence of hemodynamically significant MS during exercise	IIb	C
PMBC may be considered for severely symptomatic patients (NYHA class III/IV) with severe MS (MVA $\leq$ 1.5 cm <sup>2</sup> , stage D) who have suboptimal valve anatomy and are not candidates for surgery or at high risk for surgery	IIb	C
Concomitant mitral valve surgery may be considered for patients with moderate MS (MVA 1.6-2.0 cm <sup>2</sup> ) undergoing other cardiac surgery	IIb	C
Mitral valve surgery and excision of the left atrial appendage may be considered for patients with severe MS (MVA $\leq$ 1.5 cm <sup>2</sup> , stages C and D) who have had recurrent embolic events while receiving adequate anticoagulation	IIb	C

AF, indicates atrial fibrillation; COR, Class of Recommendation; LOE, Level of Evidence; MS, mitral stenosis; MVA, mitral valve area; NYHA, New York Heart Association; and PMBC, percutaneous mitral balloon commissurotomy.

Adapted with permission from Nishimura RA, Otto CM, Bonow RO, et al: 2014 AHA/ACC guideline for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines, *J Thorac Cardiovasc Surg.* 2014 Jul;148(1):e1-e132.

results with MVR using a mechanical valve.<sup>11</sup> Many patients with chronic MS now require valve replacement because the valve has developed significant dystrophic changes including marked thickening and shortening of all chordae, obliteration of the subvalvular space, agglutination of the papillary muscles, and calcification in both annular and leaflet tissue. Aggressive decalcification and heroic reconstructive techniques for these extremely advanced pathologic valves generally have produced poor long-term results; nevertheless, some surgeons still advocate aggressive repairs in this subset of patients.<sup>12</sup>

## MITRAL REGURGITATION

The etiology of MR is very diverse and the decision to operate on patients with MR is more complex than for patients with MS, except in patients with acute ischemic MR and endocarditis in whom indications are more straightforward. The pathologic events that produce MR are related to a number of metabolic, functional, and anatomical abnormalities.<sup>1</sup> These can be categorized into degenerative (eg, mitral prolapse and ruptured/elongated chordae), rheumatic, infectious, and ischemic diseases of the mitral valve. The recent AHA/ACC guideline separates MR into primary MR and secondary MR and is later graded based on patient symptoms and severity of the disease.<sup>2</sup>

The preferred surgical approach for primary MR is mitral valve repair which is described in a different chapter in this book. Mitral valve surgery has class I recommendation for symptomatic severe MR with left ventricular ejection fraction (LVEF) over 30% or asymptomatic severe MR with decreased LVEF (30-60%). It is important to stress that depressed ejection fraction is a poor indicator of left ventricular function in patients with MR. Ejection fraction can be preserved in patients with irreversible left ventricular failure because of regurgitant flow through the valve.<sup>13,14</sup> Depressed cardiac function (LVEF  $<$  40%) therefore usually indicates severe left ventricular dysfunction, and results of surgery are not as favorable in these patients as they are in those with normal ventricles.<sup>15,16</sup> Measurements of end-systolic volume and diameter have lately surfaced as more reliable noninvasive parameters to evaluate the status of the left ventricle and determine the optimal time for operation.<sup>17,18</sup> Therefore, LV end-systolic diameter over 40 mm is also considered Class I indication in patients with asymptomatic MR.

Mitral valve repair is indicated in patients with primary MR due to a degenerative prolapsing myxomatous valve especially if the prolapse is generalized and local findings that decrease the probability of a successful repair are absent.<sup>19-23</sup> When the probability of successful repair is low as is the case with the encounter of rheumatic MR, calcific deposits throughout the leaflet substance and shortened chordae and papillary muscles, MVR is often the most

prudent operation.<sup>24</sup> However, good results with reconstructive surgery in this patient group have been reported.<sup>25</sup> In patients with endocarditis, MVR may be required because of destruction of the valve leaflets, subvalvular mechanisms and annular abscess formation. Although repair of the valve and avoidance of prosthetic material are very desirable in septic situations, the extent of the destruction may preclude repair. Therefore, MVR is required after careful debridement of the infectious tissue and reconstruction of the valve annulus.<sup>26-28</sup>

For secondary MR, severe secondary MR in the setting of cardiac procedure has Class IIa, and symptomatic severe secondary MR has class IIb recommendation to undergo mitral valve surgery. Recently published randomized control study that compared MVR and MV repair in patients with severe ischemic MR showed no difference in mortality and LV remodeling.<sup>29</sup> However, MV repair group had 33% recurrence of moderate or severe MR compared to 2% in MVR. Other specific findings that preclude satisfactory repair include restrictive valve motion from shortened, scarred papillary muscles, acutely infarcted papillary muscle, and rupture of chordae associated with extensive calcification of valve leaflets.<sup>30-32</sup>

## CHOICE OF VALVE TYPE

### Indications for Mechanical Valve Replacement

For young patients, patients in chronic atrial fibrillation who require long-term anticoagulation, and any patient who wants to minimize the chance of reoperation, a mechanical prosthetic valve should be chosen if valve replacement is required. The St. Jude Medical bileaflet valve is the most widely used prosthetic mitral valve at present because it has good hemodynamic characteristics and is easy to insert. Recent interest in the On-X mechanical valve relates primarily to the possibility for limited anticoagulation, although this remains to be borne out from current clinical trial.<sup>33</sup> Indications to choose one prosthetic or another vary primarily by surgeon preference and occasionally depending on the state of the annulus and whether or not there have been multiple previous operations. The most recent 2014 AHA/ACC guideline has changed its recommendation from class I recommendation of mechanical valve in age 65 years to “shared decision-making process with patients preferences and risks of reoperation.”<sup>2</sup> There is a class IIa recommendation for mechanical valves in patients under age 60 years and either bioprostheses or mechanical prostheses for age between 60 and 70 years.

We have performed a propensity matching analysis in patients younger than 65 years who underwent MVR. Our results showed higher reoperation rate in bioprostheses group and higher survival in mechanical prostheses group (11 vs 13 years,  $p = .004$ ; Fig. 42-3). Therefore, we recommend mechanical prosthesis in this patient group.<sup>34</sup>

### Indications for Bioprosthetic Valve Replacement

Patients in any age group in sinus rhythm who wish to avoid anticoagulation may prefer a bioprosthetic valve. Recent 2014 AHA/ACC guideline gave Class I recommendation for bioprostheses in patients at any age in whom anticoagulation therapy is contraindicated, cannot be managed appropriately or is not desired. A bioprosthetic valve is preferred in patients greater than age 65 years and in sinus rhythm because these valves deteriorate more slowly in older patients.<sup>35</sup> In addition, some 60-year-old patients may not outlive their prosthetic valves because of coexisting comorbidities.<sup>36,37</sup> Specifically, patients who require combined MVR and coronary bypass grafting for ischemic MR and coronary artery disease have a significantly reduced long-term survival as compared to patients who do not have concomitant coronary artery disease.<sup>38-43</sup> In these individuals with little risk of reoperation, anticoagulation may better be avoided.

As 20-year results have become available for various bioprostheses, it is clear that structural valve degeneration (SVD) is the most prominent complication of these valves.<sup>44-49</sup> The durability of porcine mitral valves is less than that of aortic bioprostheses which is directly proportional to age.<sup>45</sup> Deterioration occurs within months or years in children and young adults and only gradually over years in septuagenarians and octogenarians.<sup>44,50</sup> Essentially, all valves implanted into patients younger than 60 years of age have to be replaced ultimately, and valve failure is prohibitively rapid in children and adults younger than 35 to 40 years of age; therefore, bioprostheses are not advisable in these age groups.<sup>51</sup> Nevertheless, there are still indications for mitral porcine bioprosthetic valves in young patients. In a woman who desires to become pregnant, a bioprosthesis may be used to avoid warfarin anticoagulation and fetal damage during pregnancy.<sup>52-55</sup>

Over the last decade several publications, mainly from European centers, reported on the use of unstented cryopreserved homografts<sup>56-59</sup> and stentless heterografts<sup>60-63</sup> for MVRs, particularly in patients with endocarditis. The prosthetic valve is transplanted so that donor papillary muscles are reattached to recipient papillary muscles and the annulus is sutured circumferentially. This technique has been shown to be safe and reproducible, but it does not always provide durable results and therefore should not be used in young patients.<sup>60</sup> Other reports suggest that these operations may be a feasible alternative to stented valve replacement in patients with endocarditis. Pulmonary autografts also have been used for replacing the mitral valve (Ross II procedure), but these series are small, and follow-up is relatively short.<sup>64-66</sup>

## TRENDS IN MITRAL VALVE SURGERY

Mitral valve surgery has been in a state of constant evolution since its inception. Data regarding all cardiac surgical procedures reported to the Society of Thoracic Surgeons Adult Cardiac Surgery Database (STS ACSD) demonstrate this dynamic state as more surgeons begin to repair rather

**FIGURE 42-3** Comparison between bioprosthetic valve versus mechanical valve in patients under the age of 65 years who underwent mitral valve replacement. (Reproduced with permission from Kaneko T, Aranki S, Javed Q, et al: Mechanical versus bioprosthetic mitral valve replacement in patients <65 years old, *J Thorac Cardiovasc Surg.* 2014 Jan;147(1):117-126.)

than replace mitral valves. Gammie et al evaluated trends in mitral valve surgery in the United States using the STS ACSD evaluating the years between 2000 and 2007.<sup>67</sup> In this time period, 210,529 mitral valve procedures were performed in all settings. From the study population, 58,370 patients undergoing primary mitral valve operations were identified. Over this 7-year study time line, a 50% increase in repair rates was documented. When considering the valve replacement, a 100% increase in use of bioprosthetic devices coincided with a decline in the use of mechanical valves.

Gammie and coworkers identified clear trends with respect to patient selection as well.<sup>67</sup> Compared with patients undergoing mitral valve repair, those undergoing mitral replacement tended to be older, females, more likely to have multiple comorbidities (eg, diabetes mellitus, hypertension, chronic lung disease, stroke), concomitant tricuspid valve disease, MS, and were less likely to be asymptomatic. With respect to survival, overall risk adjusted mortality was lower for mitral valve repair versus replacement (OR 0.52, 95% CI: 0.45 to 0.59,  $p < .0001$ ). The outcome with respect to choice of valve type and survival was not addressed but was felt to be confounded by patient factors that led to the initial device selection.

## HEMODYNAMICS OF MITRAL VALVES DEVICES

### Mechanical Prostheses

The designs of mechanical and bioprosthetic heart valves have evolved over the last five decades in an effort to develop the ideal replacement device for the pathologic mitral valve. The optimal heart valves exert minimal resistance to forward blood flow and allow only trivial regurgitant backflow as the occluder closes. The design must cause minimal turbulence and stasis in vivo under physiologic flow conditions. The valve must be durable enough to last a lifetime and must be constructed of biomaterials that are nonantigenic, nontoxic, nonimmunogenic, nondegradable, and noncarcinogenic. The valve also must have a low associated incidence of thromboembolism.

The opening resistance to blood flow is determined by the orifice diameter; the size, shape, and weight of the occluder; the opening angle; and the orientation of leaflet or disk occluders with respect to the plane of the mitral annular orifice for any given annular size. Least resistance to transvalvular blood flow during diastole for valves in the mitral position is provided by a large ratio of orifice to total annular area. A wide opening angle also improves the effective orifice area and results in decreased

diastolic pressure gradients. Table 42-2 shows hemodynamic assessments of each of the FDA-approved mitral valve prostheses for the most commonly used mitral valve sizes.<sup>68-71</sup> The results of in vivo assessments at rest by invasive (catheterization) or non-invasive (Doppler echocardiography) techniques are tabulated.

Blood turbulence flowing across mitral valve devices results from impedance to forward or reverse flow. This impedance can be minimized by occluder design and orientation, central flow through the orifice and limited struts or pivots extending into flow areas (Fig. 42-4). Hemolysis is the product of

**FIGURE 42-4** Flow characteristics of different mechanical valve designs. (A) Ball-and-cage. (B) Tilting-disk. (C) Bileaflet.

red blood cell destruction that is caused by cavitation and shearing stresses of turbulence, high-velocity flow, regurgitation, and mechanical damage during valve closure.<sup>72</sup> Areas of perivalvular blood stagnation and turbulence increase platelet aggregation, activation of the coagulation proteins, and thrombus formation.

Dynamic regurgitation is a feature of all prosthetic valves and is the sum of the closing volume during occluder closure and the leakage volume that passes through the valve while it is closed. The closing volume is a function of the effective orifice area and the time needed for closure. Leakage volume is inherent to the design of the valve and depends on the amount of time the valve remains in the closed position.<sup>73</sup> A small amount of regurgitant volume can be beneficial by minimizing stasis and reducing platelet aggregation; this decreases the incidence of valve thrombosis and valve-related thromboembolism.

### BALL AND CAGE MECHANICAL VALVES

**Starr-Edwards.** Introduced in 1965, the Starr-Edwards Model 6120 was the only ball-and-cage mitral valve prosthesis approved by the FDA; however, the production was discontinued in 2007 (see Fig. 42-1A). The occluder is a barium-impregnated Silastic ball in a Stellite alloy cage that projects into the left ventricle. This valve has a large Teflon/polypropylene sewing ring that produces a relatively smaller effective orifice and larger diastolic pressure gradients than other prosthetic valves of similar annular sizes. Leakage volumes are not inherent in the ball-and-cage design, and in contrast with other mechanical valves, the presence of regurgitation may indicate a pathologic process. The central ball occluder causes lateralization of forward flow and results in turbulence and cavitation that increase the risk of hemolysis and thromboembolic complications (see Fig. 42-4A).<sup>74-76</sup>

### MONOLEAFLET MECHANICAL VALVES

**Medtronic-Hall.** Tilting-disk mitral valve prostheses had better hemodynamic characteristics than ball-and-cage valves (see Fig. 42-4B) but with the development of new valve designs and technology they were taken off the market. The Medtronic Hall central pivoting-disk valve was available between 1977 and 2009 and it was based on engineering design modifications of the earlier Hall-Kaster valve<sup>77</sup> (see Fig. 42-1B). The opening angle of 70° produced regurgitation volumes of less than 5% of left ventricular stroke volume without significantly compromising forward flow. The disk occluder was allowed to slide out of the housing at the end of the closing cycle to provide a gap through which blood could flow to minimize stasis at the contact surfaces.<sup>78</sup> The large opening angle and slim disk occluder, along with a thinner sewing ring, provide improved hemodynamics with comparably larger effective orifice areas and lower mean diastolic pressure gradients for each valve size.

**Omniscience-Omni Carbon.** The Omniscience tilting-disk valve was first introduced in 1978 as a second-generation device derived from improvements to the design of the Lillehei-Kaster pivoting-disk valve.<sup>79</sup> It had a larger orifice to annular ratio, a larger opening angle of 80° and better hemodynamics compared to its predecessor. A special disk design reduced the regurgitant volume, the turbulence and the areas of stasis and shear stress. Clinical studies, however, opened a huge debate concerning this valve's hemodynamics since there was reports of a postoperative mean opening angle between 44.8<sup>69</sup> and 75.9°.<sup>80</sup> Implicated factors causing this variation included valve sizing, orientation during implantation, and anticoagulation status.<sup>80,81</sup> A subsequent generation of the Omniscience valve is the all-carbon Omnicarbon monoleaflet valve that was released in 2001 in the United States but has been in clinical use in Europe since 1984 (see Fig. 42-1C). The housing material is made of pyrolytic carbon instead of titanium. As a result of this change, the incidence of thromboembolism, valvular thrombosis, and reparations was decreased significantly compared with the Omniscience

valve prostheses.<sup>82</sup> Since 2005, however, the production of the Omnicarbon valve ended as the company decided to stop this production line.

Currently the only valve design available for implantation in the United States is the bileaflet design; it is being provided by many manufacturers.

### BILEAFLET MECHANICAL VALVES

**St. Jude Mechanical Valve.** The unique design of the bileaflet St. Jude Medical valve was introduced in 1977, and it is currently the prosthesis used most commonly worldwide (see Fig. 42-1D). Two separate pyrolytic carbon semidisks in a pyrolytic carbon housing are attached to a Dacron sewing ring. The housing has two pivot guards that project into the left atrium. The bileaflet design produces three different flow areas through the valve orifice that provide overall a more uniform, central, and laminar flow than in the caged ball and monoleaflet tilting-disk designs. The improved flow results in less turbulence and decreased transmitral diastolic pressure gradients<sup>73,83</sup> (see Fig. 42-4C) at any annulus diameter size and cardiac output compared with the caged ball and single-leaflet tilting valves.<sup>84</sup> The favorable hemodynamics in smaller sizes makes it especially useful in children. The central opening angle is 85°, with a closing angle of 30 to 35°, which along with a thin sewing ring, provides a large effective orifice area for each valve size at the expense of greater regurgitant volumes, especially at low heart rates. Asynchronous closure of the valve leaflets *in vivo* also contributes to the regurgitant volume.<sup>85</sup> The design of this prosthesis provides excellent hemodynamic function even in small sizes in any rotational plane.<sup>86</sup> The antianatomical plane, however, with the central slit between the leaflets oriented perpendicular to the opening axis of the native valve leaflets decreases the potential risk of leaflet impingement by the posterior left ventricular wall.<sup>87</sup> Rotatable cuff designs are available on newer generation models.

**Carbomedics Valve.** The Carbomedics bileaflet valve was approved by the FDA in 1986 (see Fig. 42-1E). This low-profile device is constructed of pyrolytic carbon and has no pivot guards, struts, or orifice projections to decrease blood flow impedance and turbulence through the valve.<sup>73</sup> It has a rotatable sewing cuff design and is available with a more generous and flexible sewing cuff (the OptiForm variant) that conforms more easily to different patient anatomies and allows subannular, intraannular, or supraannular suture placement. The leaflet opening angle is 78°, which with the bileaflet design provides a relatively large effective orifice area and transvalvular diastolic pressure differences only slightly greater than the St. Jude Medical bileaflet valve. Because of its narrow closing angle and large leakage volume, the Carbomedics valve does not reduce the relatively large regurgitant volume associated with the bileaflet design. Although this valve has good hemodynamic function overall, in the mitral position, the 25-mm Carbomedics valve has a relatively high diastolic pressure gradient and large regurgitant energy loss across the valve, especially at high flows. Hemodynamic

studies suggest that the Carbomedics valve should be avoided in patients with a small mitral valve orifice.<sup>73</sup>

**Advancing the Standard (ATS) Valves.** The ATS Open Pivot<sup>®</sup> bileaflet mechanical prosthesis has been in clinical use in the United States since 2000. Similar to the Carbomedics valve, the ATS valve is a low-profile bileaflet prosthesis with a pyrolytic housing and pyrolytic carbon leaflets containing graphite substrate (see Fig. 42-1F). The pivot areas are located entirely within the orifice ring, and the valve leaflets hinge on convex pivot guides on the carbon orifice ring. This design minimizes the overall height of the valve and provides a wider orifice area, and the absence of cavities in the valve ring theoretically reduces stasis or eddy currents that may develop. Valve noise, a bothersome problem for some patients, also is reduced by this design.<sup>87</sup> The opening angle is up to 85°, and the sewing cuff is constructed of double velour polyester fabric that is mounted to a titanium stiffening ring, which enables the surgeon to rotate the valve orifice during and after implantation.

**On-X Prosthesis Valves.** The On-X prosthesis was approved by the FDA in 2002. It has a bileaflet design similar to the St. Jude Medical, Carbomedics, and ATS prostheses with comparable hemodynamic performance, that is, a relatively large orifice diameter and a wide opening angle (90°) (see Fig. 42-1G). Instead of silicon-alloyed pyrolytic carbon, as used in the other mechanical prostheses, the On-X valve is made of pure pyrolytic carbon. This material is stronger and tougher than silicon-alloyed carbon and allows incorporation of hydrodynamically efficient features into the valve orifice, such as increased orifice length and a flared inlet that reduces transvalvular gradient. Early clinical results are promising and the valve produces very little hemolysis with postoperative levels of serum lactate dehydrogenase in the normal range.<sup>88,89</sup>

### Anticoagulation for Mechanical Valves

Warfarin remains to be the mainstay of anticoagulation after mechanical valve replacement in both aortic and mitral positions.<sup>90</sup> The need for anticoagulation with mechanical valves has been the leading cause of people shying away from this type of valves because of the life style changes this treatment instills. In fact, this has also been a major driving force in the recently observed shift in use of the bioprosthetic valves in younger patients despite its decreased lifespan compared to mechanical valves.<sup>90,91</sup> Given the time needed to heparin-warfarin bridging as well as the frequent need of monitoring during Warfarin treatment, efforts are being made to find an alternative. The new oral anticoagulants (dabigatran, edoxaban, rivaroxaban ...) are promising substitutes to the warfarin therapy due to their shorter half life and the lack of need to constant monitoring.<sup>90</sup> Those drugs have been FDA approved for use in nonvalvular atrial fibrillation and in treatment or prevention of deep vein thrombosis/pulmonary embolism but not for anticoagulation in

patients with mechanical valves. dabigatran was the only drug to be compared to warfarin in patients with mechanical valves during a phase 2 trial, the RE-ALIGN trial that was initiated in 2012.<sup>92</sup> Unfortunately, this trial was terminated prematurely owing to an increase in stroke, myocardial infarction and major bleeding in the dabigatran group. The FDA declared, after this study, that dabigatran is contraindicated in this patient population. In the absence of other randomized controlled studies comparing a new oral anticoagulant to warfarin in patients with mechanical valves, warfarin still holds the crown of oral anticoagulation in this patient population.

## Bioprostheses

### PORCINE VALVES

The porcine bioprosthetic mitral valves are designed to mimic the flow characteristics of the in situ aortic valve. The Hancock I mitral valve bioprosthesis was introduced in 1970. It has three glutaraldehyde-preserved porcine aortic valve leaflets on a polypropylene stent attached to a Dacron-covered silicone sewing ring. The design allows for central laminar flow through the valve, which tends to decrease diastolic pressure gradients and minimize turbulence.<sup>83</sup> The stent, however, impedes forward flow and results in relatively large diastolic pressure gradients across the bioprosthesis. The stent and the large sewing ring contribute to effective orifice areas that are smaller than those of size-matched mechanical valves (see Table 42-2).

The Hancock II porcine bioprosthesis (see Fig. 42-2A) is the more modern version of the Hancock I prosthesis. The stent is made of Delrin with a scalloped sewing ring and reduced stent profile. The leaflets are fixed in glutaraldehyde at low pressure then at high pressure for a prolonged period. To delay calcification, the leaflets are treated with sodium dodecyl sulfate.

The Carpentier-Edwards porcine valve uses a flexible stent to decrease the stress of leaflet flexion while maintaining its overall configuration (see Fig. 42-2B). The effective orifice-to-total-annulus-area ratio for the Carpentier-Edwards valve is relatively small, but exercise studies show that the effective orifice area increases significantly with increased blood flow across the valve; diastolic

gradients also increase but to a lesser degree.<sup>70,71,93</sup> Porcine bioprostheses in the mitral position should be avoided in patients with small left ventricles because of the possibility of ventricular rupture or left ventricular outflow obstruction caused by the large struts.<sup>94</sup>

The Mosaic porcine bioprosthesis is a third-generation bioprosthesis using the Hancock II stent (see Fig. 42-2C). It was introduced in the United States in 2000 and has a Delrin stent, scalloped sewing ring, and reduced stent profile. The valve tissue is pressure-free fixed with glutaraldehyde, and the prosthesis is treated with alpha-oleic acid to retard calcification.

In 2005, the FDA approved the Biocor porcine bioprosthesis (St. Jude Medical) (see Fig. 42-2E); however, it has been used and investigated for almost two decades in Europe. It belongs to the third generation of bioprostheses, and the valve tissue is pretreated in glutaraldehyde at very low pressure (<1 mm Hg), making the valve cusps less stiff with less tendency to tissue fatigue. A newer generation of this valve, the St. Jude Medical Epic valve, is identical to its precursor except that the later is treated with Linx AC ethanol-based calcium mitigation therapy.

### PERICARDIAL VALVES

Previous studies indicated poor durability of pericardial valves, namely the Ionescu-Shiley valve, caused by leaflet tearing. This led to significant changes in design, including mounting of the pericardium completely within the stent, causing less leaflet abrasion and increased durability. The Carpentier-Edwards pericardial valve uses bovine pericardium as material to fabricate a trileaflet valve and that is cut, fitted, and sewn onto a flexible Elgiloy wire frame for stress reduction (see Fig. 42-2D). The tissue is preserved with glutaraldehyde with no applied pressure and the leaflets are treated with the calcium mitigation agent XenoLogiX. Compared to the Carpentier-Edwards porcine bioprosthesis, the stent profile is reduced. Long-term durability for the Carpentier-Edwards pericardial valve is strong and compared to third-generation porcine valves, valve-related complications are similar (see Discussion later in this chapter).

Hemodynamically, pericardial valves provide the best solution to flow problems. The design maximizes use of the flow area, which results in minimal flow resistance. Figure 42-5A

**FIGURE 42-5** Flow patterns for bioprosthetic valves. (A) Pericardial bioprosthesis. (B) Porcine bioprosthesis.

shows how the cone shape of the open valve and circular valve orifice minimizes flow disturbance compared with the more irregular cone shape of the porcine valves that allow for central unimpeded flow (see Fig. 42-5B).

Structural valve deterioration is seen after long-term follow-up of patients with both porcine and pericardial bioprostheses and results in MS or MR or both. Hemodynamic studies early after operation and at 5 years reveal higher average diastolic pressure gradients and smaller effective orifice areas when compared in the same patients at the follow-up study. In some patients, these changes are sufficiently severe to require reoperation as soon as 4 to 5 years postoperatively and by 10 years the rate of primary tissue failure averages 30%. It then accelerates, and by 15 years postoperatively, the actuarial freedom from bioprosthetic primary tissue failure has ranged from 35 to 71%<sup>44,46,48,49,68</sup> (Table 42-3). Most of these patients show hemodynamic evidence of valvular deterioration before any clinical signs or symptoms.<sup>71</sup> Bioprosthetic valves have the advantage of low thrombogenicity, which must be weighed against poor long-term durability and subsequent hemodynamic deterioration and the risk of reoperation.

## OPERATIVE TECHNIQUES

### Preoperative Management and Anesthetic Preparation

Congestive heart failure (CHF) secondary to MS usually can be treated with aggressive diuretic therapy and sodium restriction preoperatively. If the patient is in rapid atrial fibrillation digoxin, beta blockers, and calcium channel antagonists can be used to slow down the ventricular rate. Patients with acute MR often are in cardiogenic shock, and they can be stabilized preoperatively with inotropes and arterial vasodilators to reduce systemic afterload. Intraaortic balloon counterpulsation also can be used for this purpose. Symptoms of CHF in patients with chronic MR are treated with diuretics and oral vasodilators. The vasodilators lower the peripheral vascular resistance, forward cardiac flow is hence increased and the regurgitant volume into the left atrium reduced.

Preferred anesthesia for MVR typically involves a combination of narcotic and inhalational agents. Ultimately, anesthetic management is dictated by the wide range of functional

disabilities and hemodynamic abnormalities of patients who present for MVR.<sup>94</sup>

Preoperative intravenous prophylactic antibiotics are administered to all patients. Monitoring should include arterial and venous lines, a urinary catheter and a pulmonary artery catheter placed before bypass to measure pulmonary pressures and cardiac output. Transesophageal echocardiography is also critical throughout the entire operation. Last but not least, temporary ventricular pacing wires are placed postoperatively, and in many instances temporary atrial pacing wires are placed for possible pacing or diagnosis of various atrial arrhythmias.

## Cardiopulmonary Bypass for Mitral Valve Replacement

Cardiopulmonary bypass is instituted by placing two right-angled cannulas into the superior and inferior venae cavae. A small (22 French) plastic or metal cannula is placed directly into the superior vena cava, above the sinoatrial node. The inferior caval cannula is placed at the entrance of the inferior vena cava, low in the right atrium. These insertion sites keep the caval catheters out of the operative field and yet maintain excellent bicaval drainage. An arterial cannula is placed in the distal ascending aorta. Bypass flows are approximately 1.5 L/m<sup>2</sup> per minute, and mild hypothermia is used with vacuum-assisted suction. Myocardial protection includes antegrade and retrograde blood cardioplegia and profound myocardial hypothermia.<sup>95</sup> Retrograde cardioplegia is useful for all valve surgery to protect the ischemic left ventricle and help remove ascending aorta bubbles. Antegrade cardioplegia, used as an initial loading dose, is augmented by intermittent retrograde cardioplegia every 20 minutes. This provides safer delivery of cardioplegia because when the atrium is retracted during valve replacement, the aortic valve is distorted, and antegrade cardioplegia tends to fill the ventricle due to aortic regurgitation.

## Exposure of the Mitral Valve

Evolution of meticulous and complicated methods of mitral valve repair and reconstruction has required optimal exposure of the mitral valve. In primary operations, median sternotomy, development of Sondergaard's plane, and incision of the left atrium close to the atrial septum provide excellent exposure<sup>96,97</sup> (Fig. 42-6). This incision is a ubiquitous one, and occasionally other incisions, such as the superior approach through the dome of the left atrium,<sup>98,99</sup> the so-called biatrial incision popularized by Guiraudon and colleagues,<sup>100</sup> division of the superior vena cava<sup>101,102</sup> and the less common but occasionally useful trans-right atrial septal incision<sup>103</sup> are used to obtain exposure. The trans-right atrial incision has in some studies been related to higher incidence of junctional and nonsinus rhythm postoperatively,<sup>104</sup> although this has not been confirmed by other studies.<sup>78</sup>

## Intracardiac Technique

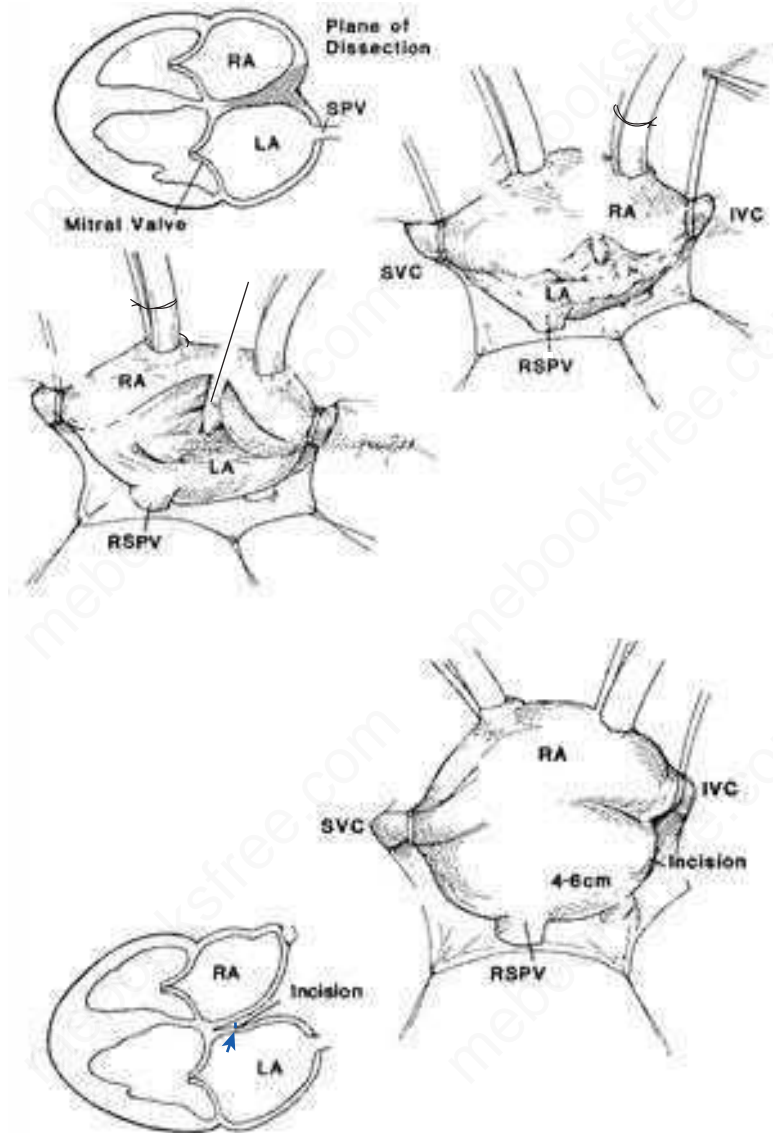

Operation entails secure fixation of a valve prosthesis to the annulus by reliable suture techniques without damage to adjacent structures or myocardium and without tissue interference with valve function. Implantation should prevent injury to anatomical structures surrounding the mitral valve annulus. Figure 42-7 shows the proximity of important cardiac structures near the mitral valve annulus. These include the circumflex coronary artery within the atrioventricular (AV) groove, the left atrial appendage, the aortic valve in continuity with the anterior mitral curtain and the AV node.

An accumulation of laboratory and clinical evidence indicates that preservation of papillary muscle-chordal attachments to the annulus is important for maintenance of left ventricular function. In patients with MS with agglutinated, fibrotic chordae, and papillary muscles, preservation of these structures probably has little effect on left ventricular dysfunction but does protect the AV groove from rupture by preserving the posterior leaflet. If fibrotic, placement of artificial Gore-Tex chordae to reattach the papillary muscles to the annulus may improve early and late preservation of cardiac output.<sup>21</sup> In patients with MR, however, it is important to preserve as much of the papillary muscle and annular interaction as possible. This can be achieved by a variety of techniques, as shown in Fig. 42-8. The anterior leaflet may be partially excised and brought to the posterior leaflet (see Fig. 42-8A) or can be partially excised and "furled" to the anterior annulus by a running Prolene suture<sup>105,106</sup> (see Fig. 42-8B).

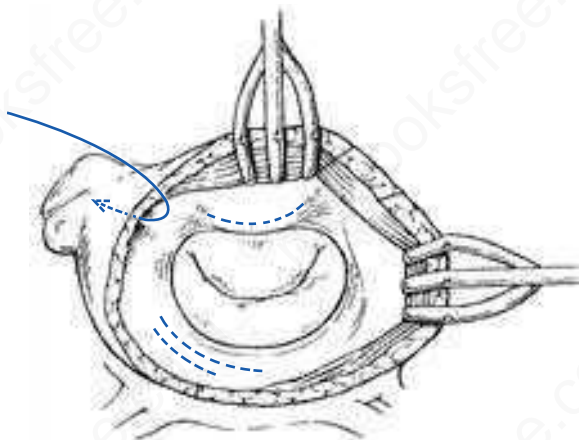

Experimental and clinical evidence suggest that preservation of the conical shape of the ventricle is important to maintain normal cardiac output<sup>107-110</sup>; cutting the papillary muscles is therefore deleterious to left ventricular function because it assumes more of a globular shape. Furthermore, preservation of the posterior leaflet and chordae has dramatically reduced the incidence of perforation of the left ventricle and AV separation during MVR.<sup>10,111,112</sup>

Suturing techniques vary according to the type of valve that is implanted. The bioprosthetic valve is inserted preferentially with the sutures placed from ventricle to atrium (noneverting or subannular). This has been shown to be the strongest type of suturing technique to the mitral annulus and is used with this valve (Fig. 42-9A).

To ensure adequate function of bileaflet or tilting-disk valves, everting sutures (atrium to ventricle to sewing ring) should be used (see Fig. 42-9B). This technique pushes the prosthetic valve out into the center of the orifice and minimizes any tissue interference of the prosthetic valve leaflets. This is particularly important if annular-chordal attachments are preserved. Teflon-pledgeted sutures, particularly with the thin sewing rings of the currently available bileaflet and tilting-disk valves, should be used. If a bioprosthetic valve is inserted, a dental mirror is used to ensure that no annular suture is wrapped around a stent strut. A running Prolene suture for implantation of mitral valves has been advocated

**FIGURE 42-6** Exposure of the mitral valve. (A) Location of Sondergaard's plane. (B,C) Development of the interatrial plane. (D) Location of the left atrial incision. (E) Cross-sectional view.

**FIGURE 42-7** Location of important structures surrounding the mitral annulus. (Used with permission from David Bichell.)

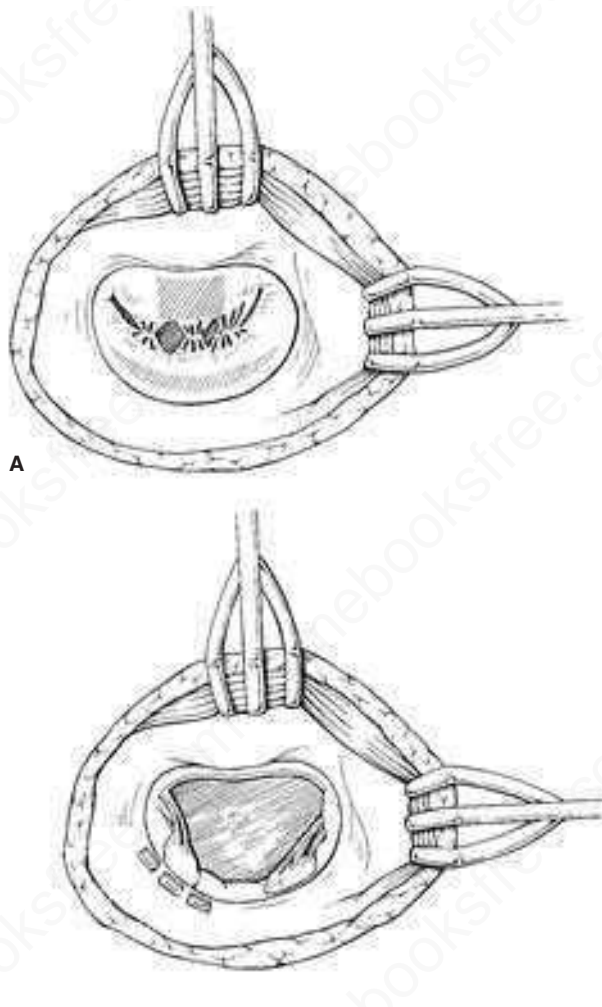

by some surgeons.<sup>113,114</sup> This technique makes a very clean suture line with minimal knots but runs the risk of valve dehiscence if an infection occurs.<sup>115</sup>

Before closure, the left atrial appendage is ligated by suture or stapled to prevent clot formation in patients with chronic atrial fibrillation, enlarged left atrium, or left atrial thrombus.<sup>116</sup> The atrium is closed by a running Prolene suture, making sure that endocardial surfaces are approximated. If needed, a left atrial catheter can be inserted through the suture line.

## ASSOCIATED OPERATIONS/ PROCEDURES

Coronary bypass is the most common procedure performed with MVR and the distal anastomosis should be performed first. This reduces lifting of the heart after the rigid mitral

**FIGURE 42-8** Techniques to maintain annular-papillary muscle continuity. (A) An ellipse is removed from the posterior leaflet, and a flap is cut from the central portion of the anterior leaflet. The anterior flap is flipped to the posterior annulus and tacked to the caudad edge of the posterior leaflet and the posterior annulus. Sutures anchoring the prosthesis include the annulus and anterior and posterior leaflet remnants to which chordae are attached. (B) The anterior leaflet is partially excised, and remnants are “furled” to the annulus by sutures used to insert the prosthesis.

valve prosthesis is in place, which can cause rupture of the myocardium or the AV groove. This also allows cardioplegia to be delivered through the bypass grafts.

Tricuspid valve repair or replacements usually are performed after replacing the mitral valve. In these cases, the mitral valve can be approached through the right atrium and a transseptal incision. After the mitral valve prosthesis is in place, the septum is closed, and the aortic cross-clamp is removed before proceeding with the tricuspid valve procedure.<sup>117</sup>

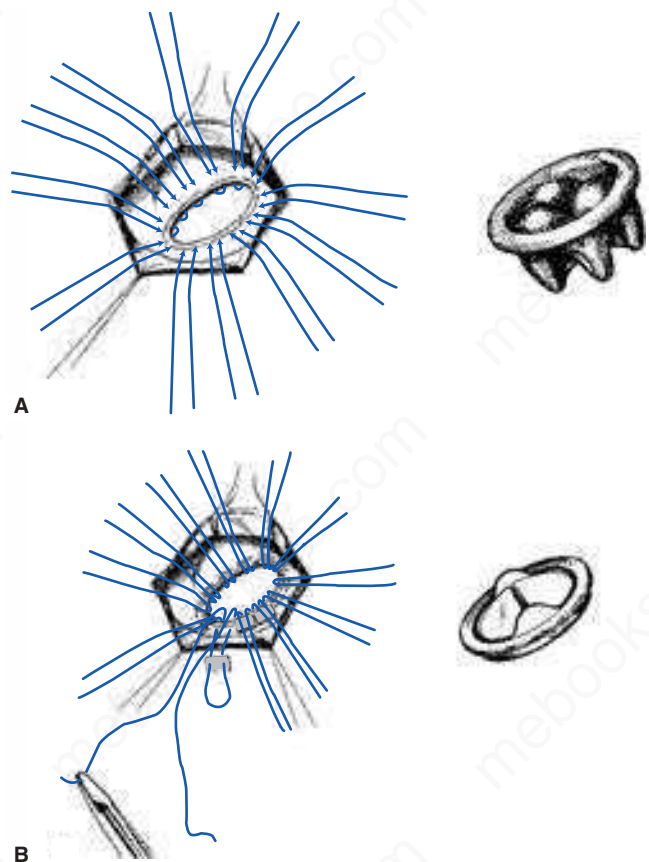

When both the aortic and mitral valves are replaced at the same operation, most surgeons begin with excising the aortic valve before proceeding with the mitral valve procedure. It is extremely difficult to expose the mitral annulus especially the anterior annulus with aortic prosthesis in place.

When excising the anterior mitral valve leaflet, care must be taken not to injure the aortic annulus and the intraannular region. The aortic valve then is sewn in after the mitral valve is in place.

## Weaning Off Cardiopulmonary Bypass

We use transesophageal echocardiography for every valve operation and particularly for mitral valves, where excellent images can be obtained. If transesophageal echocardiography is contraindicated (eg, because of esophageal disease), direct epicardial echocardiography can be used. The echocardiograms provide information about valve and left ventricular function, possible retained material in the left atrium including thrombus and removal of intracardiac air.

A careful de-airing at the end of the operation is essential and can be completed using special maneuvers. Rewarming the patient comes next and then venous return is partially occluded and the heart is gradually volume loaded. Pulmonary artery pressures are monitored carefully and pharmacologic agents, such as amrinone or dobutamine can be used particularly for right ventricular overload.

**FIGURE 42-9** Suturing techniques for prosthetic mitral valve implantation. (A) Noneverting (subannular) sutures placed from ventricle to atrium for bioprosthetic or Starr-Edwards valves. (B) Everting (supraannular) sutures placed from atrium to ventricle for bileaflet or tilting-disk valves.

## POSTOPERATIVE CARE

Postoperative care is directed toward the resumption of normal cardiac output, respiratory function, temperature control, electrolyte management, adequate renal flow and prophylaxis against bleeding. Patients with low cardiac output are managed with a variety of pharmacologic agents after providing adequate volume loading. Left atrial and especially pulmonary arterial catheters are of particular help in determining optimal balancing of volume loading and myocardial function in the first hours postoperatively.

In the intensive care unit, reduction in pulmonary interstitial fluid is aggressively pursued by diuretics in patients with severe pulmonary hypertension. Most patients with severe pulmonary hypertension can be extubated within 48 hours of surgery. Many patients with severe, longstanding mitral valve disease are cachectic and severely catabolic at the time of operation despite preoperative nutritional support. These patients generally require longer periods of ventilatory support owing to the lack of respiratory muscle strength. In patients with severe pulmonary hypertension and cardiac cachexia who require prolonged intubation, tracheostomy may be necessary to reduce ventilatory dead space and facilitate faster weaning and better pulmonary toilet.

Postoperative atrial arrhythmias are so common that their absence is unusual. Arrhythmias vary from rapid supraventricular tachycardias, usually atrial fibrillation, to junctional rhythm and heart block. These arrhythmias are treated by pharmacologic agents, pacemakers, or both. If rapid atrial fibrillation cannot be controlled pharmacologically and is destabilizing hemodynamically, emergency cardioversion is done to improve cardiac output. Pharmacologic management of supraventricular tachycardia usually is required but may precipitate the need for a prophylactic transvenous pacemaker if severe slowing of the heart rate occurs.

Anticoagulation is prescribed for all patients undergoing MVR with either a mechanical or bioprosthetic valve. In the first 6 weeks after operation, the incidence of atrial and other arrhythmias is high; thus, these fluctuating rhythms mandate anticoagulation even if the basic rhythm is sinus. In addition to rhythm concerns, the left atrial incisions and the possibility of stasis in the left atrial appendage justify full anticoagulation with warfarin for all patients. Some surgeons advocate immediate intravenous heparin until therapeutic warfarin doses can be reached.<sup>118,119</sup> Low molecular weight heparin also can be used.<sup>120,121</sup>

The therapeutic international normalized ratio (INR) after MVR is 2.5 to 3.5 depending on the type of valve, cardiac rhythm, and presence or absence of the aforementioned intraoperative risk factors for thromboembolism.<sup>116,119,120</sup> Anticoagulation levels are in the low range for patients in sinus rhythm who received tissue valves. Patients who have mechanical valves need lifelong anticoagulation. Patients who have bioprosthetic valves are evaluated at 6 to 12 weeks for cardiac rhythm abnormalities. If they are in predominantly sinus rhythm, warfarin is stopped, and one aspirin tablet is given daily indefinitely. If the patient has continuous atrial

fibrillation or fluctuating rhythms, anticoagulation with warfarin is continued. Warfarin usually is started on the second postoperative day. Addition of aspirin, 80 to 150 mg daily, to the warfarin may reduce the risk of thromboembolism<sup>122,123</sup> and may have a role in patients with prosthetic valves.<sup>124</sup>

## RESULTS

### Early Results

The hospital mortality for MVR with and without coronary bypass grafting has decreased significantly since the inception of mitral valve surgery. The current risk (2006) of elective primary MVR with and without coronary bypass grafting is 5 to 9% in most studies (range 3.3 to 13.1%).<sup>68</sup> Operative (30-day) mortality is related to myocardial failure, multisystem organ failure, bleeding, respiratory failure in the chronically ill, debilitated individual, diabetes, infection, stroke, and, very rarely, technical problems.<sup>20,40</sup> Mortality is correlated with preoperative functional class, age, and preexisting coronary artery disease.<sup>125</sup>

Published results on mitral valve surgery have improved in recent years,<sup>126</sup> probably because of preservation of papillary muscles, preventing midventricular rupture,<sup>111,112</sup> and preservation of the normal geometry of the left ventricle, which aids in the maintenance of early postoperative cardiac output.<sup>107,108,127</sup> MVR and coronary artery bypass surgery 20 to 25 years ago had an associated mortality of about 10 to 20%.<sup>39,128</sup> This mortality risk also has decreased as myocardial protection has improved with the use of blood cardioplegia and retrograde methods of administration.<sup>95,129</sup> Some studies have indicated that the risk of combined MVR-coronary artery bypass grafting is now no greater than that of mitral valve repair with an annuloplasty ring or MVR without coronary artery bypass grafting.<sup>107,130</sup> Other studies have shown significantly increased morbidity and mortality with the addition of coronary artery bypass grafting.<sup>43,131</sup> Figures from the database of the Society of Thoracic Surgeons indicate that both reoperation and emergency operation increase operative mortality<sup>132</sup> (Fig. 42-10).

### Late Results

#### FUNCTIONAL IMPROVEMENT

In more than 90% of patients after MVR, functional class improves to at least class II. A small group of patients remains in class III or IV depending on left ventricular function before surgery or other comorbidities.

#### SURVIVAL

The causes of late death in patients after MVR are primarily chronic myocardial dysfunction, thromboemboli and stroke, endocarditis, anticoagulant-related hemorrhage, and coronary artery disease. The extent of left ventricular dysfunction and patient age, particularly if myocardial and coronary diseases are combined, correlate with late mortality. The probability

**FIGURE 42-10** Operative mortality for elective, urgent, emergency, and salvage procedures for primary operations and reoperations for mitral valvular replacements. (Data from Society of Thoracic Surgeons.)

of survival after MVR at 10 years is usually around 50 to 60% (range 42 to 81%)<sup>68</sup> (Table 42-4). Long-term patient survival seems to be similar for patients with biologic and mechanical mitral valves.<sup>133-135</sup> Unlike patients with severe aortic regurgitation or aortic stenosis, arrhythmias seldom cause sudden death in patients after MVR; however, few patients die from thromboembolic stroke owing to chronic atrial fibrillation. The fact that more than 50% of patients after MVR are in chronic atrial fibrillation increases the propensity for thromboembolic stroke despite anticoagulation and for mechanical valve thrombosis if the anticoagulation protocol is altered. In addition, patients with older types of prosthetic valves who receive higher-intensity anticoagulation may develop severe anticoagulant hemorrhage.<sup>136</sup>

In patients with bioprosthetic valves, one of the important determinants of mortality is reoperation secondary to SVD<sup>48,49,68</sup> (Table 42-5). Reoperative MVR mortality has decreased significantly in the last 15 years to under 10%, even in patients who have required multiple mitral valve reoperations.<sup>129</sup> At the Brigham and Women's Hospital, operative mortality was less than 6% for reoperative mitral valve operations from 1990 to 1995.<sup>129</sup> Improved myocardial protection, earlier selection of patients for reoperation, and better perfusion techniques, including frequent femorofemoral bypass to protect the right ventricle during incision and dissection of the heart, are factors contributing to decreased mortality.<sup>107,129,137-139</sup>

### LATE MORBIDITY

The major morbidity in patients after MVR is structural valve deterioration of a bioprosthetic valve and thromboembolism and anticoagulant hemorrhage with a mechanical prosthesis. Both valve types develop perivalvular leak and infection.

**Thromboembolism.** Thromboembolism is perhaps the most common complication of both biologic and mechanical mitral prostheses but is more frequent in patients with mechanical valves. Chronic atrial fibrillation and local atrial factors, discussed earlier, increase the risk of thromboembolism

in patients with mitral prostheses. A number of recent studies have summarized the thromboembolic potential of various valves (Table 42-6), and it appears that the better the valve hemodynamics, the lower is the probability of thromboemboli. The incidence of thromboemboli in currently available bileaflet and tilting-disk valves is similar to that in bioprosthetic valves—about 1.5 to 2.0% per patient-year. Thromboembolism in patients with MVR is lower in those with a small left atrium, sinus rhythm, and normal cardiac output. It is much higher in patients with a large left atrium, chronic atrial fibrillation, and the presence of intraatrial clot.<sup>116,140</sup> Thrombosis of a mechanical valve, once a feared complication of tilting-disk valves,<sup>141,142</sup> is now relatively rare unless anticoagulation is stopped for any period of time. Valve thrombosis can be treated with thrombolytic agents if the patient is not in cardiogenic shock but requires surgery if the circulation is inadequate.<sup>143,144</sup>

**Anticoagulant Hemorrhage.** Bleeding related to anticoagulation is seen most commonly in the gastrointestinal, urogenital, and central nervous systems, and usually is proportionate to the INR. The incidence of anticoagulant-related hemorrhage has decreased markedly with hemodynamic improvements in mitral valve prostheses. New valves do not require the intensity of anticoagulation of older prostheses. Patients with streamlined bileaflet or tilting-disk valves require an INR of between 2.5 and 3.5; thus, the incidence of anticoagulant hemorrhage is reduced significantly in the newer, hemodynamically improved prostheses.<sup>145</sup> Table 42-6 lists the incidence of anticoagulant hemorrhage with various bioprostheses and mechanical valves.

### STRUCTURAL VALVE DEGENERATION

Structural valve degeneration (SVD) is the most important complication of the bioprosthetic valve. The probability of structural failure with currently available porcine valves (Hancock or Carpentier-Edwards) begins to increase 8 years after operation and reaches more than 60% at 15 years.<sup>46,48</sup>

y indicates years.

This finite durability is a major impediment to long-term success of these biologic prostheses, even though the failure rate in a patient 70 years of age or older is significantly less than in younger age groups (Table 42-7). SVD presents as MR from leaflet tear, calcific MS owing to calcification of valve leaflets or both. The appearance of a new murmur with new congestive symptoms should prompt a noninvasive investigation of the prosthesis and elective re-replacement if dysfunction is documented. SVD leading to reoperation is the cause for at least two-thirds of the reoperations in patients with bioprostheses.<sup>137,138</sup> The probabilities of SVD at 5, 10, and 15 years of the most commonly used biologic prostheses are shown in Table 42-3. With current quality controls, the incidence of SVD is virtually zero for bileaflet mechanical valves.

### PROSTHETIC VALVE ENDOCARDITIS

Mitral valve endocarditis is considerably less common than aortic prosthetic valve endocarditis,<sup>146</sup> but when it occurs, it may present as septicemia, malignant burrowing infections, abscess formation, and septic emboli. With better antibiotic prophylaxis at the time of mitral surgery and improved prophylaxis for all patients having dental or other surgical procedures, the incidence of endocarditis has been reduced substantially.

The incidence of prosthetic endocarditis is highest during the initial 6 months after surgery and thereafter declines to a lower but persistent risk.<sup>1</sup> The probability of freedom from this morbid event is shown in Table 42-8 for both mechanical and bioprosthetic valves. Biologic and mechanical valves have a similar incidence of endocarditis, except for the initial months after valve implantation, when mechanical prostheses carry a greater risk of infection.<sup>147</sup>

The diagnosis of prosthetic endocarditis is made by the presence of symptoms, appearance of a new murmur, a septic embolus, or large vegetation on echocardiogram. Blood cultures usually are positive, although a small percentage of patients have culture-negative endocarditis. Echocardiograms may show a rocking motion of the prosthesis and the presence of vegetations. The most frequent organisms are still *Streptococcus* and *Staphylococcus*; the latter is usually hospital acquired. Antibiotic therapy depends on the sensitivity of the organisms, but immediate high-dose intravenous therapy must begin as soon as possible. Experience indicates that a number of patients with bioprosthetic valvular endocarditis can be “cured” of low-potency organisms such as *Streptococcus*. However, it is unlikely that antibiotics alone can sterilize more virulent mitral valve infections, particularly *Staphylococcus*. These infections usually require urgent and

sometimes emergent surgery because of invasion of the cardiac exoskeleton.

The indications for surgical intervention in mitral valve prosthetic endocarditis are persistent sepsis, organism, congestive failure, perivalvular leak, large vegetations, or systemic infected emboli.<sup>27,28,148</sup> Operative technique is similar to other mitral procedures with respect to anesthesia, monitoring, cardioplegia, left atrial incision, and exposure of the valve. Critical to successful resolution is the complete excision of the prosthetic device and debridement of all infected tissues. Surgical technique is described in a different chapter “Surgical treatment of Mitral Valve Endocarditis.” Postoperative care should include at least 6 weeks of appropriate intravenous antibiotics. Hospital mortality is related primarily to ongoing sepsis, multisystem organ failure, or failure to eradicate the local infection and subsequent recurrent perivalvular leak.<sup>149,150</sup> Recurrence of infection depends on the type of organism and the surgeon’s ability to remove all areas of infection completely. Recurrence of infection is the single most important long-term complication.

## MITRAL ANNULAR CALCIFICATION

Calcification of the mitral annulus is a process commonly associated with increased age<sup>151,152</sup> and stress to the mitral valve apparatus.<sup>153,154</sup> Based on routine echocardiographic screening, the Framingham study group reported an incidence of mitral annular calcification of 2.8%<sup>155</sup> among the study population. Calcium deposition is most commonly observed along the posterior mitral annulus but might extend to involve the whole annulus, intervalvular fibrous body, papillary muscles and left ventricle.<sup>154,156</sup> Despite rare direct involvement of valve leaflets,<sup>151</sup> the disease process affects leaflet coaptation, restricts leaflet motion, and prevents contraction of the AV annulus.<sup>156</sup> Severe mitral annular calcification, by itself, is not an indication for mitral valve surgery; however, it confers high operative risks in patients undergoing mitral valve surgery due to increasing risks of developing serious complications (intractable hemorrhage, AV disruption, ventricular rupture).<sup>156</sup> The major challenge valve surgeons face in those operations is ensuring a strong suture line to attach the prosthesis during MVR. Sutures within the calcium deposits would almost always lead to paravalvular leaks or valve dehiscence and extensive debridement

**TABLE 42-6: Incidence of Thromboembolism and Anticoagulant-Related Hemorrhage**

may warrant annular reconstruction hence complicating the procedure further.

Surgical exposure should not be compromised in this situation and access should always be done through a complete median sternotomy. Preoperative and intraoperative echocardiographic imaging maps the calcifications and surgeon preference dictates how to best approach the mitral valve to ensure optimal visualization of the leaflets, annulus and, if needed, the left ventricle. Previously described approaches include standard left atriotomy,<sup>157</sup> transeptal access,<sup>158</sup> and finally through aortic root and dome of left atrium if concomitant AVR is required.<sup>156</sup> Since the disease is limited to the annulus in most cases, adequate debridement can be enough to ensure satisfactory valve replacement. In cases of extensive annular calcifications, patch reconstruction of the annulus may be required. The long-term benefits of annular reconstruction have been extensively studied, proven to be excellent when used by surgeons of adequate expertise and subsequently strongly recommended whenever applicable.<sup>159-161</sup> Despite being technically demanding, this technique ensures a strong suture line and gives the option of annular enlargement to fit a larger valve. Another approach described in 1994 by Nataf and colleagues is the intraatrial insertion of the mitral prosthesis.<sup>162</sup> Patients undergoing this procedure benefit from minimal calcium debridement at the expense of a higher implantation of the valve which may transfer the ventricular pressure into the atrium putting the valve at risk of dehiscence. A more recent and promising technique described by Hussain and colleagues mixed the two above-mentioned techniques. It requires the sandwiching of an annular washer posteriorly from trigone to trigone between the annulus and the sewing ring of the prosthesis.<sup>158</sup> Annular calcium debridement in this technique is limited to minimal amounts enough to fit a

prosthesis of reasonable size. Sutures can be taken through or around the calcium deposits and the washer is subsequently attached to the left atrium with running sutures to ensure adequate seal. Authors argue that the washer technique confers a superior annular support and minimizes the risk of ventricular rupture and paravalvular leak.<sup>158</sup>

#### UNCLAMPABLE ASCENDING AORTA

Calcifications in the ascending aorta are a common finding in cardiac surgery patients with varying severity. In the majority of cases, safe sites for cannulation and cross-clamping can still be found and surgeries conducted with adequate cerebral, systemic, and coronary perfusion. Porcelain aorta represents the extreme of the aortic calcification spectrum, where the traditional cross-clamping technique cannot be applied due to the very high risks of embolization and subsequent mortality.<sup>163-166</sup> Affecting 2 to 5% of the overall cardiac surgery patients, porcelain aorta is being increasingly encountered with the increasing elderly population.<sup>167-169</sup>

Preoperative screening for porcelain aorta is not routinely done which makes it sometimes an incidental intraoperative finding that warrants a change in the whole surgical approach. There is no current uniformly applicable practice as to how to address the mitral valve.<sup>170-172</sup> Maintaining cerebral and coronary perfusion, while minimizing the risk of embolization, should dictate the best approach and the initial decision as to whether find a way to clamp the aorta or not. The general approach to MVR we adopt in this patient population is schemed in Fig. 42-11. In the absence of a significant aortic valve insufficiency, the preferred approach to an isolated MVR is moderate hypothermia with ventricular fibrillation without any aortic clamp.<sup>173</sup> It will ensure adequate valve exposure and coronary perfusion

with minimal aortic manipulation.<sup>173</sup> It is important to keep perfusion pressure high to maintain the aortic valve closed and prevent air embolism. In patients with aortic insufficiency, many approaches have been described and include endoaortic balloon occlusion,<sup>174,175</sup> hypothermic

fibrillation with low bypass flow<sup>176</sup> or replacement of the calcified ascending aorta under deep hypothermic circulatory arrest.<sup>170</sup>

The use of endoaortic balloon occlusion in patients with porcelain aorta has been previously described; however, it was

**FIGURE 42-11** Approach to mitral valve replacement in patients with unclampable aorta.

abandoned by Zingone and colleagues after publishing disappointing results where the use of this device was associated with a higher than expected incidence of unfavorable events ranging from silent emboli to death.<sup>175</sup> The major drawback was the incomplete occlusion happening frequently and attempts to over inflate the balloon were associated with balloon protrusion.<sup>175</sup> Interventionists should keep in mind that if peripheral access for the balloon is sought, it should be well assessed since diffuse calcification of the femorals iliacs or descending aorta are common findings in patients with porcelain aorta.

The use of a hypothermic low flow bypass has been mostly emphasized in patients with minimal aortic valve insufficiency that worsens upon heart manipulation to obtain adequate mitral valve exposure.<sup>174,176</sup> It usually accompanies the previous technique to ensure the operative field does not get flooded with blood jeopardizing the practicality and diligence of the repair/replacement.

Eventually, replacement of the ascending aorta under deep hypothermic circulatory arrest came to be a preferred technique especially in patients with minimal comorbidities. It was first described in patients with porcelain aorta requiring aortic valve replacement in 1992<sup>168</sup> and with growing expertise, surgeons have extrapolated its applicability to mitral valve surgeries. Despite being a more invasive and radical approach, multiple studies have shown that it can be safely and effectively done.<sup>170-172</sup> It is not risk free and benefits need to be carefully weighed especially in elderly or patients with significant comorbidities, requiring multiple valve surgery or concomitant coronary artery bypass graft. Of specific concern is the cannulation strategy and cerebral perfusion. Arterial cannulation should be done under direct epiaortic guidance in the ascending aorta, common brachiocephalic trunk or axillary artery and the venous cannulation can be done directly into the right atrium or through the femoral vein. Cerebral perfusion can be instituted through antegrade or retrograde blood flow into the brain or not adopted at all while monitoring cerebral oxygenation indexes.<sup>172,176</sup>

## Patient-Prosthesis Mismatch

The concept of patient-prosthesis mismatch is not new, but was first described in relationship to aortic valve replacement by Rahimtoola in 1978.<sup>177</sup> Since his introduction, the deleterious effects of patient-prosthesis mismatch on LV remodeling, function, and early and late survival with aortic valve replacement have been well documented. The notion of mitral valve patient prosthesis mismatch (MVPPM) in the adult was first proposed in a case report in 1981 again by Rahimtoola.<sup>178</sup> Most MVPPM was described in relation to pediatric mitral valve surgery, resulting in re-replacement rates approaching 30%, largely the result of somatic growth versus fixed prosthesis size. Recently, the possibility of such patient prosthesis mismatch in the mitral position has become an area of increased interest among adult cardiac surgeons. At this time, MVPPM has been studied through in vitro pulse generator analysis demonstrating that an index geometric orifice area

less than 1.3 to 1.5 cm<sup>2</sup>/m<sup>2</sup> could potentially result in any patient having a high postoperative transprosthetic gradient. Similar studies performed in the clinical arena suggest that an index effective orifice area (IEOA) less than 1.3 to 1.5 cm<sup>2</sup>/m<sup>2</sup> as measured by the continuity equation may increase the risk for MVPPM. Using this criterion, Lam and coworkers demonstrated a potential for MVPPM of roughly 32% in a recent series of 884 patients. In this population, patients at elevated risk for MVPPM measured at IEOA 1.0 to 1.25 cm<sup>2</sup>/m<sup>2</sup> were at a significantly higher risk for development of postoperative CHF than those with IEOA greater than 1.25 cm<sup>2</sup>/m<sup>2</sup>. Although a weak association with CHF and pulmonary hypertension was noted, no direct correlation was found between MVPPM and the development of postoperative pulmonary hypertension.

Jamieson and coworkers recently evaluated the potential impact of MVPPM and long-term survival.<sup>179</sup> In contrast to prior reports, this study of nearly 2500 patients refuted the notion that MVPPM had any relation to mortality. Instead predictors of overall mortality included age, New York Heart Association III or IV, competent coronary artery disease, ventricular dysfunction, prosthesis type, body mass index, and preexisting pulmonary hypertension.

Certainly some degree of patient prosthesis mismatch may occur as a result of MVR. The surgeon should be aware of the potential for MVPPM, particularly in the setting of particularly small annulus size in patients resulting in the need for implantation of a small prosthetic device resulting in a high transprosthetic gradient. As such, foreknowledge of the devices specific IEOA may assist allowing the surgeon to choose a device that might minimize MVPPM. Unfortunately, unlike the aortic position, in which aortic root enlargement will allow for valve upsizing, the mitral position cannot be corrected as simply. As a result, in patients with particularly small mitral valve area, some degree of patient prosthesis mismatch may be unavoidable. This phenomenon remains an area of active clinical investigation.

## Mitral Prosthetic Paravalvular Leak

Paravalvular leaks occur after valve replacement surgeries with an incidence of 7 to 17% in the mitral position and minimal clinical sequelae in the majority of cases.<sup>134,180</sup> It is estimated that only 1 to 5% of those patients develop serious clinical consequences (heart failure, endocarditis, and hemolysis) and require reintervention to modify their outcomes.<sup>181,182</sup> This leak arises whenever there is an incomplete seal between the prosthesis sewing ring and the mitral annulus and it has been associated with risk factors including technical (suturing technique and size and shape of the prosthesis), annular calcification, and infection.<sup>183</sup> Early occurrence of this leak has been linked to the technical risk factors, whereas late occurrence seem to happen as a results of suture dehiscence caused by infectious processes or suturing through annular calcifications.<sup>183</sup> A paravalvular leak should be therefore suspected in any patients with a new onset murmur after valve surgery or symptoms of anemia or heart failure and cardiac

echocardiography is needed to confirm the finding of a systolic jet into the left atrium.

Once complications arise, patients should be evaluated for operative or transcatheter closure of the leak. Until few years ago, re sternotomy was the only option available where the leak can be repaired through direct resuturing or patching or the whole valve replaced.<sup>184-186</sup> The main drawback of surgical reentry, however, is its association with high rate of procedure failure (12-35%) and mortality (4-13%).<sup>187,188</sup> The underlying disease process is still present in addition to the tissue frailty and the fact that this is a reoperation would drive surgeons away from this procedure especially in the presence of multiple comorbidities.<sup>189</sup> Recently, however, high-risk patients with paravalvular leak were offered an alternative percutaneous option.

Percutaneous paravalvular leak repair is a catheter-based technique during which a closure device is deployed to obliterate and seal the leak area. This procedure is not free of risk and requires advanced technical expertise in catheter-based closure-device implantations. The approach to the mitral valve can be transeptal, transaortic, and/or transapical, and the decision on the approach depends mainly on the location of the leak, the vascular access, the presence of mechanical valves, the presence of paravalvular calcification, and the size and shape of the orifice.<sup>183,190</sup> The optimal goal of this technique is to ensure maximal closure with minimal impingement on the valve leaflets and the challenges include the ability to adequately visualize the leak, estimate its spatial characteristics, and find the device that best suits this type of leak.<sup>183,190-192</sup> Angiography, transesophageal echocardiography, 3D echocardiography, and 3D-4D computed tomography angiography are available for use during this procedure to ensure best estimation of the device geometrics and flow hemodynamics.<sup>183</sup> In the absence of devices specifically designed for this purpose, the Amplatz family of occluder devices, commonly applied for ASD, VSD, and PDA closure, are used off-label. Two disk devices like the Amplatz Vascular plug (AVP II most used in USA and AVP III) are preferred because they hold a lower risk of embolization and are better suited for the commonly encountered geometrics of the leak.<sup>183,192</sup> In certain instances multiple small devices are used to close one single defect. Long-term benefits of this technique have been reported by multiple case series which included also paravalvular aortic leaks as well. These studies reported acceptable successful implantation rates (63 and 91%) as well as favorable short- and midterm outcomes in groups of very high operative risk patients.<sup>191,193,194</sup> Long-term mortality, however, remains very high in this patient population because of the baseline high-risk profile they have.

## TRANSCATHETER TREATMENT

Introduction of transcatheter valve replacement has reshaped the treatment strategy for aortic valve replacement. In the United States, it is currently approved for aortic stenosis patients with high or prohibitive risk. Transcatheter mitral valve replacement (TMVR) has been performed by means of

valve-in-valve technique.<sup>195</sup> This technique uses the stent of the previous bioprostheses as an anchor for the transcatheter valve; however, it not yet approved by the FDA. Some series report excellent outcome with improvement in the postprocedural gradient. This technique is commonly performed through transapical approach,<sup>195</sup> but other approaches via transfemoral/transseptal and transjugular are reported.<sup>196</sup>

There are many hurdles for the native TMVR. Currently, native mitral annulus is not rigid enough to hold the transcatheter valve. Also, the varied etiology, the complex anatomy, the difficulty in measuring the size of the valve, the exposure to increased pressure in case of paravalvular leak, the risk of left ventricular outflow tract obstruction and the excellent result of mitral valve repair are some of the difficulties that TMVR will face. Nonetheless, the technology will evolve and we may see a new transcatheter valve which will solve all these issues in the near future.

# VALVULAR HEART DISEASE (OTHER)

*This page intentionally left blank*

# Tricuspid Valve Disease

Richard J. Shemin • Peyman Benharash

The tricuspid valve consists of three leaflets (anterior, posterior, and septal), the chordae tendineae, two discrete papillary muscles, the fibrous tricuspid annulus, and the right atrial and right ventricular myocardium (Fig. 43-1A). Valve function depends on coordination of all these components. The anterior leaflet is the largest. The septal leaflet is the smallest and arises medially directly from the tricuspid annulus above the interventricular septum. Because the small septal wall leaflet is fixed and is relatively spared from annular dilation, tricuspid annular sizing has been based on the dimension of the base of the septal leaflet.<sup>1,2</sup> The posterior leaflet often has multiple scallops. The anterior papillary muscle provides chordae to the anterior and posterior leaflets, and the medial papillary muscle provides chordae to the posterior and septal leaflets. The septal wall gives chordae to the anterior and septal leaflets. There may be accessory chordal attachments to the right ventricular free wall and the moderator band.

Right ventricular dysfunction and dilation lead to chordal tethering contributing to loss of leaflet apposition.<sup>2</sup> In addition, dilation of the free wall of the right ventricle (RV) results in tricuspid annular enlargement, primarily in its anterior/posterior (mural) aspect, resulting in significant functional tricuspid regurgitation (fTR) as a result of leaflet malcoaptation<sup>3</sup> (Fig. 43-1B).

The tricuspid annulus has a complex three-dimensional structure, which differs from the more symmetric “saddle-shaped” mitral annulus. The tricuspid annulus is dynamic and can change markedly with loading conditions. During the cardiac cycle, there is a ~20% reduction in annular circumference (~30% reduction in annular area) with atrial systole.<sup>4,5</sup> This distinct shape has implications for the design and application of currently available annuloplasty rings in the tricuspid position. Most commercially available rings or bands are essentially planar except for the Edwards MC<sup>3</sup> annuloplasty system.

Fukuda et al.<sup>4</sup> studied the shape and movement of the healthy and diseased tricuspid annulus performing a real-time three-dimensional transthoracic echocardiographic study. Healthy subjects had a nonplanar, elliptical-shaped tricuspid annulus, with the posteroseptal portion being “lowest” (toward the right ventricular apex) and the anteroseptal portion the

“highest” (Fig. 43-2). Patients with fTR generally had a more planar annulus, which was dilated primarily in the septal-lateral direction, resulting in a more circular and flat shape as compared with the elliptical shape in healthy subjects.<sup>5</sup>

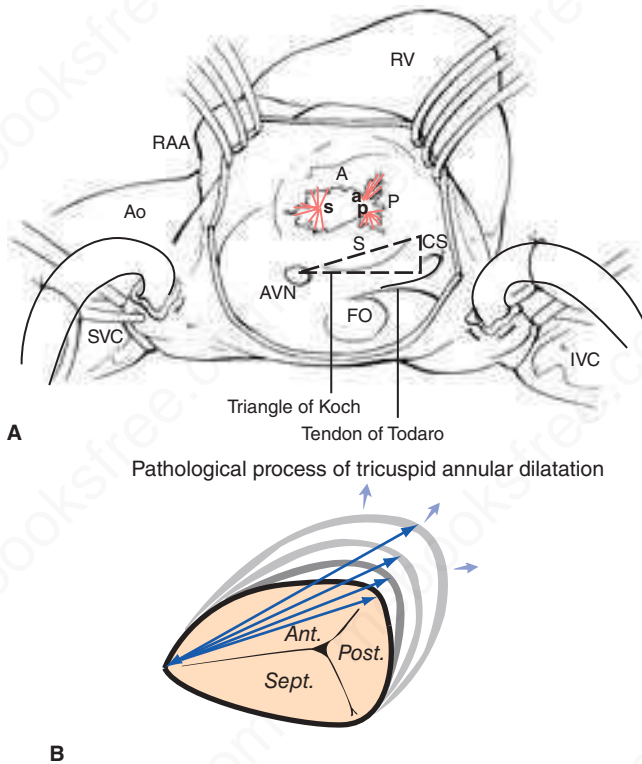

## CLINICAL PRESENTATION

The most common presentation of TR is secondary to cardiac valvular pathology (mostly mitral valve disease) on the left side of the heart. As pulmonary hypertension develops, leading to right ventricular dilatation, the tricuspid valve annulus will dilate. The circumference of the annulus lengthens primarily along the attachments of the anterior and posterior leaflets. The septal leaflet is fixed between the fibrous trigones, preventing lengthening (Fig. 43-1B). With progressive annular and ventricular dilatation, the chordal papillary muscle complex becomes functionally shortened, causing leaflet tethering. This combination prevents leaflet apposition, resulting in valvular incompetence.<sup>6-9</sup>

Eisenmenger syndrome and primary pulmonary hypertension lead to the same pathophysiology of progressive right ventricular dilatation, tricuspid annular enlargement, and valvular incompetence. A right ventricular infarction produces either disruption of the papillary muscle or a severe regional wall motion abnormality. This prevents normal leaflet apposition by a tethering effect on the leaflets. Marfan's syndrome and other variations of myxomatous disease affecting the mitral and tricuspid valves can lead to prolapsing leaflets, elongation of chordae, or chordal rupture, producing valvular incompetence.

Blunt or penetrating chest trauma may disrupt the structural components of the tricuspid valve. Dilated cardiomyopathy in the late stages of biventricular failure and pulmonary hypertension produces TR.<sup>10-13</sup> Infectious endocarditis can destroy leaflet tissue, mostly in drug addicts with staphylococcal infection.<sup>14-16</sup>

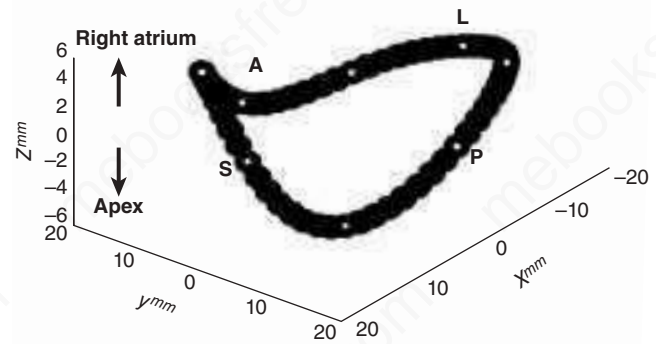

The carcinoid syndrome leads to either focal or diffuse deposits of fibrous tissue on the endocardium of valve cusps, cardiac chambers, intima of the great vessels, and coronary sinus. The white fibrous carcinoid plaques, if present on the ventricular side of the tricuspid valve cusps, adhere the leaflet

**FIGURE 43-1** (A) Surgical view of the tricuspid valve complex. The tricuspid valve consists of three leaflets: anterior (A), posterior (P), and septal (S). There are two main papillary muscles, anterior (a) and posterior (p). The septal papillary muscle (s) is rudimentary, and chordae tendineae arise directly from the ventricular septum. Adjacent structures include the atrioventricular node (AVN), coronary sinus ostium (CS), and the tendon of Todaro, forming the triangle of Koch. Ao = Aorta; FO = foramen ovale; IVC = inferior vena cava; RAA = right atrial appendage; RV = right ventricle; SVC = superior vena cava. (B) Direction of progressive tricuspid valve annular dilatation. (B. Reproduced with permission from Dreyfus GD, Corbi PJ, Chan KM, et al: Secondary tricuspid regurgitation or dilatation: which should be the criteria for surgical repair? *Ann Thorac Surg.* 2005 Jan;79(1):127-132.)

tissue to the right ventricular wall, preventing leaflet coaptation.<sup>17-19</sup> Rheumatic disease of the tricuspid valve is always associated with mitral valve involvement, and the deformity of the tricuspid tissue results in a tricuspid valve stenosis as well as regurgitation<sup>20</sup> (Table 43-1).

A unique cause of TR is the result of pacemaker or defibrillator leads, which cross from the right atrium into the RV and may directly interfere with leaflet coaptation. This entity has been reported in case reports and small series but is likely more significant and prevalent than currently perceived. In a recent report by Kim et al., the effect of transtricuspid permanent pacemaker or implantable cardiac defibrillator leads on 248 subjects with echocardiograms before and after device placement was studied. TR worsened by one grade or more after implant in 24.2% of subjects and that TR worsening was more common with implantable cardiac defibrillators than permanent pacemakers.<sup>21,22</sup>

**FIGURE 43-2** Three-dimensional shape of the tricuspid annulus based on a three-dimensional transthoracic echocardiographic study in healthy subjects. Note that the annulus is not planar and an optimally shaped annuloplasty ring may need to mimic this configuration. A indicates anterior; L, lateral; P, posterior; S, septal. (Reproduced with permission from Fukuda S, Saracino G, Matsumura Y, et al: Three-dimensional geometry of the tricuspid annulus in healthy subjects and in patients with functional tricuspid regurgitation: a real-time, 3-dimensional echocardiographic study, *Circulation.* 2006 Jul 4;114(1 Suppl):I492-I498.)

The current guidelines do not recommend lead extraction for patients with existing TR and transtricuspid pacing leads, because the risks of lead extraction are significant and there is potential for injury to the tricuspid valve if the lead is adherent to the valve apparatus.<sup>23</sup>

It has also been shown at 5 years after successful tricuspid valve repair, 42% of patients with a pacemaker had severe TR, almost double the incidence of those without pacemaker implantation.<sup>24</sup> This suggests removing a transtricuspid lead and replacing it with an epicardial lead at the time of tricuspid valve surgery may reduce late repair failure.

**TABLE 43-1: Causes of Tricuspid Regurgitation**

Primary causes (25%)

- Rheumatic
- Myxomatous
- Ebstein anomaly
- Endomyocardial fibrosis
- Endocarditis
- Carcinoid disease
- Traumatic (blunt chest injury, laceration)
- Latrogenic (pacemaker/defibrillator lead, RV biopsy)

Secondary causes (75%)

- Left heart disease (LV dysfunction or valve disease) resulting in pulmonary hypertension
- Any cause of pulmonary hypertension (chronic lung disease, pulmonary thromboembolism, left to right shunt)
- Any cause of RV dysfunction (myocardial disease, RV ischemia/infarction)

RV, right ventricular; LV, left ventricular.

## Tricuspid Regurgitation

Patients with TR have the presenting symptoms of fatigue and weakness related to a reduction in cardiac output. Atrial fibrillation is common. Jugular vein distention is found, especially during inspiration, when a physiologic increase in venous return is accentuated. Right-sided heart failure leads to ascites, congestive hepatosplenomegaly, pulsatile liver, pleural effusions, and peripheral edema. In the late stages, these patients are wasted with cachexia, cyanosis, and jaundice. Hepatic cardiac cirrhosis can develop in neglected cases.

Echocardiography is routinely used to assess the severity of TR in clinical practice. The exam is performed in an integrative manner using color Doppler flow mapping of the direction and size of the TR jet. In addition, the morphology of continuous wave Doppler recordings across the valve and pulsed wave Doppler of the hepatic veins can be used.<sup>25</sup>

Serial assessments of TR must be interpreted within the clinical context, because functional mitral regurgitation (MR) severity can be affected by multiple factors, such as volume status (preload) and afterload. Right ventricular shape is complex as compared with the left ventricle, appearing crescent shaped in cross-section and triangular when viewed en face.<sup>26</sup> Right ventricular function can be assessed quantitatively in the four-chamber view by measuring the end-diastolic and end-systolic area to calculate the fractional area change of the RV.<sup>27</sup> Although right ventricular chamber dimensions may be obtained during echocardiography, magnetic resonance imaging is emerging as an improved technique for assessing right ventricular diastolic and systolic volumes.<sup>28</sup> More recently, the tricuspid annular peak systolic excursion, or apical movement of the annulus as measured on echocardiography, as been validated as a sensitive measure of RV function.<sup>29</sup> Other echocardiographic findings include a shift in the atrial septum to the left and paradoxical septal motion, consistent with right ventricular diastolic overload. Pulsed Doppler and color-flow studies help to identify systolic right ventricular to right atrial flow with inferior vena cava and hepatic vein flow reversal. Contrast-enhanced echocardiography can be useful, with a rapid saline bolus injection producing microcavities that are visible on echo, demonstrating to-and-fro motion across the valve orifice and reversal into the inferior vena cava and hepatic veins. Possible ASD or patent foramen ovale should be sought. Endocarditis vegetations are clearly visible on echocardiography. The valve may be destroyed, and septic pulmonary emboli are a common feature. The tricuspid valve in carcinoid syndrome is thickened with retracted leaflets fixed in a semiopen position throughout the cardiac cycle.<sup>29-34</sup>

## Tricuspid Stenosis

Tricuspid stenosis (TS) is most commonly rheumatic. It is extremely rare to have isolated TS because some degree of TR will be present.<sup>35-37</sup> Mitral valve disease coexists with occasional involvement of the aortic valve. The third still have a significant prevalence of rheumatic mitral and tricuspid valvular disease. The anatomical features are similar to those of

mitral stenosis, with fusion and shortening of the chordae and leaflet thickening. Fusion along the free edges and calcific deposits on the valve are found late in the disease. The preponderance of cases is in young women.

The diastolic gradient between the right atrium and RV is significantly elevated even at 2 to 5 mm Hg mean pressure. As the right atrial pressure increases, venous congestion leads to distention of the jugular veins, ascites, pleural effusion, and peripheral edema. Over time, the right atrial wall thickens, and the atrial chamber dilates.

Clinical features are consistent with reduced cardiac output producing the symptoms of fatigue and malaise. Significant liver engorgement produces right upper quadrant tenderness with a palpable liver with a presystolic pulse. Ascites produces increased abdominal girth. Significant peripheral edema or anasarca can develop. Severe TS may mask or reduce the pulmonary congestion of mitral stenosis owing to reduced blood flow to the left side of the heart. The low output state of the patient is prominent.

Echocardiography reveals the diagnostic features of diastolic doming of the thickened tricuspid valve leaflets, reduced leaflet mobility, and a reduced orifice of flow. The Doppler flow pattern across the tricuspid valve has a prolonged slope of antegrade flow.

## Functional Tricuspid Regurgitation

Secondary tricuspid regurgitation, also called fTR, may become worse over time, leading to severe symptoms, biventricular heart failure, and death.<sup>24</sup> IA large retrospective echocardiographic analysis of 5223 Veterans Administration patients by Nath et al. showed that independent of echo-derived pulmonary artery systolic pressure, left ventricular ejection fraction, inferior vena cava size, and right ventricular size and function, survival was worse for patients with moderate and severe TR than for those with no TR.<sup>38</sup>

Pulmonary arterial hypertension from any cause is known to be associated with the development of secondary tricuspid regurgitation. However, not all patients with pulmonary hypertension develop significant tricuspid regurgitation, and the mechanisms of secondary TR are multifactorial.

Mutlak and colleagues<sup>39</sup> studied 2139 subjects with mild (<50), moderate (50-69), or severe ( $\geq 70$ ) elevations in pulmonary artery systolic pressure. In their analysis, increasing PASP was independently associated with greater degrees of TR (odds ratio, 2.26 per 10 mm Hg increase). However, many patients with high PASP had only mild TR (mild TR in 65.4% of patients with PASP 50-69 mm Hg and in 45.6% of patients with PASP  $\geq 70$  mm Hg). Other factors, such as atrial fibrillation, pacemaker leads, and right heart enlargement, were also importantly associated with TR severity. The authors concluded that the cause of TR in patients with pulmonary hypertension is only partially related to an increase in transtricuspid pressure gradient. It remains unproved if surgical annuloplasty, in the setting of pulmonary hypertension, alters the natural course of right ventricular dilation and recurrent TR.

Thus, functional tricuspid incompetence is progressive. Surgical treatment of left-sided valvular lesions is not always

adequate to resolve or prevent progressive TR. This is particularly true when pulmonary hypertension persists.

## SURGICAL EXPOSURE

Tricuspid valve annuloplasty performed with either mitral and/or aortic valve operations is accomplished either through a full or partial lower sternotomy approach or less invasive right minithoracotomy exposure with mitral valve procedures. Bicaval venous cannulation with caval snares is essential to isolate the right atrium. The cannula can be placed conventionally via the right atrium or less invasively via the femoral vein. A superior vena cava cannula can be inserted via the internal jugular vein.

Left-sided valve repair or replacement (mitral and/or aortic) is performed under blood cardioplegic arrest with

antegrade and/or retrograde administration, moderate systemic hypothermia, and optional surface cooling. The mitral valve can be exposed through a left atrial incision posterior to the intraatrial septum or through a right atrial and transseptal incision (Fig. 43-3). The transseptal incision is particularly useful when there is an aortic valve prosthesis, when a mitral and tricuspid valve procedure is required or in a reoperation.

After completing the mitral valve procedure and deairing maneuvers, the aorta is vented and unclamped. Attention can be turned to the tricuspid valve during rewarming and cardiac reperfusion. Using the beating heart technique, the caval snares are tightened around the venous drainage cannula and a right atriotomy is performed to expose the tricuspid valve. Misplacement of a suture potentially adversely affecting the cardiac conduction system can be assessed immediately and corrected.

**FIGURE 43-3** (A) The superior and inferior venae cavae are cannulated, an oblique atriotomy incision is made, and stay sutures are placed on the right atrial wall to aid exposure. For transatrial exposure of the mitral valve, an incision is placed in the fossa ovale and extended superiorly through the interatrial septum. The superior aspect of the septal incision is extended, if necessary, into the dome of the left atrium behind the aorta. (B) Stay sutures in the interatrial septum are used for retraction. Use of retractors is avoided to prevent injury to the AV node. The mitral prosthesis is implanted in an anti anatomic orientation. (C) The interatrial septum is closed primarily or by using a pericardial patch with a continuous 4-0 Prolene suture.

In the reoperative setting, with a dilated RV adherent or close to the sternum, it is prudent to expose the femoral artery and vein for rapid cannulation in the case of injury to the RA or RV during sternal reentry. It is also recommended to establish fem-fem bypass prior to sternotomy to decompress the RA and RV allowing a safer sternotomy to be performed.

Approaching the tricuspid valve through a right minithoracotomy has the advantage of avoiding adhesions and possible injury to the RV during sternotomy. Femoral vein and internal jugular vein cannulae are positioned outside the right atrium and confirmed by echo. Caval snares below the cannula tips ensure venous drainage. Coronary sinus return is controlled by a sucker in its ostium.

If the operation includes the mitral valve, exposure can be simplified by using a right atrial incision and transseptal approach. If atrial fibrillation is present, a Maze procedure can be added to the technical maneuvers.

## ANNULOPLASTY TECHNIQUES

Techniques to deal with a dilated tricuspid valve annulus with normal leaflets and chordal structures include plication of the posterior leaflet's annulus (bicuspidization), partial purse-string reduction of the anterior and posterior leaflet annulus (DeVega-style techniques), and rigid or flexible rings or bands placed to reduce the annular size and achieve leaflet coaptation (Fig. 43-4). Preoperative and intraoperative echocardiograms are valuable assessment tools to help the surgeon understand the structure and function of the valve.<sup>30-34</sup>

The degree of pulmonary hypertension, right ventricular dilatation, and systolic function, coupled with the size of the right atrium, must be factored into the surgical decision-making process. The classical technique of inserting a finger via a purse-string suture, into the right atrium to palpate the

tricuspid valve and withdrawing the fingertip 2 to 3 cm from the valve orifice, so as to access the force of the regurgitant jet is of historical importance in the current era of cardiac surgery. The intraoperative transesophageal echocardiogram (TEE) allows the surgeon to access the degree of tricuspid regurgitation and look for reversal of flow in the inferior cava. Assessment of the repair with TEE under appropriate loading conditions ensures leaving the operating room with confidence that the repair is functioning satisfactorily.

Classic surgical teaching has been that in patients with minimal right atrial enlargement and +1 to +2 regurgitation, TR will resolve once left-sided valve lesions are addressed. Recent literature, however, has documented the variability in the resolution of TR after dealing effectively with the left-sided valvular lesions.

The pathologic process of fTR requires an understanding that the tricuspid annulus is a component of both the tricuspid valve and the right ventricular myocardium. For the tricuspid valve to leak, the tricuspid annulus and therefore the RV must be dilated. Without dilation of these structures, there is little chance that TR can occur.

Dilation of the tricuspid annulus occurs in the anterior and posterior directions (see Fig. 43-1B) corresponding to the free wall of the RV. In addition to tricuspid dilatation, the degree of TR is also directly related to three important factors: the preload, afterload, and right ventricular function. Thus, TR is difficult to assess accurately because these dynamic factors can interfere with the observed severity of regurgitation. Therefore, significant TR may not be detected echocardiographically despite considerable dilatation of the tricuspid valve annulus.

An understanding of these important fundamental concepts seem to contradict current practice regarding the management of secondary TR, which focuses on assessment of the severity of TR and advocates treatment of the primary lesion

**FIGURE 43-4** Predominant surgical repair techniques for functional tricuspid regurgitation (TR) in the presence of a dilated annulus. (A) Dilated tricuspid annulus with abnormal circular shape, failure of leaflet coaptation, and resultant TR. (B) Rigid or flexible annuloplasty bands are used to restore a more normal annular size and shape (ovoid), thereby reducing or eliminating TR. The open rings spare the atrioventricular node (AVN), reducing the incidence of heart block. (C) DeVega suture annuloplasty partially plicates the annulus reducing annular circumference and diameter. (D) Suture bicuspidalization is performed by placement of a mattress suture from the anteroposterior to the posteroseptal commissure along the posterior annulus. CS = Coronary sinus.

alone (ie, mitral valve disease). Treatment of the mitral valve lesion alone only reduces the RV afterload, but does not correct tricuspid annular dilatation, RV preload, and function. Once the tricuspid annulus is dilated, its size cannot return to normal spontaneously, and it may in fact continue to dilate further. This explains why some patients require a second operation for TR years after the initial mitral valve surgery. The reoperative risks in this setting are very high owing to poor myocardial function and difficulty with sternal reentry with a dilated RV.

Tricuspid annular dilatation is the primary mechanism in the development of fTR. Dreyfus and colleagues postulated that annular size may be a more reliable indicator of late outcomes than the degree of TR. Moreover, successful treatment of functional (secondary) tricuspid valve pathology may necessitate the correction of tricuspid annular dilatation in addition to mitral valve surgery even when TR is mild.

Over a 12-year period, these authors performed tricuspid valve repair for secondary tricuspid valve dilatation irrespective of the severity of TR because secondary tricuspid dilatation may or not be accompanied by TR. Tricuspid annular dilatation can be measured objectively, whereas TR can vary according to the preload, afterload, and right ventricular function.

Dreyfus and colleagues prospectively studied more than 300 patients to determine whether surgical repair of the tricuspid valve, based on tricuspid dilatation alone rather than TR, could lead to potential benefits.<sup>40</sup> Tricuspid annuloplasty was performed only if the tricuspid annular diameter was greater than twice the normal size ( $\geq 70$  mm) regardless of the grade of regurgitation. Patients in Group 1 (163 patients, 52.4%) received mitral valve repair (MVR) alone. Patients in Group 2 (148 patients, 47.6%) received MVR plus tricuspid annuloplasty. Tricuspid regurgitation increased by more than two grades in 48% of the patients in Group 1 and in only 2% of the patients in Group 2 ( $p < .001$ ).

The authors concluded that remodeling annuloplasty of the tricuspid valve based on tricuspid dilatation improved functional status irrespective of the grade of regurgitation. Considerable tricuspid dilatation can be present even in the absence of substantial TR. Tricuspid dilatation is an ongoing disease process that will, with time, lead to severe TR.<sup>40</sup>

More aggressive use of tricuspid annuloplasty appears to help improve the early postoperative course and prevent residual or progressive TR. Increasingly functional MR and TR coexist. Matsunaga and Duran analyzed TR in a group of patients who underwent successful revascularization and MVR for functional ischemic MR. They concluded that fTR is frequently associated with functional ischemic MR. After MVR, close to 50% of patients have residual TR that increases over time. The annular size may become the objective criteria, regardless of the degree of TR, to determine the need for a tricuspid annuloplasty.<sup>41</sup>

Special note should be taken in assessing the foramen ovale for patency. A patent foramen should always be sutured closed, reducing the possibility of paradoxical embolism or arterial desaturation from right-to-left shunting.

## Surgical Repair of the TV

The main surgical approaches to rectify fTR (occurring in the presence of a dilated annulus with normal leaflets and chordal structures) involve rigid or flexible annular bands (open or closed), which are used to reduce annular size and achieve leaflet coaptation, as with mitral valve disease. Another less commonly used technique involves posterior annular bicuspidalization. This surgical technique places a pledget-supported mattress suture from the anteroposterior commissure to the posteroseptal commissure along the posterior annulus. This is based on prior studies by Deloche et al.<sup>42</sup> that showed posterior annulus dilation occurs in fTR and that a focal posterior tricuspid annuloplasty can be effective in selected cases. Other approaches include edge-to-edge (Alferi-type) repairs as described by Castedo et al.<sup>43,44</sup> and partial purse-string suture techniques to reduce the anterior and posterior portions of the annulus (DeVega-style techniques; see Fig. 43-4). DeVega and flexible annuloplasty bands appear to have a lower freedom from recurrent TR than rigid annuloplasty rings.<sup>24,45-47</sup>

In the absence of simultaneous tricuspid valve repair, the prevalence of TR in the postoperative period after mitral valve surgery depends to some degree on the mechanism of MR. Matsuyama et al.<sup>48</sup> reported in a study of 174 patients that only 16% of patients who underwent nonischemic (ie, degenerative) mitral valve surgery without tricuspid valve surgery developed 3 to 4+ TR at 8-year follow-up. Conversely, TR appears to be far more prevalent in patients undergoing MVR for functional ischemic MR. In the series by Matsunaga et al.<sup>49</sup> 30% of patients undergoing MVR for functional ischemic MR had at least moderate TR before surgery. In the postoperative period, the prevalence of at least moderate TR increased over time, from 25% at less than 1 year, 53% at 1 to 3 years, and 74% at greater than 3 years of follow-up.

Significant residual tricuspid valve insufficiency contributes to a poor postoperative result, even after successful MVR. King et al.<sup>50</sup> studied patients requiring subsequent tricuspid valve surgery after mitral valve surgery. They had high early and late mortality. The authors encouraged a policy of liberal use of tricuspid annuloplasty at initial mitral valve surgery. Surgical series have shown that successful tricuspid valve repair (primarily when combined with other valve surgeries) resulted in a significant improvement in recurrent TR, survival, and event-free survival. Accordingly, 50 to 67% of patients undergoing surgery for mitral valve disease have been reported to undergo concomitant surgical tricuspid valve repair or replacement (although this may approach 80% in some dedicated centers).<sup>45,51,52</sup>

## Specific Techniques

### BICUSPIDIZATION

After the caval snares are tightened, the right atrium is opened via an oblique incision. Exposure and assessment of all aspects of the tricuspid valve structure should be performed before choosing the technique of annuloplasty. Suture plication to

**FIGURE 43-5** (A) Tricuspid valve bicuspidization is accomplished by plicating the annulus along the posterior leaflet. Two concentric, pledgeted 2-0 Ethibond sutures are used. (B) The sutures are tied, obliterating the posterior leaflet, effectively creating a bicuspid AV valve. Saline is injected into the RV to test the competency of the repair. (C) As an option to support the bicuspidization repair, a flexible ring may be placed. Prior to ring implantation, measuring the intertrigonal distance determines the annular size. As an option, the ring can be inserted using a continuous 4-0 Prolene suture. Care is taken to avoid the AV node. (D) As another option, the ring can be implanted above the coronary sinus.

deal with mild dilatation of the annulus is accomplished by placing pledgeted mattress sutures from the center of the posterior leaflet to the commissure between the septal and posterior leaflets. A second suture often is necessary to further reduce the annulus, ensuring proper leaflet coaptation while providing an adequate orifice for flow. An annuloplasty ring can be inserted to further support the annular reduction (Fig. 43-5).

#### DeVega TECHNIQUE

The DeVega technique also can be employed for mild-to-moderate annular dilatation.<sup>53</sup> This technique employs a 2-0 Prolene, Gortex, or Dacron polyester suture placed at the junction of the annulus and right ventricular free wall,

running from the antero-septal commissure to the postero-septal commissure. The second limb of the suture is placed through a pledget and run parallel and close to the first suture line in the same clockwise direction, placing it through a second pledget at the postero-septal commissure. The suture is tightened, producing a purse-string effect and reducing the length of the anterior and posterior annulus to provide adequate leaflet coaptation and orifice of flow (Fig. 43-6).

The judgment regarding the degree of annular reduction has varied from the guideline of being able to insert two and one-half to three fingerbreadths snugly through the valve orifice to using the ring annuloplasty sizers designed for the tricuspid valve. An annuloplasty sizer, chosen by measuring the intertrigonal distance, can be used as a template while tying the pursestring suture to achieve the proper degree

**FIGURE 43-6** (A) A modified DeVega annuloplasty technique is shown. A single pledgeted 2-0 Prolene suture is placed. Care is taken to avoid the area of the AV node. (B) The suture is tied, completing the annuloplasty. Injecting saline into the RV using a bulb syringe and compressing the pulmonary artery tests the valve for competency.

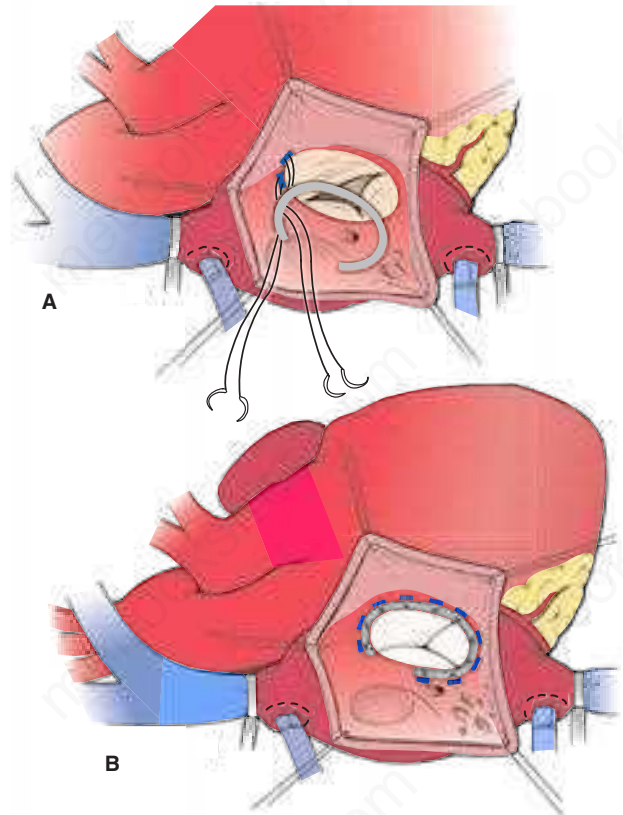

of reduction. The DeVega and suture plication techniques should be reserved for mild annular reductions and situations in which the structural integrity of the annulus is not absolutely necessary for long-term success (ie, fTR expected to resolve over time). In these situations, the annuloplasty provides a competent tricuspid valve during the early postoperative course while the heart remodels after surgical treatment of the left-sided valvular lesions.<sup>54-56</sup>

### RINGS AND BANDS

Significant degrees of annular reduction requiring durability are best accomplished with rigid rings (eg, Carpentier-Edwards and MC3), flexible rings (eg, Duran), or flexible bands (eg, Cosgrove annuloplasty system, and Medtronic Tri-Ad Adams annuloplasty ring). The length of the base of the septal leaflet (ie, the intertrigonal distance) determines the size of the ring or band. These devices avoid suture placement in the region of the atrioventricular (AV) node (apex of the triangle of Koch) to avoid postoperative conduction problems. The mattress sutures are placed circumferentially, with wider bites on the annulus and smaller corresponding bites through the fabric of the ring or band, producing annular plication mostly along the length of the posterior leaflet. The

result allows the tricuspid valve orifice to be occluded primarily by the leaflet tissue of the anterior and septal leaflets. Overly aggressive annular reduction can lead to ring dehiscence owing to excessive tension on the tenuous tricuspid valve annular tissue<sup>57,58</sup> (Fig. 43-7).

A recent review of a 790-patient series for the durability and risk factors for failure of a repair was reported by McCarthy and colleagues.<sup>59</sup> The authors reported that TR one week after annuloplasty was 3+ or 4+ in 14% of patients. Regurgitation severity remained stable over time with the Carpentier-Edwards ring ( $p = .7$ ), increased slowly with the Cosgrove-Edwards band ( $p = .05$ ), and rose more rapidly with the DeVega ( $p = .002$ ) and Peri-Guard ( $p = .0009$ ) procedures. Risk factors for worsening regurgitation included higher preoperative regurgitation grade, poor left ventricular function, permanent pacemaker, and repair type other than ring annuloplasty. Right ventricular systolic pressure, ring size, preoperative New York Heart Association (NYHA) functional class, and concomitant surgery were not risk factors. Tricuspid reoperation was rare (3% at 8 years), and hospital mortality after reoperation was 37%. The authors concluded that tricuspid valve annuloplasty did not consistently eliminate functional regurgitation, and over time, regurgitation increased importantly after Peri-Guard and DeVega

**FIGURE 43-7** (A) The Carpentier-Edwards ring annuloplasty is shown. A sizer measuring the intertrigonal distance was used to determine the ring size. Multiple interrupted, pledgeted 2-0 Ethibond sutures are placed at the atrioannular junction. All sutures are inserted before seating the ring. (B) The valve is seated and the sutures are tied.

annuloplasty techniques. Therefore, these repair techniques should generally be abandoned and transtricuspid pacing leads be replaced with epicardial ones.

## INTRAOPERATIVE ASSESSMENT OF THE REPAIR

Assessment of tricuspid valve competence after the annuloplasty requires filling the RV with saline and observing leaflet coaptation. This assessment is best performed with the heart beating and the pulmonary artery occluded to allow right ventricular volume to generate enough intracavitary pressure to close the tricuspid valve tightly. If the result appears inadequate, downsizing the ring or ring replacement should be performed. Final assessment is by TEE examination after completely weaning from cardiopulmonary bypass with appropriate volume and afterload adjustment.

## TRICUSPID VALVE REPLACEMENT

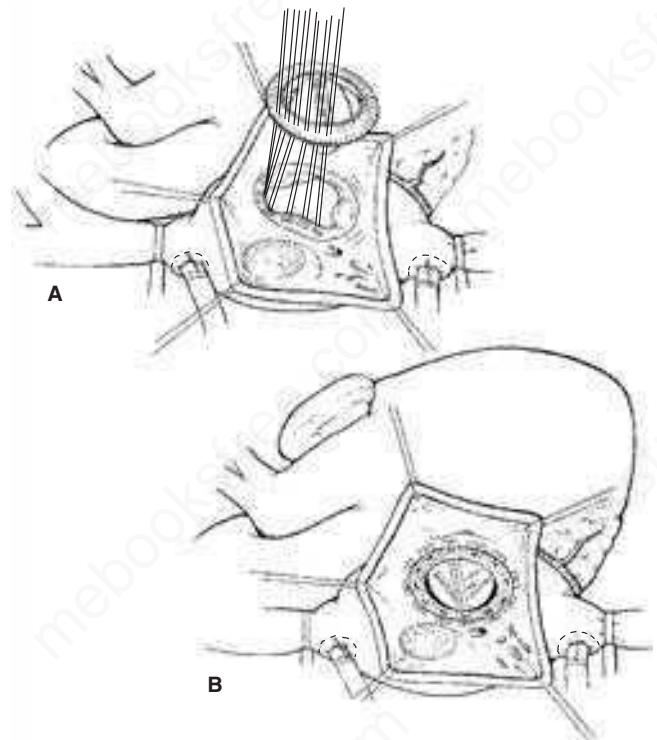

The technique for secure fixation of a tricuspid valve is with pledgeted mattress sutures using an everting suture technique for mechanical valves and either a supra-annular or an intraannular technique for a bioprosthesis. The tricuspid valve septal and posterior leaflets are left in place, preserving the subvalvular structures and helping to avoid injury to the conduction system (Fig. 43-8). Often there is concern that the anterior leaflet could billow and obstruct the right ventricular outflow tract. The central portion of the leaflet can be excised and still preserve the chordal attachments.

Tricuspid valve replacement with a homograft is more complex. Homograft tissue consists of cadaveric mitral valve apparatus.<sup>60-62</sup> Sizing is performed by measuring the intratriangular distances. Fixation of the papillary muscles is either intracavity (RV) or through the wall of the RV. This requires judgment and experience to gauge proper chordal length. The annulus is run with a monofilament suture-line. An annuloplasty ring is inserted to prevent dilatation and ensure adequate leaflet coaptation.

Special care is necessary in suture placement to avoid conduction disturbances. Suture placement and tying with the heart beating allow for immediate detection of rhythm disturbances. Similar to mitral valve replacement, leaflet and chordal preservation should be performed, or Gore-Tex suture should be used as artificial chordae to maintain annular papillary muscle continuity.

A recent report documented the use of a stentless porcine valve in endocarditis in which the commissural posts were anchored to the right ventricular septal, anterior, and posterior walls. Orientation is critical to be sure that the right ventricular outflow tract is straddled by two of the commissural posts.<sup>63</sup> Low profile mitral bioprosthesis should be chosen.

Carpentier techniques for MVR can be applied to the tricuspid valve. Traumatic disruptions, occasionally endocarditis with healed lesions and perforations, or the rare myxomatous valve can be repaired. Pericardial patching of perforations, partial leaflet resections of the anterior (limited)

**FIGURE 43-8** (A) Tricuspid valve replacement is performed with a St. Jude Medical valve. The native leaflets are left in situ, and the pledgeted 2-0 Ethibond sutures are passed through the annulus and the edges of the leaflets. (B) The valve is seated, and the sutures are tied. The subvalvular apparatus is visualized to ensure that there is no impingement of the prosthetic valve leaflets. The valve can be rotated if necessary to prevent leaflet contact with tissue.

or posterior (extensive) leaflets, chordal transfer, artificial Gore-Tex chordae, Alfieri suture and ring annuloplasty are standard techniques used to produce competent valves and avoid replacement.<sup>64-66</sup>

## ENDOCARDITIS

In extensive infections, total excision of the tricuspid valve is possible if pulmonary pressures and the pulmonary vascular resistance are not elevated.<sup>66-68</sup> Blood flows passively through the right side of the heart to the lungs. After eradication of the infection, a second-stage procedure with valve replacement can be performed months to years later.

In patients with tricuspid valve endocarditis due to intravenous drug use, the second-stage valve insertion should be performed preferably after controlling the drug dependence or curing the accompanying addiction. Late survival and reinfection are correlated directly with continued drug use. Patients with less severe endocarditis can have one-stage procedures with prosthetic replacement or localized leaflet excision and repair.<sup>69,70</sup> Homograft tissue often is versatile for partial or total tricuspid valve repair or replacement but has the limitations of availability, technical difficulty, and limited follow-up. The stentless aortic porcine valve is a novel option.<sup>63,64</sup>

## PROSTHETIC VALVE CHOICE

The choice of prosthesis follows an algorithm similar to that used for valve replacement in other cardiac valve positions. The patient's age, anticoagulation considerations, childbearing wishes, and social issues are all factors in valve choice. The previously reported poor results with mechanical valves in the tricuspid position were mainly due to valve thrombosis. Most of these reports were during the era of cage-ball and tilting-disk prostheses.<sup>71</sup> Reports with the St. Jude bileaflet valve have provided encouraging data, allowing the surgeon to recommend a mechanical valve with confidence to younger patients who do not have a contraindication to anticoagulation.<sup>72-78</sup>

This strategy will avoid the not uncommon situation in the past in which patients received a bioprosthetic on the right side and a mechanical prosthesis on the left. Bioprostheses, both porcine and of pericardial tissue, have functioned well in the tricuspid position.<sup>79-82</sup> Compared to the mitral position, bioprosthetic valves in the tricuspid position exhibit longer durability with a longer duration of freedom from structural valve dysfunction.<sup>83</sup>

Table 43-2 summarizes multiple reports from the literature. The reports either compare bioprosthetic and mechanical valves in the tricuspid position or present follow-up of bioprosthetic valves alone. The bioprostheses, either porcine or pericardial valves, have excellent freedom from degeneration and re-replacement for structural valve degeneration. In 1984, Cohen and colleagues reported on six simultaneously implanted and then explanted valves from the mitral and tricuspid positions. Degenerative changes were less extensive for the bioprosthetic valves in the tricuspid position than in the mitral position. However, thrombus and pannus formation (interpreted as organized thrombotic material) were observed more frequently in the tricuspid position.<sup>83</sup>

At 9 years, Nakano's review of the Carpentier-Edwards bovine pericardial valve reported a freedom from structural degeneration of 100% and nonstructural dysfunction of 72.8%.<sup>81</sup> The cause of nonstructural dysfunction was pannus formation on the ventricular side of the cusps. Often subclinical, echocardiographic follow-up after 5 years reveals up to a 35% incidence of this anatomical finding.

Guerra reported similar changes in simultaneously explanted porcine valves.<sup>84</sup> The tricuspid position had less structural tissue degeneration and calcification than the mitral position. The report described the presence of pannus on the ventricular side of the cusps and interference with cusp pliability and function.

Nakano's 2001 report of bioprosthetic tricuspid valves reported an 18-year freedom from reoperation of 63%.<sup>80</sup> Freedom from structural deterioration was 96%, and nonstructural dysfunction was 77%. Reoperation, replacing previously placed bioprosthetic valves occurred in 12 of 58 survivors. In 6 of the 12 patients, the primary indication for reoperation was tricuspid dysfunction, and 7 of the 12 had pannus formation on the ventricular side of the cusps (Fig. 43-9). This rate of degeneration and the subclinically

high incidence of pannus formation, often eventually leading to reoperation, are concerning.

Bioprosthetic valves in the tricuspid position require close echocardiographic follow-up. Possible anticoagulation of bioprosthetic valves in the tricuspid position can reduce the incidence of pannus formation. The reported data in the literature categorize pannus formation as nonstructural degeneration; therefore, clinical surgeons should be aware of future reports following this potentially serious clinical problem.

It is always possible to place large bioprosthetic or mechanical valves in the tricuspid position. Prostheses with more than a 27-mm internal diameter do not have clinically significant gradients. Therefore, hemodynamic performance is rarely an issue for tricuspid valve replacement. The data demonstrate excellent results with modern bileaflet mechanical valves. Series comparing bioprosthetic and mechanical valves have been consistent in demonstrating equality during the period of follow-up. The development of thrombus on a bileaflet valve can be treated successfully with thrombolysis.

A recent review by Filsoufi and a meta-analysis of biologic or mechanical prostheses in the tricuspid position both conclude that there is no survival benefit of a bioprosthesis over a mechanical valve<sup>85-87</sup> (Fig. 43-10). Some patients with mitral valve disease and TR undergoing surgery do not require surgical treatment of the tricuspid valve. Guidelines to identify these patients are poorly developed. Experience has shown that careful observation of the patient preoperatively is quite valuable. Absence of tricuspid valve regurgitation during periods of good medical control, absence of TR by TEE at the time of operation, minimal elevation of pulmonary vascular resistance, and absence of right atrial enlargement are helpful findings that permit the surgeon to replace the mitral valve confidently without performing an annuloplasty or replacement of the tricuspid valve. If unrepaired, reassessment of the tricuspid valve by TEE after weaning from cardiopulmonary bypass is essential. TEE assessment of residual TR under anesthesia can be misleading if the loading conditions are different from the conditions in an awoken patient.

If TR persists and elevated right atrial pressures greater than left atrial pressures are encountered with an underfilled, well-contracting left ventricle, tricuspid repair should be performed. A patent foramen ovale with interatrial shunting must be identified and closed surgically. Hemodynamically, when right atrial pressure is greater than left atrial pressure, the foramen may open, leading to systemic desaturation from a right-to-left shunt.

Temporary right ventricular dysfunction caused by RCA air embolism often requires a brief return to cardiopulmonary bypass, repeat of deairing maneuvers, elevation of the systemic blood pressures, TEE evaluation for residual intracavity air, and a search for the characteristic echogenic brightness in the myocardial distribution of the RCA confirming the suspicion of air embolism. Treatment should include 10 to 15 minutes of cardiopulmonary bypass support and reweaning from cardiopulmonary bypass, with inotropic support, elevated blood pressure, and reassessment of the TR and cardiac function.

(Reproduced with permission from Nakano K, Ishibashi-Ueda H, Kobayashi J, et al: Tricuspid valve replacement with bioprostheses: long-term results and causes of valve dysfunction, *Ann Thorac Surg.* 2001 Jan;71(1):105-9.)

Bioprosthetic valves have the safety feature of not developing thrombosis or requiring anticoagulation. Bioprostheses are being considered in younger patients since percutaneous valve in valve treatment for structural deterioration is being performed with excellent results. When choosing the size of the bioprostheses, it is important to consider the size of the valve to insure the percutaneous valve-in-valve option is feasible.

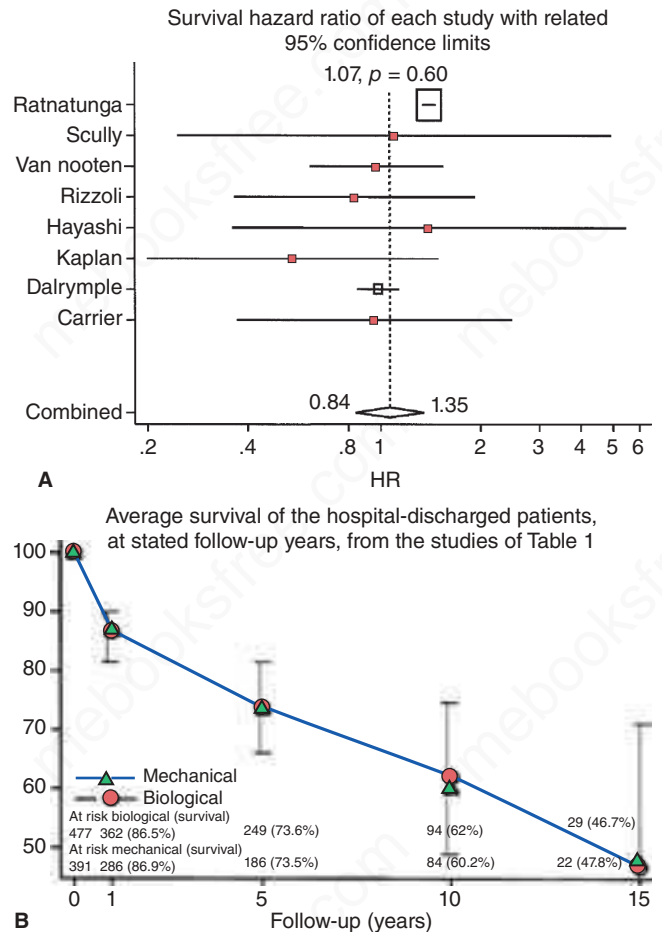

**CONCLUSION**

Historical clinical experience has demonstrated that up to 20% of patients undergoing mitral valve replacement receive a tricuspid annuloplasty, but less than 2% require replacement. Traditionally, the surgeon’s clinical judgment and experience have guided the approach to tricuspid surgery, ultimately leading to variability in reported clinical data. The accuracy of these decisions can be enhanced by assessment of risk factors for persistent or progressive tricuspid valve regurgitation. Recent studies have taught us that our ability to make these judgments is flawed and unpredictable.

We have learned about the dilated tricuspid valve annulus, the progression of TR in spite of successful left-sided surgery, and the unpredictable resolution of pulmonary hypertension. Failure to improve can have adverse impacts on late morbidity, mortality, and residual or progressive TR. Therefore, the current recommendation is to pursue aggressively tricuspid annuloplasty with remodeling rings or bands.

Older studies showed patients undergoing a tricuspid valve annuloplasty during a mitral valve replacement have more advanced disease than those having mitral valve replacement alone. This is evidenced by the elevation in operative mortality (approximately 12 vs 3%) and the progressive increased hazard of late death (5-year survival of 80 vs 70%) despite good valve function. However, these patients achieved good functional results (NYHA Class 1-2). It is unknown what the survival and functional result would have been if tricuspid repair had not been performed in these patients, but one presumes that it would have been worse. In the current era, adding an annuloplasty can have minimal adverse impact in the perioperative period and seems to confer long-term benefit.

The durability of simple annuloplasty techniques such as bicuspidization and the DeVega technique has been

**FIGURE 43-10** Meta-analysis of bioprosthetic vs mechanical valves replacing the tricuspid valve. (A) Survival hazard. (B) Survival curve of hospital survivors.

satisfactory when employed only for mild-to-moderate degrees of fTR with successful resolution of pulmonary hypertension after the mitral valve operation. Extensive experience with the tricuspid annuloplasty using the Duran, Carpentier-Edwards, and MC<sup>3</sup> rings or bands have resulted in an 85% freedom from moderate-to-severe TR at 6 years. The subsequent requirement for tricuspid reoperation is very low. Inadequate resolution of the mitral disease and persistent pulmonary hypertension with right ventricular dilatation and dysfunction are the major predictors of poor late results.

The American College of Cardiology/American Heart Association 2014 Practice Guidelines for the surgical management of patients with TR (Table 43-3)<sup>88</sup> are driven by the individual patient's clinical status and the cause of their tricuspid valve abnormality. The guidelines state that the timing of surgical intervention for TR remains controversial, as do the surgical techniques. At present, surgery on the tricuspid valve for significant TR should occur at the time of mitral valve surgery, as TR does not reliably resolve after mitral valve surgery. TR associated with dilatation of the tricuspid annulus should be repaired, to prevent tricuspid annular dilation progressing and producing severe TR.<sup>89-96</sup>

Patients requiring tricuspid and mitral valve replacement have operative mortalities from 5 to 10% by current standards. Actuarial survival rates are 55% at 10 years (Fig. 43-10A, B). Advanced right ventricular failure or arrhythmia causes late death. Patients who need valve replacement for endocarditis comprise a unique subgroup with the additional risk for

death owing to sepsis, reinfection, and the complications related to drug addiction.

Complete heart block can occur immediately postoperatively owing to damage to the conduction system during mitral and tricuspid valve surgery. This complication can be minimized intraoperatively by performing the tricuspid valve procedure on the perfused beating heart, as described earlier. Late heart block remains a persistent risk with a 25% actuarial incidence at 10 years for patients with mitral and tricuspid prostheses. The presence of two rigid prosthetic sewing rings can produce ongoing trauma and lead to AV node dysfunction over time. Late development of heart block rarely occurs after mitral valve replacement and tricuspid annuloplasty.

The surgical treatment of tricuspid valve disease presents the surgeon with challenges requiring clinical and intraoperative judgment. Following the principles presented in this chapter, appropriate decisions should lead to optimal clinical outcomes. The data support the safe use of mechanical bileaflet prostheses in select patients. A lingering concern is the pannus formation on the ventricular side of bioprosthetic cusps. This observation should be followed closely as future clinical series are reported.

Many surgeons prefer bioprosthetic valves. More recently, with percutaneous valve in valve re-replacement strategies for degenerated stented bioprostheses, this option should gain increasing safety. It is important to know the valve internal diameter to be sure a valve-in-valve option will be available for the patient.

### TABLE 43-3: 2014 ACC/AHA Guidelines Pertaining to the Surgical Management of Tricuspid Value Disease/Regurgitation

#### Class I

Tricuspid valve repair is beneficial for severe TR in patients MV disease requiring MV surgery. (*Level of evidence: B*)

#### Class IIa

1. Tricuspid valve replacement or annuloplasty is reasonable for severe primary TR when symptomatic. (*Level of evidence: C*)
2. Tricuspid valve replacement is reasonable for severe TR secondary to disease/abnormal tricuspid value leaflets not amenable to annuloplasty or repair. (*Level of evidence: C*)

#### Class IIb

Tricuspid annuloplasty may be considered for less than severe TR in patients undergoing MV surgery when there is pulmonary hypertension or tricuspid annular dilatation. (*Level of evidence: C*)

#### Class III

1. Tricuspid valve replacement or annuloplasty is not indicated in asymptomatic patients with TR whose pulmonary artery systolic pressure is less than 60 mm Hg in the pressure of a normal MV. (*Level of evidence: C*)
2. Tricuspid valve replacement or annuloplasty is not indicated in patients with mild primary TR. (*Level of evidence: C*)

ACC, indicates American College of Cardiology; AHA, American Heart Association; TR, tricuspid regurgitation; and MV, mitral valve.

# Multiple Valve Disease

Hartzell V. Schaff • Rakesh M. Suri

Pathologic changes in the cardiac valves requiring surgical correction of more than one valve can result from rheumatic heart disease, degenerative valve diseases, infective endocarditis, and a number of other miscellaneous causes. Further, valve dysfunction may be primary; that is, a direct result of a disease process, or secondary; that is, caused by cardiac enlargement and/or pulmonary hypertension. Surgical management is influenced both by the underlying cause of valve dysfunction and, when valves are involved secondarily, by the anticipated response to replacement or repair of the primary valve lesion. In addition, the consequences of various combinations of diseased valves on left and right ventricular geometry and function frequently are different from the remodeling as a result of single-valve disease. This chapter addresses pathophysiologic considerations in multivalvular heart disease, surgical techniques, and management of commonly encountered etiologies.

Repair of multiple lesions was necessary even in the early development of operative management of valvular heart disease (Table 44-1). The first triple-valve replacement during a single operation was reported in 1960, and simultaneous replacement of all four valves was reported in 1992.<sup>1</sup>

Experience from clinical practice indicates that multiple valve disease requiring surgical correction occurs in a few common combinations. As seen in Table 44-2, multiple procedures account for approximately 15% of all operations on cardiac valves; 80% of these operations involve the aortic and mitral positions. Replacement of the mitral and tricuspid valves (with or without aortic replacement) accounts for 20% of operations. Only rarely is the combination of aortic and tricuspid disease encountered.

## PATHOPHYSIOLOGY OF MULTIPLE VALVE DISEASE

Valvular regurgitation may result from the pathologic process affecting the valve directly or may be secondary to alterations in ventricular morphology caused by other valve lesions; this

secondary or functional regurgitation affects the atrioventricular valves. In some patients, secondary valvular regurgitation may be expected to improve with repair or replacement of the primarily diseased valve. In other patients, the secondary disease process may have advanced to the stage that valve function will not improve following correction of the primary lesion, and thus simultaneous surgical correction should be considered.

## Primary Aortic Valve Disease with Secondary Mitral Regurgitation

Isolated aortic valve lesions can cause secondary regurgitation of the mitral valve and rarely, the tricuspid valve. Severe aortic valve stenosis with or without left ventricular dilatation frequently is associated with some degree of mitral valve regurgitation. In one series, 67% of patients with severe aortic valve stenosis had associated mitral valve leakage.<sup>2</sup> When the mitral valve is structurally normal, its regurgitation would be expected to improve with relief of left ventricular outflow obstruction;<sup>4</sup> mild mitral valve regurgitation may, at times resolve almost completely after aortic valve replacement. Improvement in mitral valve regurgitation results from both decreased undergoing intraventricular pressure and ventricular remodeling.<sup>5</sup> If mitral valve regurgitation is severe, some degree of persistent regurgitation is expected after aortic valve replacement, and mitral valve annuloplasty may be required. In contrast, with aortic valve stenosis and mitral valve regurgitation associated with a structurally abnormal mitral valve, repair or replacement of the mitral valve usually is necessary. A recent report alleges that moderate MR has an adverse impact on survival in elderly patients undergoing aortic valve replacement and suggests that those with intrinsic mitral valve disease should be considered for concurrent correction.<sup>6</sup>

Thus determination of the morphology and pathophysiologic severity of each valve lesion is critically important in planning surgical management, and preoperative and

intraoperative echocardiographic studies are necessary in all patients suspected of having multiple valve disease. Often, transthoracic echocardiography can define the etiology of mitral and tricuspid valvular regurgitation. When valve regurgitation is entirely secondary, the mitral valve leaflets will appear thin and freely mobile, without prolapsing segments. Mitral (and tricuspid) valve regurgitation secondary to rheumatic disease is readily identified when leaflets are thickened and chordae are shortened; fibrosis of these structures restricts leaflet mobility. Leaflet prolapse with or without ruptured chordae tendineae also may cause atrioventricular valve regurgitation.

Transesophageal echocardiography images the heart from a retrocardiac position, which avoids interference from interposed ribs, lungs, and subcutaneous tissue. A high-frequency (5-MHz) transducer is employed, which yields better resolution than that of images obtained with routine transthoracic imaging with 2.25- to 3.5-MHz transducers.<sup>7</sup> Thus transesophageal echocardiography provides the best image of the mitral and tricuspid valves and may be obtained preoperatively. Intraoperative transesophageal Doppler echocardiography should be employed in all patients having valve repair or replacement, and the technique is especially important for assessment of response of MR to relief of left ventricular outflow obstruction.<sup>8</sup> In some cases, preoperative left ventriculography may help to quantify left atrioventricular valve leakage. Right ventricular angiocardiography also can be useful in determining the degree of tricuspid valve dysfunction, but it is rarely employed in current practice.<sup>9</sup>

### Tricuspid Valve Regurgitation Secondary to Other Valvular Disease

Secondary tricuspid valve regurgitation commonly is associated with rheumatic mitral valve stenosis, and the exact cause is unknown.<sup>10,11</sup> Some authors believe that secondary tricuspid valve regurgitation is a result of pulmonary artery hypertension and right ventricular dilatation.<sup>12</sup> As with the mitral valve, tricuspid valve annular dilatation in those with severe TR is asymmetric. Most enlargement occurs in the annulus subtended by the free wall of the right ventricle, and there is little dilation of the annulus adjacent to the septal leaflet of the tricuspid valve.<sup>13,14</sup> Although pulmonary artery hypertension with secondary enlargement of the right ventricle and tricuspid valve annulus may be an important contributing factor in secondary tricuspid regurgitation (TR), it is not the sole mechanism. For example, congenital heart lesions such as tetralogy of Fallot produce

systemic pressure in the right ventricle, yet severe tricuspid valve regurgitation rarely is seen in these patients. Similarly, important tricuspid valve regurgitation is uncommon in children with ventricular septal defects who have enlargement of the right ventricle associated with variable degrees of pulmonary hypertension.

Furthermore, clinical experience suggests that other mechanisms must play a role in development of secondary tricuspid valve regurgitation. Patients who have had mitral valve replacement for rheumatic mitral valve stenosis may develop regurgitation of their native tricuspid valve years after initial operation, and many patients have only modest elevation of pulmonary artery pressure.<sup>15,16</sup> Recent evidence points to a progressive immunologic process in rheumatic valve disease, which can lead to severe TR many years after successful percutaneous or surgical management of the mitral valve.<sup>17</sup>

It is useful to classify secondary mitral and tricuspid valve regurgitation as mild, moderate, and severe.<sup>14</sup> Usually, patients with mild tricuspid valve regurgitation do not have clinical signs and symptoms of right-sided heart failure. Also, mild TR demonstrated by preoperative echocardiography may appear even less severe in the operating room under general anesthesia. In most instances, mild secondary TR does not require intervention.

Patients with echocardiographic evidence of significant regurgitation who do not have symptoms or have their symptoms controlled by medical treatment are managed with a DeVega suture annuloplasty or a partial-ring annuloplasty.<sup>18</sup> Patients with severe secondary TR and clinical evidence of right-sided heart failure (eg, pulsatile liver, distended neck veins, and peripheral edema with or without ascites) are most frequently managed by concomitant ring annuloplasty or tricuspid valve replacement.<sup>19</sup>

The degree of pulmonary hypertension may influence surgical management of secondary tricuspid valve regurgitation. Kaul et al<sup>20</sup> grouped 86 patients with functional TR in association with rheumatic mitral valve disease according to the degree of pulmonary hypertension. One group had severe pulmonary hypertension (mean pulmonary pressure 78 mm Hg), and a second group had moderate pulmonary hypertension (mean pulmonary artery pressure 41 mm Hg). Patients with moderate pulmonary hypertension preoperatively had more advanced right-sided heart failure and right ventricular dilatation, and many of these patients continued to have tricuspid valve regurgitation following mitral valve surgery without tricuspid valve surgery. The patients with severe pulmonary hypertension all showed regression of TR, and 28% had complete resolution following mitral valve surgery without operation on the tricuspid valve.

The difficulty with interpretation and generalization of current literature guiding management of secondary functional TR is the significant heterogeneity in both patient disease substrate and surgical procedure performed. The incidence of severe late TR has been reported to be approximately 68% up to 30 years following mitral replacement for rheumatic disease.<sup>21</sup> The risk of significant late secondary TR is as high as

74% 3 years following repair of ischemic MR.<sup>22</sup> The most frequently identified risk factors for TR progression from these series include older age, female gender, rheumatic etiology, atrial fibrillation, the absence of a Maze operation.<sup>21-24</sup> Therefore, most would agree that correction of moderate or greater TR at the time of surgery for rheumatic mitral disease is indicated to prevent the development of symptoms associated with TR progression.<sup>25</sup> Less clear however is whether long-term survival is improved by such intervention.<sup>24</sup> Recent evidence suggests that remodeling annuloplasty in the patients with tricuspid annular dilatation ( $\geq 70$  mm) at the time of mitral repair significantly decreases the risk of subsequent functional deterioration compared with those having tricuspid valve repair.<sup>26</sup> Furthermore, reliance on tricuspid annular dilation alone as suggested by Dreyfus et al<sup>26</sup> has recently been challenged.<sup>27</sup>

In contrast, although mitral valve prolapse is the most frequent cause of MR in the developed world, there are few reports addressing the incidence and fate of functional TR following successful mitral valve repair. Recent data suggest that moderate or less functional TR does not progress as aggressively following repair of leaflet prolapse as in rheumatic or ischemic mitral disease subsets.<sup>28,29</sup> Outcomes following isolated mitral valve repair or replacement for degenerative MR with less than severe coexistent functional TR at Mayo Clinic support the notion that risk of TR progression is low after MVr or MVR for MV prolapse. The authors recommend timely MV surgery before the development of left atrial dilatation or pulmonary hypertension, which would be expected to decrease the risk of TR progression during follow-up. Current indications for concomitant tricuspid valve repair under these circumstances include: (1) moderately severe or severe TR, (2) right-sided heart failure symptoms with moderate or severe TR, (3) moderate TR with one of the followings: primary tricuspid valve disease, structural abnormalities of the tricuspid valve (including impingement of the tricuspid leaflets by pacemaker leads), a dilated right atrium and right ventricle, severe pulmonary hypertension, or atrial fibrillation.<sup>19</sup>

A long-term outcome study of the prognostic impact of isolated TR confirmed that the presence of a mild-to-moderate isolated TR was not associated with a survival difference in comparison to those with trivial regurgitation, even after multivariable adjustment ( $p = .34$ ).<sup>30</sup> (In summary, asymptomatic, less-than-moderate functional TR associated with degenerative mitral valve disease is unlikely to progress or impact survival following successful mitral valve repair.)

## VALVE SELECTION FOR MULTIPLE VALVE REPLACEMENT

When multiple valve replacement is confined to the left ventricle, replacement valves are generally chosen from the same class with respect to the need for anticoagulation and projected longevity. There are no theoretical or practical advantages to use of a tissue valve and a mechanical valve for mitral and aortic valve replacement, and studies show no reduction in the risk of thromboembolism, valve-related morbidity, or late death.<sup>31,32</sup>

In addition, a lower reoperation rate is reported for patients with two mechanical valves in the left ventricle compared with patients with one mechanical and one tissue valve.<sup>31</sup>

For tricuspid valve replacement, alone or in conjunction with other valve procedures, use of a bioprosthesis may have advantages in regard to minimizing risk of valve thrombosis.<sup>33,34</sup> Furthermore, there are few hemodynamic considerations in selecting a tricuspid prosthesis; the greater hemodynamic efficiency of mechanical valves compared with bioprostheses rarely is an issue in atrioventricular valve replacement, especially the tricuspid valve, in which the annulus diameter in adults is often 33 mm or more. In vitro studies demonstrate only minimal hemodynamic improvement with atrioventricular valves larger than 25 mm.<sup>35</sup>

## SURGICAL METHODS

### Aortic and Mitral Valve Replacement

#### CANNULATION

Arterial inflow is established by cannulation of the distal ascending aorta near the pericardial reflection just to the left of the origin of the innominate artery (Fig. 44-1A). Venous cannulation is simplified by using a two-stage cannula in the right atrium for venous return. Individual cannulation of the superior and inferior venae cavae is reserved for operations that require right atrial or ventricular incisions (Fig. 44-2A). Provisions for intraoperative autotransfusion are used routinely, and antifibrinolytic drugs such as aprotinin or epsilon-aminocaproic acid (Amicar) may be useful, especially in reoperations, in which pericardial adhesions may worsen bleeding.<sup>36</sup>

#### CARDIOPLEGIA

If the aortic valve is competent, myocardial protection during aortic cross-clamping is achieved by initial infusion of cold (4 to 8°C) blood cardioplegia through a tack vent placed in the aorta proximal to the clamp. The volume of cardioplegia needed to achieve diastolic arrest and uniform hypothermia depends on the heart size and the presence of aortic valve regurgitation. Generally, the initial volume of cardioplegia required for hearts with multiple valve disease is higher than that required for coronary revascularization because of myocardial hypertrophy. For patients without cardiac enlargement, we infuse approximately 10 mL/kg of body weight, whereas 15 mL/kg of body weight is used for patients with significant degrees of myocardial hypertrophy. Repeat infusions of 400 mL of cardioplegia are given directly into the coronary ostia at 20-minute intervals during aortic occlusion. We use custom-designed, soft-tipped coronary perfusion catheters to minimize the potential for trauma to the coronary ostia during intubation and infusion.<sup>37</sup>

If aortic valve regurgitation is moderate or severe, cardioplegia is infused directly into the coronary ostia. Initial aortotomy is facilitated by emptying the heart using suction on an aortic tack vent and temporarily reducing the cardiopulmonary bypass flow rate to maximize

venous return. Some surgeons prefer retrograde infusion of cardioplegia,<sup>38</sup> and if this method is used, even larger volumes are necessary because of non-nutritive flow through the coronary venous system and variation in coronary venous anatomy.<sup>39,40</sup>

#### PROCEDURE

After cardioplegia, the aortic valve is inspected through an oblique aortotomy extended into the noncoronary aortic sinus (see Fig. 44-1B). Aortic valve regurgitation caused by cuspal perforation or prolapse of a congenitally bicuspid valve often can be repaired,<sup>41</sup> but the decision for or against aortic valve repair should take into consideration whether or not a mitral valve prosthesis will be needed. For example, even though aortic valve repair might seem technically possible, prosthetic replacement may be the best option for a patient who requires mitral valve replacement and will be maintained on warfarin for long-term anticoagulation.

Severe calcification of the valve, whether it is bicuspid or tricuspid, necessitates replacement;<sup>42</sup> therefore, the cusps are excised and annular calcium debrided carefully. The aortic annulus then is calibrated; experience has shown that subsequent replacement of the mitral valve usually reduces the aortic annular diameter by shortening the circumference that is in continuity with the attachment of the anterior mitral valve leaflet. Therefore, we routinely identify (but do not break the sterile packaging of) two aortic prostheses: one corresponds to the calibrated dimension, and the other is the next size smaller. Final selection of the aortic prosthesis is made after mitral valve replacement or repair.

Although exposed first, the aortic valve usually is replaced after mitral valve repair or insertion of the mitral valve prosthesis. Sutures placed in the portion of the aortic valve annulus that is continuous with the anterior leaflet of the mitral valve pull the anterior leaflet superiorly toward the left ventricular outflow area and thus hinder exposure of this area as viewed through the left atriotomy.

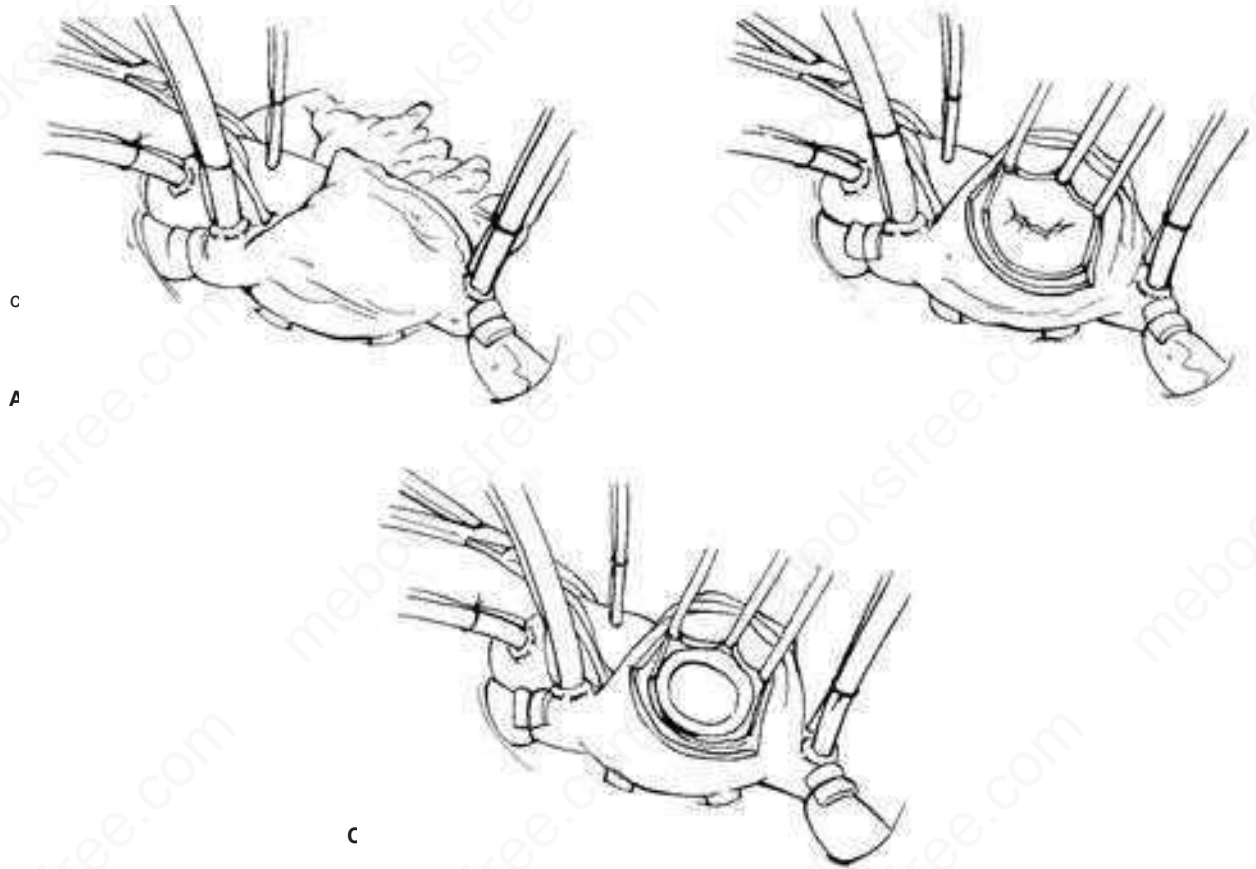

If the aortic annulus is small, it can be enlarged with a patch of pericardium.<sup>43</sup> This technique increases annular diameter by 2 to 4 mm or more, and only rarely are more radical techniques necessary.<sup>44-46</sup> Another maneuver to accommodate as large a prosthesis as possible is to place the necessary sutures for the mitral valve repair or replacement but not secure the mitral prosthesis until the aortic valve is implanted. This eliminates downsizing of the aortic prosthesis but does not compromise insertion of sutures in the superior portion of the mitral valve annulus.

After removal of the aortic valve, the right atrial cannula is repositioned, and the mitral valve is exposed through an incision posterior to the interatrial groove (see Fig. 44-1B). The presence or absence of thrombi in the left atrium is noted, and the mitral valve is inspected. When there is rheumatic disease of the aortic valve, the mitral valve almost always will be involved to some extent. If aortic valve replacement is necessary, the surgeon should have a low threshold for replacing a diseased mitral valve because scarring and fibrosis of the rheumatic process are progressive, and mitral valve

**FIGURE 44-1** Aortic and mitral valve replacements showing sequence of (A) cannulation and (B) exposure of valves. (C-E) Mitral and aortic valve replacements showing the sequence of replacement of the mitral and aortic valves.

**FIGURE 44-2** Combined mitral valve and tricuspid valve operation. The panels illustrate (A) cannulation, (B) transseptal incision, and (C) combined mitral valve and tricuspid valve operation: mitral replacement. (Superior vena cava snare not shown.)

repair (commissurotomy for stenosis or leaflet repair and annuloplasty for regurgitation) is less durable than repair for degenerative disease.<sup>47-49</sup> In contrast, when aortic valve replacement is necessary because of calcification of a bicuspid valve or senescent calcification, repair of mitral valve regurgitation owing to degenerative causes can be expected to give predictably good long-term results. Repair of the mitral valve is described in Chapter 41.

In preparation for replacement, the anterior leaflet of the mitral valve is excised, and when possible, a portion of the posterior leaflet with its chordal attachments is preserved to maintain left ventricular papillary muscle-annular continuity.<sup>50-52</sup> Some surgeons make a special effort to preserve the anterior leaflet and its chordal attachments, believing that this has a further beneficial effect on ventricular performance.<sup>53</sup> The mitral prosthesis is implanted using interrupted mattress sutures of 2-0 braided polyester reinforced with felt pledgets, which can be situated on the atrial or ventricular side of the valve annulus (see Fig. 44-1C). The leaflets of mechanical valves should be tested for free mobility following valve seating.

When atrial fibrillation is present preoperatively, we obliterate the left atrial appendage by oversewing its orifice from within the left atrium or ligating it externally. The left

atriotomy is closed from each end with running polypropylene sutures. Vent tubing is inserted through the partially closed left atriotomy and left in place while the aortic valve is being replaced (see Fig. 44-1D).

After appropriate exposure, the aortic prosthesis is sewn in place with interrupted 2-0 polyester mattress sutures backed with felt pledgets, and the aortotomy is closed, usually with two layers of 4-0 polypropylene. Any remaining air is evacuated from the heart with the usual maneuvers, and a tack vent in the ascending aorta is placed on suction as the aortic clamp is removed. The vent is removed from the left atrium, and closure of the left atriotomy is secured.

In patients with annuloaortic ectasia, the mitral valve sometimes can be visualized and replaced through the enlarged aortic annulus.<sup>54</sup>

### Aortic Valve Replacement and Mitral Valve Repair

Intraoperative transesophageal echocardiography is useful in assessing the degree of MR and, importantly, in identifying the cause of valve leakage. When mitral valve regurgitation is only moderate and leaflet morphology is normal, we expect mitral valve function to improve following relief of

**FIGURE 44-3** (A) Mitral valve repair and (B) tricuspid valve repair using a partial-ring annuloplasty. (Superior and inferior venae cavae snares not shown.)

severe aortic stenosis. In all other instances, the valve should be inspected directly to determine the need for repair or replacement.

Sternotomy, cannulation, and assessment of the aortic valve proceed as described previously. When there is no indication of tricuspid valve disease and no other right atrial procedures are planned, venous return is obtained through a single two-staged cannula (Fig. 44-3A). Specific techniques of mitral valve repair depend on operative findings.<sup>55</sup> Localized prolapse of a portion of the posterior leaflet with or without ruptured chordae usually is managed by triangular excision of that segment and repair with continuous 4-0 polypropylene suture.<sup>56</sup> Ruptured chordae to the anterior leaflet are replaced with 4-0 or 5-0 polytetrafluoroethylene (PTFE) sutures inserted into papillary muscle and through the free edge of the prolapsing leaflet.<sup>57</sup>

Almost all leaflet repairs are supplemented with a posterior annuloplasty. Interrupted 2-0 braided polyester mattress sutures are placed along the posterior circumference of the annulus ending at the right and left fibrous trigones (see Fig. 44-3A). Sutures then are spaced evenly through a flexible 6.0- to 6.5-cm-long partial ring; this standard length can be obtained by using a flexible 63-mm posterior annuloplasty band.<sup>49,58</sup> Following annuloplasty, competence of the mitral valve is tested by filling the ventricle with saline or blood; the atrium then is closed, and the aortic valve prosthesis is sewn into place.

### Mitral Valve Replacement and Tricuspid Valve Replacement or Repair

In most instances, tricuspid valve regurgitation is caused by annular dilatation.<sup>59</sup> The severity of tricuspid valve leakage can be determined by transesophageal echocardiography before bypass and by digital exploration of the right atrium just before venous cannulation. Under general anesthesia,

changes in blood volume and cardiac output can cause significant fluctuation in the amount of regurgitation, and most often the severity of tricuspid valve leakage is lessened in the immediate prebypass period.

The patient's clinical condition must be correlated with echocardiographic findings and intraoperative assessment of the tricuspid valve. Patients with an enlarged, pulsatile liver, peripheral edema, and jugular venous distention are likely to require tricuspid valvuloplasty following mitral valve replacement or repair. Patients without the stigmata of right-sided heart failure usually have less severe valve leakage, and tricuspid valve function may improve without direct repair or replacement after left-sided valvular lesions are corrected.

The decision for repair or replacement of functional tricuspid valve regurgitation at the time of mitral valve replacement is important because the risk of subsequent reoperation is high. In our earlier experience, operative mortality was 25% in patients who required later reoperation for tricuspid valve regurgitation. Further, TR progresses in 10 to 15% of patients after replacement of rheumatic mitral valves.<sup>60</sup> Therefore, we maintain a liberal policy for annuloplasty or prosthetic replacement at initial operation.<sup>61</sup>

### PROCEDURE

For operations on the tricuspid valve, insertion of a Swan-Ganz catheter is optional; if one is used, the catheter is withdrawn from the right heart chambers during inspection and assessment of the tricuspid valve. We prefer direct cannulation of the inferior and superior venae cavae.<sup>62</sup> After commencement of cardiopulmonary bypass and cardioplegia, the cavae are snared around the venous cannulae, and the interatrial septum and tricuspid valve are exposed through a right atriotomy (see Fig. 44-2A). A decision for repair or replacement of the tricuspid valve is made, and the necessary prosthesis is identified.

When the tricuspid valve is also addressed, we tend to expose the mitral valve through an incision in the interatrial septum, which crosses the fossa ovalis and can be extended superiorly (see Fig. 44-2B). Care should be taken during retraction to avoid tearing the septum inferiorly toward the coronary sinus and triangle of Koch. Alternatively, the mitral valve can be exposed through a standard left atriotomy posterior to the interatrial groove.

After repair or replacement of the mitral valve (see Fig. 44-2C), the septal or left atrial incision is closed, and the tricuspid valve is repaired or replaced. For tricuspid valve repair, we use either the DeVega method or ring annuloplasty.<sup>12,18,63,64</sup> Both techniques are based on the observation that the anterior and posterior valve portions of the tricuspid valve annulus are more prone to dilatation than the septal leaflet portion of the annulus, as described previously. When ring annuloplasty is indicated, we prefer a flexible device such as the Cosgrove-Edwards prosthesis<sup>65</sup> or a partial Duran ring (see Fig. 44-3B). The use of a partial ring avoids placement of sutures in the annulus near the penetrating bundle of His and reduces risk of injury to conduction tissue. There have been conflicting reports regarding the superiority of DeVega procedure versus prosthetic annuloplasty in improving freedom from recurrent TR.<sup>66-68</sup>

### Minimally Invasive Approaches

Although addressed elsewhere in this textbook, minimally invasive approaches to primary and reoperative left- and right-sided valvular heart disease have been proposed. Various cannulation and cardioplegia techniques have been described as determined by the pattern of valve disease and patient anatomy.<sup>69a,b</sup>

### Tricuspid Valve Replacement and Pulmonary Valve Replacement for Carcinoid Heart Disease

If there is no involvement of the mitral and aortic valves,<sup>59,70</sup> tricuspid and pulmonary valve replacement usually can be performed without the need for aortic occlusion and cardioplegic arrest. It is important to exclude the presence of a patent foramen ovale to eliminate the risk of air entering the left atrium, and if a defect in the atrial septum is identified, it is closed using a brief period of aortic occlusion. In the past, our strategy for patients with carcinoid heart disease was to replace the tricuspid valve and excise the diseased pulmonary valve.

Subsequent experience has suggested that right ventricular function is better preserved with a competent pulmonary valve, so we now favor pulmonary valve replacement rather than valvectomy.<sup>71</sup> Tricuspid valve replacement always is indicated, and it is usually necessary only to remove the anterior leaflet. A recent review of 200 patients with carcinoid heart disease at our institution demonstrated that prognosis has improved in the current era and that valve

replacement surgery was independently associated with prolonged survival.<sup>72</sup>

Carcinoid disease produces fibrosis and retraction of the leaflets, so anchoring sutures (interrupted mattress sutures of 2-0 braided polyester backed with felt pledgets) can be inserted into the remaining septal and posterior leaflets. We prefer to position the pledgets on the ventricular side of the valve annulus. If exposure is difficult, a brief period of aortic clamping and cardioplegic arrest is used during placement of sutures in the posterior and septal leaflets; the aortic cross-clamp is removed, and the heart is allowed to beat rhythmically. The remaining sutures are placed, and all sutures are secured with observation of the electrocardiogram. If atrioventricular block develops, the sutures in the area of the penetrating bundle of His are removed and reinserted in a more superficial location.

Pulmonary valve replacement is performed through a longitudinal incision across the valve annulus onto the outflow portion of the right ventricle. We prefer to insert the prosthetic valve using a continuous 3-0 polypropylene suture, anchoring the sewing ring to the native valve annulus for approximately two-thirds of the valve annulus and then anteriorly to a pericardial patch that is used routinely to augment the valve annulus and facilitate closure of the pulmonary artery and right ventricle.

### Triple-Valve Replacement

Operative preparation is similar to that described previously. Usually left-sided valvular lesions are corrected before tricuspid valve procedures. Again, if there is aortic valve regurgitation, the aortotomy is performed first, and cardioplegia is administered; simultaneously, we snare the caeae and open the right atrium. After excision of the aortic valve and calibration of the annulus, the interatrial septum is incised, and the mitral valve is repaired or replaced. Next, the aortic valve is implanted, and after closure of the aortotomy and septotomy, the tricuspid valvuloplasty or prosthetic replacement can be performed without aortic cross-clamping.<sup>73</sup>

## RHEUMATIC HEART DISEASE AFFECTING MULTIPLE VALVES

As shown in Table 44-3, rheumatic valvulitis is a common cause of multiple valve disease. Autopsy studies show that almost all patients with rheumatic heart disease have some involvement of the mitral valve, although it is not always evident clinically.<sup>74</sup> The percentages of multiple valve involvement in two autopsy studies of patients with rheumatic heart disease are shown in Table 44-4.

Forty-seven percent of those studied had involvement of more than one valve. Mitral and aortic valve disease was the most common combination and was present in 34% of patients; the second most common combination was mitral, aortic, and tricuspid valve disease (9%). A recent report has suggested that all four valves might be involved with the rheumatic process.<sup>75</sup>

Long-term follow-up of children with rheumatic heart disease suggests that approximately 50% of patients have multivalvular involvement.<sup>76,77</sup> In a study of patients undergoing mitral valvotomy for rheumatic mitral stenosis (Table 44-5), 13% had clinical evidence of other rheumatic valve stenosis or regurgitation. Most of these patients had associated rheumatic aortic disease.<sup>78</sup>

Rheumatic heart disease can cause valve stenosis, regurgitation, or a combination of lesions. The percentages of 290 patients with specific valvular lesions from four studies of multiple valve disease are shown in Table 44-6. Mixed lesions producing stenosis and regurgitation were encountered most commonly in both aortic and mitral valves.

### Rheumatic Mitral Stenosis with Rheumatic Aortic Regurgitation

Approximately 10% of patients with rheumatic mitral valve stenosis also have rheumatic aortic regurgitation.<sup>79,80</sup> Clinical and laboratory characteristics of patients with mitral stenosis and aortic regurgitation are summarized in Table 44-7.

### PATHOPHYSIOLOGY

In patients with mitral valve stenosis and aortic valve regurgitation, decreased cardiac output minimizes the classic signs of aortic regurgitation (eg, waterhammer pulse, head bobbing, and visibly pulsating capillaries). Also, concomitant mitral stenosis reduces left ventricular volume overload, which is a characteristic of isolated aortic regurgitation.<sup>81</sup> The underfilling of the left ventricle characteristic of mitral stenosis is offset by overfilling secondary to aortic valve regurgitation. Pulmonary artery hypertension characteristic of mitral stenosis usually is present.

### OPERATIVE DECISION-MAKING

Patients with rheumatic mitral stenosis and rheumatic aortic regurgitation of more than a mild degree usually require replacement of both valves. Aortic valve repair is

possible using techniques such as cuspal extension with glutaraldehyde-treated bovine or autologous pericardium<sup>82</sup> or the Trussler technique.<sup>83</sup> Although early results with cuspal extension have been good, inexorable progression of valve fibrosis may necessitate later prosthetic replacement for many patients.<sup>84</sup>

Preoperative transthoracic and intraoperative transesophageal echocardiography aids in assessing function of the aortic valve in patients requiring surgery for mitral stenosis. At operation, the degree of ventricular filling and amount of aortic root distention with infusion of cardioplegia are clues to important aortic valve regurgitation. As stated previously, if mitral valve replacement is necessary, serious consideration should be given to replacement of the aortic valve when there is moderate or worse leakage owing to rheumatic valvulitis.

Great care should be exercised to avoid ventricular distention if ventricular fibrillation occurs before aortic clamping. If ventricular fibrillation develops, distention of the heart can be prevented by inserting a left ventricular vent and compressing the heart manually. Also, even mild or moderate degrees of aortic regurgitation can complicate cardioplegia delivery through the proximal aorta.

Elevated LVEDP	38% (10)

LVEDP, left ventricular end-diastolic pressure; LVH, left ventricular hypertrophy.

## Rheumatic Mitral Stenosis with Rheumatic Aortic Stenosis

### PATHOPHYSIOLOGY

In contrast to isolated mitral stenosis, in which ventricular function frequently is preserved, the combination of mitral and aortic stenosis is associated with ventricular hypertrophy and diastolic dysfunction. The pressure load from the aortic stenosis causes a concentric hypertrophy with a small, noncompliant ventricular cavity.<sup>80</sup> Mitral stenosis compromises the ventricle's ability to maintain cardiac output (in contrast to isolated aortic stenosis, in which cardiac output is maintained).<sup>85,86</sup> The decrease in cardiac output minimizes the signs and symptoms of aortic stenosis and may make the diagnosis of aortic stenosis difficult.<sup>87</sup> Other hemodynamic parameters are similar to those of isolated mitral stenosis, for example, elevation of left atrial and pulmonary arterial pressures.<sup>86,88</sup>

### OPERATIVE DECISION-MAKING

Although mitral valve stenosis sometimes can be treated effectively with valvuloplasty, commissurotomy for rheumatic aortic stenosis is indicated rarely. Thus, for patients with both aortic and mitral valve stenoses caused by rheumatic heart disease, we favor prosthetic replacement with mechanical prostheses if patients can manage long-term anticoagulation. If aortic valve stenosis is only mild and the decision is made not to replace the aortic valve at the time of mitral valve replacement, then the patient should be followed carefully, because more than 50% will develop moderate to severe disease by 15 years postoperatively.<sup>89</sup> The combination of aortic stenosis and mitral stenosis may present unique problems for the surgeon. First, concentric hypertrophy of the left ventricle may displace the mitral valve orifice anteriorly, producing poor exposure through a standard atriotomy; several maneuvers and alternative incisions are described for patients in whom mitral valve exposure is difficult.<sup>87,90-94</sup> Also, the small left ventricular cavity may impinge on struts of a stent-mounted bioprosthesis. There is also the potential for left ventricular outflow

obstruction from high-profile prostheses in the mitral position in patients with aortic and mitral valve stenoses and small left ventricular cavity size.

## Rheumatic Mitral Regurgitation with Rheumatic Aortic Regurgitation

### PATHOPHYSIOLOGY

The combination of mitral and aortic valve regurgitation produces severe volume overload of the left ventricle. The reduction of impedance to ejection allows the ventricle to empty further, reducing ventricular wall tension with a resulting increase in the velocity of shortening.<sup>95</sup> Chronic volume overload increases stroke volume and distention of the left ventricle so that a larger stroke volume can be achieved with less myocardial fiber shortening than in normal hearts.<sup>80</sup> Patients who respond to increased volume load by left ventricular dilatation appear to tolerate surgical correction better than patients with left ventricular hypertrophy owing to an increased pressure load.<sup>80</sup> Patients with aortic valve regurgitation have augmented stroke volume to maintain an adequate cardiac output, but when MR coexists, part of the augmented stroke regurgitates into the left atrium and pulmonary veins. For this reason, when aortic regurgitation is severe, concomitant MR greatly reduces systemic cardiac output and can produce severe pulmonary congestion.<sup>96</sup>

### OPERATIVE DECISION-MAKING

As stated previously, aortic valves involved with rheumatic disease usually require replacement. When the mitral valve also has rheumatic involvement, we replace the mitral valve at the time of aortic valve operation. After the aortic valve is excised, the mitral valve is inspected visually if it is suspected of being diseased or the degree of regurgitation is severe.

## MYXOMATOUS AND PROLAPSING VALVE DISEASE AFFECTING MULTIPLE VALVES

Myxomatous degeneration is the most common etiology of MR requiring surgical correction in North America, and myxomatous aortic valve disease with annular dilatation is perhaps the most common cause of aortic regurgitation.<sup>97-99</sup> Most cases of isolated mitral or aortic valve prolapse are not associated with known connective tissue disorders.

**TABLE 44-8: Incidence of Echocardiographic Evidence of Aortic Valve Prolapse in Patients with Mitral Valve Prolapse**

	Ogawa et al <sup>104</sup>	Rippe et al <sup>103</sup>	Mardelli et al <sup>171</sup>	Total
Number of patients with MVP	50	400	75	525
Aortic valve prolapse	24% (12)	3% (11)	20% (15)	7% (38/525)
Aortic regurgitation	16% (8)	1% (4)	—	3% (12/450)
Aortic and mitral valve replacement	2% (1)	—	—	2% (1/50)

MVP, mitral valve prolapse. Number of patients in parentheses.

However, the coexistence of both mitral and aortic valvular prolapse together frequently can be seen in patients with connective tissue diseases such as Marfan's syndrome, Ehlers-Danlos syndrome, osteogenesis imperfecta, and others.<sup>96</sup>

Aortic valve regurgitation in patients with Marfan's syndrome is caused by progressive enlargement of the sinus portion of the aorta and the aortic valve annulus, that is, annuloaortic ectasia.<sup>100,101</sup> The principal causes of MR in patients with Marfan's syndrome are mitral annular dilatation, floppy or prolapsing leaflets, and mitral annular calcification.<sup>101</sup> The pathologic lesion in Marfan's syndrome is cystic medial necrosis, which is characterized by degeneration of elastic fibers and infrequent cysts.<sup>101</sup> Alterations in the synthesis and cellular secretion of fibrillin are responsible for the phenotypic characteristics of many patients with Marfan's syndrome.<sup>102</sup> Some patients have myxomatous cardiovascular lesions and annuloaortic ectasia without the other clinical characteristics of Marfan's syndrome.

Two-dimensional echocardiographic studies show that the frequency of aortic valve prolapse in patients with mitral valve prolapse varies between 3 and 24%<sup>103,104</sup> (Table 44-8). In one necropsy study, the frequency of MR in Marfan patients with aortic aneurysms (most with aortic regurgitation) was 54% (7 of 13).<sup>101</sup> About 17% of patients who undergo surgery for myxomatous aortic valve require surgical correction of MR (Table 44-9).

**TABLE 44-9: Frequency of Mitral Valve Procedures in Patients Undergoing Aortic Valve Repair or Replacement for Myxomatous Degeneration, Prolapse, or Root Dilatation**

	David <sup>172</sup>	Gott et al <sup>173</sup>	Shigenobu et al <sup>97</sup>	Agozzino et al <sup>100</sup>	Bellitti et al <sup>99</sup>	Total
All aortic surgery	18	270	13	69	25	395
Number requiring concomitant mitral surgery	3 (17%)	36 (13%)	5 (38%)	16 (23%)	3 (12%)	73 (16%)

Although multiple valve involvement with myxomatous degeneration usually manifests as MR in combination with aortic regurgitation, in some cases, all four valves may be involved.<sup>105</sup> It is not clear whether the underlying pathology of isolated mitral valve prolapse is the same as the cardiovascular lesions that occur in Marfan's syndrome and other multiple-floppy-valve syndromes.<sup>106,107</sup>

## Diagnosis, Signs, and Symptoms

Signs and symptoms of aortic and mitral valve regurgitation are reviewed in the section on rheumatic valvular disease. In addition to complete evaluation of the aortic and mitral valves and proximal aorta, patients with Marfan's syndrome should have assessment of the descending aorta for aneurysm or chronic dissection.

## Operative Decision-Making

If annuloaortic ectasia is not present, patients with mitral and aortic valve regurgitation caused by myxomatous degeneration are candidates for repair of both valves. The aortic valve is inspected initially, and the decision for repair or prosthetic replacement is made depending on cuspal morphology. If tissue is sturdy and there is little prolapse or prolapse is limited to one cusp, repair can be undertaken with commissural narrowing and cusp resuspension. Often, aortic valve regurgitation is central, and simply narrowing the annulus by commissural plication restores valvular competence. Outcome of repair of both mitral and aortic valves has been good in terms of patient survival and freedom from valve-related complications, but reoperation is necessary in 35% of patients 10 years after the initial procedure; patients with most severe aortic valve regurgitation have an increased risk of late reoperation.<sup>108</sup> If tissue is attenuated, or if multiple cusps have severe prolapse, the valve is replaced.

In most instances, patients with Marfan's syndrome and aortic regurgitation require composite replacement of the aortic valve and ascending aorta.<sup>109</sup> Occasionally, moderate aortic regurgitation can be repaired at the time of aortic replacement by suspending the aortic valve inside a tube graft or remodeling the sinus portion of the aorta.<sup>110</sup> Even if the aortic valve is replaced with a composite graft and mechanical valve, the surgeon should favor repair of associated mitral regurgitation.<sup>111</sup> Gillinov and colleagues reported that valvuloplasty is possible in approximately 80% of patients with MR and Marfan's syndrome and that 5 years postoperatively 88% of patients are free of significant mitral valve insufficiency.<sup>112</sup>

## Myxomatous Mitral Regurgitation with Tricuspid Regurgitation

Myxomatous degeneration also may involve the tricuspid valve, and presentation of mitral and tricuspid valve regurgitation owing to degenerative disease is not uncommon. In one study, 54% of patients with mitral valve prolapse also had tricuspid valve prolapse; however, most of these

patients did not have significant regurgitation.<sup>96</sup> As with TR associated with rheumatic mitral disease, preoperative and intraoperative echocardiography is important in evaluating tricuspid disease in patients with myxomatous mitral regurgitation. In contrast with rheumatic disease, myxomatous mitral and tricuspid regurgitation almost always lends itself to valve repair.

## SENILE CALCIFIC AORTIC VALVE DISEASE WITH MULTIPLE VALVE INVOLVEMENT

Unlike aortic stenosis caused by rheumatic disease, in which associated mitral valve disease is common, senile calcific aortic stenosis usually presents as an isolated lesion. Although the combination of mitral valve disease and senile calcific aortic stenosis is uncommon, senile aortic calcification is a frequent cause of aortic valve stenosis.<sup>98</sup> The incidence of senile calcific aortic disease has increased steadily in the last 20 years. Therefore, although mitral valve disease associated with calcific aortic stenosis is less common than that seen with rheumatic disease of the aortic valve, as the incidence of calcific aortic stenosis increases, so does the likelihood of encountering patients with disease of both valves.

## Patterns of Multiple Valve Involvement with Calcific Aortic Stenosis

### CALCIFIC AORTIC STENOSIS WITH INFECTIVE ENDOCARDITIS OF THE MITRAL VALVE

Stenotic aortic valves frequently are sites of infective endocarditis. As discussed in the section on endocarditis, the mitral valve may become involved with infective endocarditis by common abscess, by verrucous extension, or from a jet lesion, and infection may cause mitral valve aneurysm, perforation, and/or chordae disruption.<sup>113</sup> Management of these patients usually requires aortic valve replacement and assessment of the mitral valve at the time of operation. Vegetations of the mitral valve sometimes can be removed and perforations patched if the remaining tissue is sturdy and appears healthy.

### CALCIFIC AORTIC STENOSIS WITH FUNCTIONAL MITRAL VALVE DISEASE

Senile calcification of the aortic valve may lead to mixed stenosis and regurgitation,<sup>98</sup> and the volume load from regurgitation may lead to left ventricular dilatation and secondary MR of an otherwise normal mitral valve.<sup>98</sup> MR secondary to aortic valvular disease is discussed in the section on pathophysiology of multiple valve disease.

### CALCIFIC AORTIC STENOSIS WITH CALCIFICATION OF THE MITRAL VALVE

Degenerative calcification is an age-related process usually affecting the aortic and mitral valves. In a study of patients older than 75 years of age, one-third had degenerative aortic

**TABLE 44-10: Comparison of Early Outcome between Patients having Multiple Valve Surgery for Infective Endocarditis and Patients having Multiple Valve Surgery for other Reasons<sup>9,106</sup>**

	Class II	Class III	Class IV
Multiple valve procedures for infective endocarditis	20% (15)	33% (3)	20% (5)
Multiple valve procedures for other causes	16% (25)	12% (25)	36% (25)

Operative mortality is expressed as percentage, and numbers of patients are in parentheses.

or mitral calcification.<sup>96</sup> About 25 to 50% of patients with calcific aortic stenosis have calcification of the mitral valve annulus. Generally, patients with associated mitral annular calcification are older, have more severe aortic stenosis, and are more often female when compared with patients with aortic stenosis without mitral annular calcification.<sup>114</sup> Mills reported 17 patients undergoing mitral valve replacement for valvular disease related to severe annular calcification. Four of these patients also had concomitant aortic valve replacement.<sup>115</sup> Mitral annular calcification may exist in the setting of rheumatic or myxomatous disease.<sup>116</sup> These patients may have increased incidence of conduction defects,<sup>117</sup> aortic outflow murmurs, coronary artery disease,<sup>118</sup> and stroke.<sup>119</sup> Mitral repair or replacement is facilitated in some circumstances by removal of the annular calcium bar and pericardial reconstruction.<sup>120</sup>

Table 44-10 compares New York Heart Association (NYHA) class-matched groups that had multiple valve procedures for infective endocarditis and for other reasons.

## CARCINOID HEART DISEASE AFFECTING MULTIPLE VALVES

Valvular heart disease develops in about 50% of patients with carcinoid tumors; patients with primary carcinoid tumor in the small intestine are more likely to have carcinoid heart disease than those with carcinoid tumors in other locations.<sup>1</sup> In most cases, the tricuspid and pulmonary valves are involved. We have offered valvular surgery to patients with severe symptoms of right-sided heart failure caused by carcinoid heart disease whose systemic carcinoid symptoms are controlled by octreotide and/or hepatic dearterialization.<sup>121</sup> Patients who are being considered for complete resection of hepatic metastases after control of the primary tumor are also candidates for extirpation of cardiac disease and valve replacement. A recent review of 200 patients with carcinoid heart disease from our institution revealed that survival has improved over the past decade. Multivariate analysis indicated that valve replacement surgery was associated with a risk reduction of 0.48.<sup>70</sup>

## Diagnosis, Signs, and Symptoms

Jugular venous distention with v-waves (from TR) and a-waves (from tricuspid stenosis) can be evident. Right ventricular enlargement can produce a pericardial lift. Most patients have murmurs from the tricuspid and pulmonary valves.<sup>121</sup> Patients often demonstrate ascites and liver enlargement as a result of either right-sided heart failure or hepatic metastases or both. Therefore, these findings are not necessarily indicative of severe tricuspid valve regurgitation.

The electrocardiogram of patients with carcinoid heart disease often shows low voltage (85%), right bundle-branch block (42%), and evidence of right atrial enlargement (35%).<sup>1,121</sup> The chest x-ray characteristically shows cardiomegaly (69%), pleural effusions (58%), and pleural thickening (35%).<sup>121</sup>

## Echocardiography

Echocardiographic findings of carcinoid heart disease include thickening and reduced motion of the tricuspid valve leaflets; the pulmonic valve cusps may be thickened and retracted. Fusion of the pulmonary valve commissures results in a stiff fibrotic ring that may cause a stricture in the entire pulmonary orifice. Pulmonary regurgitation and stenosis both may be present.<sup>122</sup>

## Invasive Studies

Cardiac catheterization is not necessary unless ischemic symptoms or a history of myocardial infarction suggests coronary artery disease.

## Pathophysiology

Carcinoid heart disease results from deposition of plaques on the endocardium of the valves and atria; this usually occurs on the right side of the heart. However, plaques can develop on the mitral and aortic valves when there is carcinoid tumor in the lungs or in the presence of intracardiac shunting that bypasses the lungs. Valves are damaged by exposure to circulating substances released from carcinoid tumors such as serotonin and bradykinin. Both these components are inactivated by the lungs and the liver; the relationship between tumor location and the location of cardiac lesions is summarized in Table 44-11.<sup>123</sup> The plaques usually deposit on the downstream side of the cardiac valves, causing adherence of the leaflet to the underlying structures and producing functional regurgitation. Carcinoid plaque deposition also may constrict the valve annulus and produce stenosis.<sup>1</sup>

The dominant functional lesion of carcinoid heart disease is tricuspid valve regurgitation; the valve is fixed in a semio-pen position so that some degree of stenosis is present. Fibrosis and plaque deposition also affect the pulmonary valve, causing mixed stenosis and regurgitation, which increases the degree of TR.<sup>1</sup>

**TABLE 44-11: A Comparison of Venous Drainage, Presence of Liver Metastases, and Carcinoid Plaque Location in Relation to Location of Primary Carcinoid Tumor<sup>174</sup>**

Tumor location	Venous drainage	Liver metastases	Plaque location
Gut	Portal	Yes	Right-sided
Ovary	Systemic	No	Right-sided
Bronchial	Pulmonary	No	Left-sided

## Operative Decision-Making

### TIMING OF OPERATION

The primary indications for surgery are increasing symptoms of congestive failure with objective evidence of valvular disease.<sup>124</sup> Again, it should be noted that some of the signs of right-sided heart failure, such as peripheral edema, ascites, and hepatomegaly, can be caused by the primary disease. Another indication for operation may be progressive right ventricular enlargement in the absence of symptoms. In a small series of carcinoid patients, right ventricular size and function did not correlate with operative or late mortality.<sup>121</sup> Currently, we employ exercise testing to provide an objective assessment of the functional status and a guideline to the timing of cardiac surgery. If the primary cause for debilitation is right-sided heart failure, it is reasonable to offer valve replacement even though the prognosis may be guarded.<sup>125</sup>

### Tricuspid Valve Operation

The tricuspid valve always requires replacement, and in our earlier experience, we used mechanical prostheses because of the possibility of carcinoid plaque formation on a bioprosthesis. However, review of our patients and those reported previously shows little difference in patient survival with mechanical or tissue valves. Bioprostheses are selected for patients who have liver dysfunction that would complicate anticoagulation with Coumadin and those who will undergo subsequent hepatic resection or hepatic artery embolization.

### Pulmonary Valve Options

As stated previously, we now advise valve replacement rather than excision when the pulmonary valve is involved.

Management of the carcinoid syndrome during and early after operation is critically important, and this has been simplified greatly by treatment with long-acting octreotide; this is supplemented intraoperatively with intravenous administration of short-acting octreotide when there is evidence of flushing and vasodilatation.<sup>126</sup> Preoperative steroids and antihistamines also can be used to prevent adverse effects from tumor-released mediators.<sup>126,127</sup> We usually give octreotide, 500 µg intravenously, before induction of anesthesia, with additional intravenous doses given as needed at the onset

**TABLE 44-12: Rare Causes of Multiple Valve Disease Requiring Surgery**

Disease	Valves replaced or repaired
Methysergide/ergotamine toxicity <sup>96</sup>	Aortic and mitral
Fenfluramine-phentermine <sup>175</sup>	Left and right heart valves
Ergot-derived dopamine agonists <sup>176</sup>	Left and right heart valves

and termination of cardiopulmonary bypass. Postoperatively, octreotide is continued, and the dose is adjusted according to the severity of the flushing and vasodilatation. Aprotinin, a kallikrein inhibitor, may mitigate the effects of substances released by carcinoid tumors during anesthesia and reduce intraoperative and postoperative bleeding.<sup>126</sup>

## RARE CAUSES OF MULTIPLE VALVE DISEASE

Table 44-12 lists some rare causes of multiple heart valve disease that require surgical correction.

## RESULTS OF MULTIPLE VALVE SURGERY

### Long- and Short-Term Mortality

Survival following multiple valve surgery has improved along with refinements in myocardial protection; for example, mortality for multiple valve operations performed using normothermic ischemic arrest was approximately 40%;<sup>128</sup> the use of cardioplegic arrest reduced operative risk by three-fourths.<sup>80,128,129</sup> In recent reports,<sup>130</sup> operative mortality (30-day mortality or hospital mortality) ranges from about 6 to 17% (Table 44-13, part A). The 5-year actuarial survival is 60 to 88% (see Table 44-13, part B), and the 10-year actuarial survival is 43 to 81% (see Table 44-13, part C).

<sup>§</sup>Results reported graphically.

Comparisons to isolated aortic and mitral valve procedures from the same series are included when available. If statistical analysis between the results of multiple and single valve procedures was reported, the p values are included. If a series was limited to a single valve type, it is listed.

AVR, isolated aortic valve replacement; B-S, Björk-Shiley; C-E, Carpentier-Edwards; DVR, double-valve replacement; MIPB, medtronic intact porcine bioprosthesis; MP, mitroflow pericardial; MVR, isolated mitral valve replacement; N.S., not statistically significant; SJM, St. Jude Medical.

Risk factors identified for morbidity and mortality following multiple valve surgery include advanced NYHA class,<sup>131-133</sup> advanced age,<sup>131-135</sup> current or prior myocardial revascularization,<sup>134</sup> ejection fraction,<sup>131</sup> presence of coronary artery disease,<sup>131,132</sup> aortic stenosis,<sup>136</sup> elevated pulmonary artery pressure,<sup>134</sup> TR,<sup>136</sup> and diabetes mellitus.<sup>134</sup>

Clearly, operative mortality is influenced by patient selection,<sup>133</sup> and comparisons among studies are of limited value.<sup>133</sup> Causes of death after multiple valve surgery are low cardiac output,<sup>133,136-139</sup> myocardial infarction,<sup>134</sup> technical failure,<sup>139</sup> multiple-organ failure,<sup>34</sup> ventricular rupture,<sup>101,134,137</sup> and mechanical obstruction of the prosthetic leaflet.<sup>101,138</sup> Comparisons of late survival between patients having multiple valve versus single-valve replacement are inconsistent. Some studies show poorer survival<sup>132</sup> after multiple valve replacement, and others report no significant difference in survival.<sup>34,125,128,135-140</sup> The discrepancy in these results may be because the majority of deaths in many reports are secondary to progression of coronary artery disease and noncardiac causes rather than valve-related issues.<sup>129,131</sup> The presence of coronary artery disease and concomitant coronary artery surgery increases mortality following multiple valve surgery.<sup>134,141,142</sup>

Some causes of early death following multiple valve surgery are perhaps less common today owing to changes in practice.

In a necropsy study from 1963 to 1985 of patients who died early following double-valve replacement, prosthetic valve dysfunction secondary to mechanical interference was evident in almost 50%, and ventricular rupture had occurred in 15% of patients.<sup>101</sup> Most of these patients received Starr-Edwards caged-ball prosthetic valves. Mechanical failure of low-profile tilting-disk prostheses that are in current use is rare, and early valve-related death with this type of prosthesis is very unusual.<sup>34,132,133,143</sup> The current practice of preserving the posterior leaflet and chordal attachments of the mitral valve during prosthetic replacement may decrease the chance of ventricular disruption.<sup>144</sup>

## Thromboembolism

Thromboembolic rates following multiple valve replacement are shown in Table 44-13, part D, and range from 1 to 7% per patient-year for double-valve replacement. Ten years postoperatively, freedom from thromboembolic events ranges from 77 to 89% (see Table 44-13, part E). Although the data presented in Table 44-13, part D, along with other sources,<sup>145</sup> do not indicate significant differences between single-valve replacement and multiple valve replacement, some reports suggest that both mechanical<sup>146</sup> and bioprosthetic<sup>147</sup> valves have an increased risk of thromboembolism in the mitral position.

This risk is present early (90 days after operation) in patients undergoing multiple valve replacement that includes a bioprosthetic mitral valve.<sup>147</sup>

## Anticoagulation-Related Hemorrhage

Rates of anticoagulant-related hemorrhage following multiple valve replacement, as with single-valve surgery, depend on target international normalization ratio (INR).<sup>148</sup> Risks of hemorrhage are reported to be 0.1 to 4.5% per patient-year following multiple valve surgery (see Table 44-13, part F). Alvarez et al reported a significantly higher rate of anticoagulant-related hemorrhage following multiple valve replacement than following single-valve replacement.<sup>136</sup>

## Prosthetic Valve Infective Endocarditis

Rates of infective endocarditis following multiple valve surgery range from 0.2 to 2.5% per patient-year, as shown in Table 44-13, part G. In comparison with isolated valve surgery, Alvarez et al reports that prosthesis infection is more frequent following double-valve replacement than following either isolated aortic ( $p < .05$ ) or mitral valve replacement ( $p < .001$ ).<sup>136</sup>

## Valve Performance

Rates of bioprosthetic structural deterioration relate to valve position; tissue valves appear to fail earlier in the mitral position than in the aortic position. When multiple valve replacements include the mitral valve, the rates of deterioration are similar<sup>149</sup> or even worse than<sup>145</sup> isolated mitral valve replacement (see Table 44-13, part H).

## COMPARISON OF BIOPROSTHETIC VALVES TO MECHANICAL VALVES

Comparisons of outcomes of patients with two or more mechanical prostheses with those of patients with two or more bioprostheses show similar rates of thromboembolism,<sup>28,148</sup> but freedom from operation favors those with multiple mechanical valves.<sup>31,150,151</sup> As might be expected, anticoagulation-related hemorrhage is less in patients with two bioprosthetic valves,<sup>150,152</sup> but there is no clear advantage of one prosthesis over the other in terms of early and late mortality.<sup>31,150,152</sup>

## Results of Tricuspid Valve Procedures with Other Valve Procedures

### RESULTS OF MITRAL AND TRICUSPID VALVE OPERATIONS

Reported operative mortality following mitral valve replacement and tricuspid valve repair or replacement is approximately 12 to 15%,<sup>153</sup> and 65 to 75% of patients are alive 5 years postoperatively.<sup>134,153</sup> Outlook for patients with lesser

degrees of TR at the time of mitral valve replacement is good; 5-year actuarial survival for patients with TR who do not have tricuspid valve repair or replacement is 80 to 84%, and 10-year survival is 62 to 77%.<sup>154</sup>

## Triple-Valve Surgery

The median age of 8021 triple-valve patients studied in the STS ACSD was 67 years; 60% were women; 4488 (56%) had NYHA class III to IV symptoms; and mean ejection fraction was 50%. The frequency of mitral valve repair increased over the period of the study from 13 to 41%. Tricuspid valve repair also became more frequent over time from 86 to 96%. The incidence of early death declined from 17 to 9%. Importantly, the performance of mitral and tricuspid valve repair (vs replacement) diminished the likelihood of postoperative death.<sup>155</sup>

## Double-Valve Replacement

In North America, mortality for mitral and tricuspid replacement was 16.8% (n=1,130). For patients having mitral valve repair and tricuspid valve replacement (n=216) mortality was 10.2%, and for patients undergoing mitral valve replacement and tricuspid valve repair (n=11,448) mortality was 10.2%. Operative risk of combined mitral and tricuspid valve repair was 8.0% (n=8,262).<sup>155a</sup> Independent predictors of mortality were age, renal failure with dialysis, emergency status, second or more reoperations, later surgical date, and valve repair. The authors suggested that expanding efforts to repair mitral and tricuspid valves in patients requiring double-valve surgery appear warranted.

Rates of thromboembolism in patients with double-valve replacements are reported to be 5% per patient-year.<sup>62</sup>

## Other Results

The operative mortality for double re-replacement is about 10 to 20%.<sup>132,156</sup> Incidence of postoperative ventricular arrhythmias is higher in patients having combined valve surgery than in those having single-valve surgery.<sup>157</sup> Hemolysis may be more common with multiple valve disease or following multiple valve replacement.<sup>158,159</sup>

The incidence of perivalvular leak following multiple valve surgery is about 4% per patient-year and may be more frequent following multiple valve surgery than following single-valve surgery.<sup>138,140</sup>

When multiple valve surgery is combined with myocardial revascularization, the morbidity and mortality are 12 to 24%.<sup>141,160</sup> Early death in this group of patients is associated with prolonged perfusion time, the need for postoperative inotropic support, and high blood loss.<sup>165</sup>

Triple-valve surgery via a right thoracotomy has been reported.<sup>161,162</sup> Proposed benefits include quicker return to normal activity, a shorter mechanical ventilation time, and less blood loss. The ability to disseminate the techniques necessary for the performance of this procedure in the general cardiac surgical community will need to be further explored.<sup>163</sup>

# Valvular and Ischemic Heart Disease

Kevin D. Accola • Clay M. Burnett

Recently, there have been exciting developments involving new technologies for the surgical treatment of valvular heart disease associated with coronary artery disease (CAD). Interventional therapies for coronary artery obstruction have been extended to multivessel disease with hybrid procedures (targeted percutaneous interventions staged with limited access surgical coronary bypass surgery) and continues to change the number and nature of patients referred for surgery.<sup>1</sup> Similarly, the surgical treatment of structural valvular heart disease has continued to expand with advances in techniques for repair, as well as total valve replacement and valve-sparing repair options for both aortic and mitral valve abnormalities.<sup>2</sup> Most recently, bioprosthetic valve manufacturing advances in regard to calcium mitigation, tissue processing, and hemodynamically superior prosthetic valve stent designs have improved prosthetic valve durability, thereby broadening the valve replacement options for young and old alike.<sup>3</sup> The advent of transcatheter valve replacement (TAVR procedures) has also quickly become a commercial reality and has proven to be safe and efficacious in numerous studies. The stunning early success of the TAVR approach has allowed this remarkable new option to become commonplace in many institutions in hospitals around the world.<sup>4</sup> Most importantly, perhaps, is that transcatheter valvular interventions have provided very high-risk patients, such as the elderly or those with a myriad of threatening comorbidities, a viable new option to consider.

There are numerous issues the surgeon must consider when planning treatment strategies in the patient with combined valvular and CAD. It is uncommon for today's surgeon to see a patient with simple aortic or mitral valvular disease who also has straightforward proximal CAD. Indeed, it is more often a patient presents with complex, acute valvular/ventricular pathology, with superimposed diffuse, CAD. The prevalence of presurgical interventional options means that patients now undergo more aggressive medical therapy and multiple intracoronary dilation attempts before being referred for surgical evaluation. As a result, they are often referred at an older age and with more complex comorbidities, with more diffuse disease, persistent dysrhythmias, and worsening ventricular function. This older, sicker cohort of patients now referred for surgery are understandably at much

higher risk for postoperative morbidity and mortality than in previous eras. Consequently, contemporary surgeons often face difficult therapeutic dilemmas that usually requires a more flexible, systematic, and thoughtful approach. In fact, current decision-making is more often a result of multidisciplinary heart teams, utilizing broad, evidence-based data as a foundation for complex medical decisions.<sup>5</sup>

The pathophysiologic combination and interaction between valvular heart disease and associated CAD is complex. Progressive valvular heart disease clearly impacts ventricular function. The additional impact of CAD has synergistic potential to further affect ventricular morphology and physiology. In particular, the deterioration in contractile strength caused by myocardial infarction and subsequent regional wall motion injury causes progressive distortion of ventricular shape as the infarcted muscle compensates through tissue remodeling. Loss of contractile strength and remodeling after ischemic injury eventually leads to cavity dilation, with resulting effects not only on ventricular function, but also on mitral valve performance. As valvular and subvalvular elements lose their important geometric relationships, functional valvular incompetence develops. In patients with valvular heart disease, coronary obstructions may be symptomatic or asymptomatic, but the decision to intervene surgically is often made regardless of the presence of ischemic symptoms, in order to have a protective effect toward the additive pathophysiology of concomitant cardiac diseases.

Under most circumstances, surgeons attempt to treat both valvular and CAD simultaneously. However, a combined approach leads to a prolonged and potentially complicated procedure. Accordingly, the increased risks of a combined operation demand a defined and focused operative strategy. Historically, combined coronary artery and valve operations have had an increased risk for early and late mortality compared to operations for isolated valvular heart disease (Fig. 45-1). This complexity increases the need for careful preoperative assessment of myocardial function and an understanding of the impact on ventricular function of the changing afterload and pre-load associated with valve surgery. Therefore, in adult patients with combined valvular and

**FIGURE 45-1** Long-term survival of DVS patients with or without concomitant CABG. (Reproduced with permission from Leavitt BJ, Baribeau YR, DiScipio AW, et al: Outcomes of patients undergoing concomitant aortic and mitral valve surgery in northern new England, *Circulation*. 2009 Sep 15;120(11 Suppl):S155-S162.)

ischemic heart disease, the assessment of intrinsic left ventricular function assumes paramount importance during the initial consultative process. Clinical signs and symptoms of left ventricular failure should be diligently sought. In addition to history, physical examination, and routine laboratory tests, preoperative echocardiography is mandatory. Intraoperative transesophageal echocardiography (TEE) is used to correlate preanesthetic imaging and is utilized for accurate planning of all valvular interventions, and has become standard of care in most institutions. Immediately after weaning from cardiopulmonary bypass support, intraoperative TEE is carefully reviewed by the surgeon, anesthesiologist, and imaging team to evaluate the repair. If necessary, resumption of cardiopulmonary bypass support can then be done to perform additional repair efforts; the post-bypass TEE is critical for this evaluation, and requires a commitment from the entire team to be sure that the reparative efforts are optimal before the operation is terminated.

It is also important preoperatively to attempt to distinguish heart failure resulting from valvular disease from myocardial dysfunction owing to coronary ischemia. Myocardial viability assessment may be useful in eliciting ventricular size and functional changes that are exacerbated under stress conditions and may help delineate the underlying pathology, especially of the mitral valve. At cardiac catheterization, in addition to coronary artery angiography, left ventricular end-diastolic pressure and pulmonary pressures measurements may yield additional information about left- and right ventricular function and supplement noninvasive assessments of valve function and coronary anatomy. In centers where it

is available, positron emission tomography (PET) scans and other radioisotope imaging studies can help determine the viability of myocardium with potential reversible ischemia.<sup>6</sup> These assessments are critically important before embarking on concomitant valve and coronary artery surgery; both for determining the operative risk, as well as planning the scope and extent of the surgical approach.

The assessment of valve pathology is covered in detail in previous chapters on isolated valvular heart disease. As has been noted, coronary angiography is not mandatory in all patients with valvular pathology who are about to undergo valve surgery. However, given the prevalence of CAD in aging Western populations, coronary angiography is usually performed in all patients greater than 40 years of age, and selects younger patients with suggestive symptoms or significant risk factors. More recently, patients felt to be at low risk for coronary occlusive disease may be adequately screened with coronary computed tomographic angiography.<sup>7</sup>

Because of the wide pathophysiologic spectrum of valvular and CAD, several frequently encountered valve and coronary artery combinations are considered in this chapter, including: (1) aortic stenosis (AS) with CAD, including strategies for moderate AS, (2) aortic regurgitation plus CAD, (3) mitral regurgitation plus CAD, (4) mitral stenosis plus CAD, (5) AS and mitral regurgitation plus CAD, and (6) aortic regurgitation and mitral regurgitation plus CAD.

Patients may have combined pathology of stenosis and insufficiency, but to avoid unproductive complexity, and because one lesion usually dominates, the somewhat arbitrary categorization noted above will be maintained during

the ensuing discussion. For each entity, the clinical presentation, the pathophysiology of the disease state and its correction, the operative and management approach, short- and long-term results are discussed. Today's surgeon must also be familiar with evolving hybrid techniques, such as staged coronary artery stenting and percutaneous aortic valve replacement (AVR) in the management of patients with combined valve and CAD.<sup>8</sup> Since these new innovative strategies are rapidly gaining acceptance as appropriate options in highly select patients, this chapter will also briefly review some of the more common hybrid approaches where applicable.<sup>9-12</sup>

## AORTIC STENOSIS AND CORONARY ARTERY DISEASE

Aortic stenosis is one of the more frequently encountered valvular lesions in adult populations and will continue to increase in prevalence due to our aging population. Degenerative calcific AS is most common in patients in their sixties, seventies, and eighties<sup>13-15</sup> and often is associated with CAD.<sup>16</sup> This disease combination is usually gratifying to treat because the response to surgical relief of AS and coronary artery obstructions is significant, immediate, and relatively durable.

### Clinical Presentation

Patients with AS are asymptomatic initially due to compensatory mechanisms within the left ventricle. Eventually patients can present with angina pectoris, congestive heart failure, syncope, or some combination of these as the stenosis progresses and the compensatory mechanisms begin to fail. When significant coronary artery obstruction is present, in addition to valvular obstruction, angina pectoris is almost always manifest. However, angina pectoris can occur in the absence of significant coronary artery obstructions due to insufficient diastolic coronary flow across a severely stenotic valve. Identifying symptoms of myocardial ischemia or congestive heart failure in patients with concomitant AS and significant CAD is generally straightforward. Accurate discrimination of subtle neurologic symptoms, such as syncope, presyncope, transient ischemic symptoms, or orthostatic hypotension, may be more difficult to elicit, and careful questioning regarding transient symptomatology is required. Symptoms suggestive of carotid artery obstruction should be sought and appropriately evaluated with carotid artery ultrasound and Doppler scanning, since the murmur of AS often radiates into the neck and can obscure the detection of bruits.

Prominent findings on physical examination include the typical late-packing mid-systolic crescendo murmur heard in the aortic area, radiating into the right neck. Signs of congestive heart failure with rales on chest auscultation or peripheral extremity edema may be present in later stages. The electrocardiogram may show left ventricular strain and increased QRS height due to left ventricular hypertrophy. If the patient has suffered a recent or remote myocardial infarction, then

typical ischemic electrocardiographic changes may also be present. The echocardiogram usually shows calcified and immobile aortic valve leaflets producing a contracted aortic orifice with the resultant compensatory hypertrophied left ventricle. Evidence of calcifications extending into the sinuses of Valsalva and/or the left ventricular outflow tract should be carefully evaluated. Significant acceleration of trans-valvular flow velocities, estimates of reduced outflow areas, and flow turbulence with Doppler confirms the reduced outflow area. The transaortic valvular gradient also can be determined at catheterization and is often helpful, though modern m-mode echocardiography and Doppler imaging analysis has supplanted catheter gradient assessments in many hospitals due to correlated accuracy.

The preoperative evaluation of patients with AS, CAD, and poor ventricular function is complicated. Patients with poor ventricular function often generate relatively low transaortic valve gradients. This renders the calculation of valve area for the assessment of critical AS less accurate. In those cases where poor cardiac output from left ventricular failure leads to a less-than-expected gradient across the left ventricular outflow tract, the morphologic demonstration of valve immobility and heavy leaflet calcification is an important confirmatory sign that hemodynamically significant AS is present. Fortunately, even in the presence of a low gradient, if echocardiographic signs of significant valve stenosis are present, and if left ventricular intracavitary pressure exceeds 120 mm Hg in systole, mortality rates for valve replacement are acceptable, and the clinical response to surgery is typically good.<sup>17</sup> In stark contrast, however, a poorly contractile, thinned-out left ventricle with low transvalvular gradients in the presence of low intracavitary systolic pressures, usually suggests that the operation carries high risks, and due to inadequate ventricular reserve, may be of very limited benefit. On the other hand, a poorly contractile ventricle that has normal, or even increased wall thickness, will usually recover significant contractile force if a substantial amount of reversible ischemic myocardium is demonstrated, and if the degree of AS is significant. In addition to ventricular function, other important determinants of the risks and advisability of surgery include patient age, functional status (ie, "frailty index"), presence of previous cardiac operations, and the presence of other comorbidities that affect end-organ function, especially renal and pulmonary function.

### Pathophysiology

Aortic stenosis produces impairment of left ventricular emptying during systole, which ultimately is the source of all the symptoms and signs of AS. Most patients with AS have hypertrophied and thick-walled left ventricles to overcome the obstructive valve orifice. Contractile function is initially good, and ejection fraction is usually maintained because of these compensatory mechanisms for some time. In later stages of the disease, the ventricle begins to fail due to persistently severe afterload resistance, with enlargement

**FIGURE 45-2** Starling curve of heart failure.

and global diminution of contractile function as the patient progress up the Starling curve of heart failure (Fig. 45-2). At any stage of the disease, the additional presence of critical coronary artery obstruction can cause specific regional wall motion abnormalities that may be exacerbated by stenosis of the aortic valve. Significant three-vessel CAD may itself lead to temporary global ventricular dysfunction, which may be reversible with revascularization apart from any valve replacement effects.

In patients with critical AS and good ventricular function, valve replacement immediately reduces left ventricular afterload. Because most patients with AS have thick-walled hypertrophied ventricles, intraoperative subendocardial ischemia may be more difficult to avoid during aortic cross-clamping and subsequent cardioplegic arrest. Although revascularization should not decrease left ventricular contractility, and should actually improve it long-term, some myocardial stunning with a temporary decrease in global and regional left ventricular contractility inevitably results from the surgical procedure.<sup>18-21</sup> This, of course, assumes even more important pathophysiologic significance in patients with poor ventricular function preoperatively. Diastolic dysfunction may also occur postoperatively, causing a less compliant left ventricle. The most extreme example of this was the so-called “stone heart”<sup>22</sup> that occasionally plagued early cardiac surgery pioneers who first attempted AVR surgery. Fortunately, modern myocardial preservation strategies have eliminated this feared complication through the liberal use of antegrade and retrograde delivery techniques and more physiologic cardioplegic solutions that optimally protects myocardial cellular integrity and tissue function.

Postoperatively, patients usually enjoy a dramatic improvement in symptoms. Relief of left ventricular outflow obstruction immediately leads to enhanced cardiac output and perfusion of vital organs. In addition, left ventricular remodeling and regression of hypertrophy usually occurs over time.<sup>21</sup> Simultaneous correction of myocardial ischemia can lead to improved subendocardial perfusion, as well as recruitment of formerly hibernating myocardium. The optimal final result is regression of hypertrophied ventricular mass, improved

diastolic relaxation, balanced transmural coronary perfusion, and elimination of left ventricular outflow obstruction, culminating in recovery of normal ventricular function.

## Moderate Aortic Stenosis and Coronary Artery Disease

Symptomatic, severe AS is universally agreed to benefit from AVR at the time of coronary revascularization, but the management of patients with CAD and either mild or moderate AS continues to remain a matter of controversy. The earliest debates centered on the anticipated risks of a future reoperation, particularly in a population of advanced age, versus the risks of imposing on a patient a more complex initial operation with subsequent lifelong prosthetic valve concerns that may not be immediately necessary. Given the relatively reduced 10-year survival in advanced age patients undergoing cardiac surgery, valve durability was not considered to be a central factor limiting the success of a combined initial AVR/coronary artery bypass graft (CABG) strategy. Thus, the initial opinion favored a liberal AVR/CABG combination approach in patients with moderate AS, as the reoperative risks were considered the more dangerous of the two options. However, the early STS data base for AVR/CABG outcomes clearly showed a mortality nearly double that for isolated CABG (6-7% and 2-3%, respectively)<sup>23</sup> challenging the belief that initial combined valve-CAD operations were generally safer in terms of primary mortality and morbidity risks. Moreover, as experience with reoperations has grown, more recent studies demonstrate much lower risks of reoperation for AVR in post-CABG patients that rival levels similar to initial AVR/CABG procedures.<sup>24</sup> In fact, the lowered risks of redo sternotomy for primary AVR after previous CABG (6-7%) has now shifted the debate from one of concerns over the risks of reoperation, to predicting the incremental progression in AS if it is withheld at the initial CAD surgery.<sup>25-27</sup>

Although there is no clearly identified method of predicting valvular progression, and surgical expertise is critical in formulating a surgical strategy and timing of intervention, estimates of the rate of progression of AS may help provide support for valve replacement, even without hemodynamically critical disease.<sup>28</sup> For instance, it has been established that the rate of valvular progression is more rapid if the valve is heavily calcified, and if the patient has advanced atherosclerotic systemic disease or renal failure.<sup>25</sup> Studies also demonstrate that age and valvular gradient at the time of diagnosis are important criteria to consider.<sup>27</sup> Verhoye et al<sup>29</sup> found that using echocardiography on a serial basis, AVR is recommended to be added to the revascularization procedure for younger patients (<70 years) if their peak gradient is >25-30 mm Hg, on the assumption of reasonable longevity and the probability AS would bear future symptoms. In older patients (>80 years), competing causes of mortality rationally increases the thresholds for concomitant replacement, and AVR is added only if their peak gradient exceeds 50 mm Hg, as longevity is often related to other factors before AS progression occurs.<sup>25</sup> Furthermore, studies show that reoperation

for AVR after CABG rarely occurs within 5 years of CABG.<sup>26</sup> Consequently, from a survival standpoint, little is gained from adding AVR to patients >80 to 85 years of age at the time of coronary revascularization unless the valve is symptomatic or has severe, but incidentally identified hemodynamics.<sup>25,26</sup> In certain extremely high-risk cohorts, a multidisciplinary team may decide on a “hybrid” approach, utilizing percutaneous coronary artery stenting for major coronary artery obstruction, followed by percutaneous AVR (TAVR).<sup>30-32</sup>

Despite the recent trend outlined above favoring isolated CABG when concomitant moderate AS exists, there is also evidence that favors concomitant valve replacement in some patients with moderate AS who are referred for surgical myocardial revascularization.<sup>33-36</sup> In one study,<sup>33</sup> survival rates at both 1 year and 8 years were superior for patients who underwent valve replacement for moderate AS (gradient >30 mm Hg or gradient <40 mm Hg with valve area between 1.0 and 1.5 cm<sup>2</sup>). One-year survival was 90% in those having valve replacement compared to 85% in patients having CABG alone. Similarly, 8-year survival (55 vs 39%) was statistically significantly better ( $p < .001$ ). Although this data may reveal some bias in healthier patients receiving concomitant AVR/CABG than their more chronically ill peers who were felt not to tolerate more extensive surgery and were only offered isolated CABG, it remains true that this dichotomy of patient groups is commonly seen in clinical practice. Thus, support for both strategies is rational and expected, and can be used to maintain a flexible approach when faced with moderate AS and severe CAD in patients of wide-ranging clinical conditions.<sup>25-29</sup>

In summary, given the absence of convincing data that unilaterally supports an operative strategy for the treatment of moderate AS, at the time of surgical coronary revascularization, it is best to individualize patient selection carefully, relative to surgeon and institutional expertise and practice. Significant patient comorbidities, and risk/benefit assessment, including an accurate estimate of expected rehabilitation potential (particularly in frail, elderly candidates), must be contemplated. Review of the initial and recent data and strategies derived from both experience, as well as available relevant data demonstrates that a flexible and individualized approach is warranted to yield the best patient outcomes.

## Operative Management

Monitoring for surgery of the aortic valve and coronary arteries includes catheters and measurements that have become standard for most cardiac surgical operations. These include an arterial line (usually in the radial artery for blood pressure and blood gases) and an optional pulmonary artery catheter for measurement of pulmonary artery pressures, and cardiac output by thermodilution, with optical sensors for continuous estimation of mixed venous oxygen saturation. While the pulmonary artery catheter has a balloon at its tip, occlusion wedge pressure is rarely measured in the perioperative period because of the danger of pulmonary artery rupture. Particularly useful information

is provided by continuous measurement of mixed venous oxygen saturation. Of late, use of arterial flow or central venous monitoring devices, along with TEE, provides satisfactory estimates of continuous cardiac outputs and monitoring of volume management. This has significantly reduced our reliance on traditional, but more invasive, pulmonary artery catheters.

The perfusion setup is standard and similar to that for isolated coronary artery bypass. A single aortic cannula is ordinarily placed in the distal ascending aorta. A single two-stage venous cannula is placed via the right atrial appendage with its tip positioned in the inferior vena cava. After establishment of cardiopulmonary bypass, the patient is usually cooled to 32 to 34°C, during which time a left ventricular vent is positioned via the right superior pulmonary vein. With the heart well emptied, the aortic cross-clamp is applied during a temporary reduction in pump flow. Thereafter, the heart is arrested with cold (4°C) potassium crystalloid or blood cardioplegia. Low aortotomy incisions are recommended for maximal visibility, with the incision directed toward the noncoronary sinus if annular or root enlargement is anticipated. After valve excision, implant techniques according to each surgeon's preference is performed. In situations of low-lying coronary ostia, suture techniques may need to be varied to prevent ostial compression. Prior to closure, the valve and coronary ostia are carefully reinspected a final time for clearance and embolic debris, and the aorta is closed. Deairing maneuvers are routine, and TEE aids assurance of complete removal, as well as early detection of proper prosthetic function.

A combination of antegrade and retrograde cardioplegia is optimal. The initial dose of cardioplegia (15 mL/kg) is typically split into a two-thirds antegrade and one-third retrograde dose, with subsequent doses of 200 to 300 mL cardioplegia delivered via the retrograde catheter every 20 minutes throughout the duration of cardiac arrest during the operation. This is particularly convenient because retrograde cardioplegia can be given even after the aortic root is opened without disrupting exposure or flow of the operation. In patients with significant left ventricular hypertrophy, light ventricular and inferior septal protection by retrograde cardioplegia perfusion alone may be inadequate. Handheld direct antegrade perfusion directly into the coronary ostia may be helpful.

The combination of aortic valve disease and CAD in patients has historically been accepted to be a marker of significantly reduced longevity.<sup>37</sup> In the elderly, with reduced life expectancies, bioprosthetic valve durability remains the valve of choice, particularly when associated with concomitant CAD.<sup>38</sup> Currently, with the advent of new bioprosthetic valve technology with calcium mitigation processing, and proven structural longevity, there is a trend toward increased tissue valve utilization.<sup>39,40</sup> As a result, many younger age patients considering the obligation of lifelong anticoagulation and the improvements in valve design and durability are opting to receive bioprosthetic valves instead of mechanical prostheses.

**FIGURE 45-3** Adjusted survivorship by age among patients undergoing AVR + CABG. (Reproduced with permission from Likosky DS, Sorensen MJ, Dacey LJ, et al. Long-term survival of the very elderly undergoing aortic valve surgery, *Circulation* 2009 Sep 15;120(11 Suppl):S127-S133.)

## Results

Early hospital mortality after concomitant AVR and CABG ranges from approximately 2 to 10%. In earlier studies, but more recent studies suggest that modern operative management reveals very similar outcomes and mortality risks in patients having isolated AVR and those having combine AVR/CABG.<sup>26,35,36,48,42-47</sup> Higher mortality is observed in patients with more severe symptoms of heart failure and impaired ventricular function preoperatively, as well as the elderly or other patients with numerous comorbidities. The most frequent causes of operative death are low-output cardiac failure, myocardial infarction, and arrhythmia. Incremental risk factors for hospital death include patient age, functional class, diffuse CAD, and poor preoperative ventricular function. In a number of studies, late survival has ranged from 60 to 80% at 5 years and 50 to 75% at 8 years postoperatively (Fig. 45-3).<sup>33,42-47</sup> By multivariate analysis, risk factors for reduced late survival include older age, cardiac enlargement, and more severe preoperative clinical symptoms. The use of a mechanical prosthesis at valve replacement has been associated with similar long-term survival though lower long-term event-free survival.<sup>39</sup> Nonetheless, many elderly patients still have acceptable results following relief of AS, even those undergoing redo valve surgery that is combined with coronary revascularization.<sup>47</sup> As discussed previously, choice of valve type is a complex issue that takes on even more importance in combined valve-coronary artery surgery. A frank discussion of the advantages and drawbacks of each valve option continues to be an important component of the preoperative evaluation and planning for this type of surgery. In some circumstances, consideration of alternative procedures such as coronary artery stenting followed by percutaneous valve

replacement may be indicated and necessary in otherwise inoperable or extreme risk patients.<sup>5,8,49</sup>

## AORTIC REGURGITATION AND CORONARY ARTERY DISEASE

Significant isolated aortic regurgitation occurs less often in older populations, though it may be associated with AS when the valve becomes immobile. Aortic valvular regurgitation is also less often encountered with significant CAD than in patients with AS. Most series of patients undergoing AVR and CABG include a relatively small number (10 to 25%) of patients with aortic insufficiency as compared to AS.<sup>36,42-44</sup> Although the operative management of patients with aortic regurgitation and CAD is similar to that previously described, aortic insufficiency produces different pathophysiologic effects that have implications for perioperative management. Moreover, the presence of an incompetent aortic valve introduces nuances to the intraoperative management and myocardial protection of these patients, primarily due to preoperative ventricular decompensation.

## Clinical Presentation

Patients with aortic regurgitation and CAD usually present in one of three ways. The aortic regurgitation may be asymptomatic and detected incidentally during evaluation for symptomatic coronary disease. Second, the patient may be asymptomatic, yet a routine physical examination reveals a murmur of aortic insufficiency that leads to cardiac evaluation and detection of coronary disease. Finally, patients may present relatively late in the course of valvular heart disease

with congestive heart failure caused by decompensation of the volume-overloaded left ventricle from long-standing insufficiency or with superimposed ischemic ventricular damage from combined CAD. Insufficiency of the aortic valve may also occur with dilatation of the ascending aorta that often involves with the coronary sinuses, particularly in patients with bicuspid valvular anatomy. Patients, therefore, may present within a broad spectrum of clinical signs and symptoms ranging from no symptoms and essentially normal physiology, to classic ischemic syndromes and severe congestive heart failure. The physical signs also depend on the nature of the presentation. In general, all patients with significant aortic insufficiency have an audible early diastolic regurgitant murmur. In late stages, rales and peripheral edema and other advanced signs of congestive heart failure usually occur with a prominent diastolic murmur.

The preoperative evaluation of a patient with aortic insufficiency and CAD is no different from that previously described for patients with AS and ischemic heart disease. Echocardiography is particularly useful in detecting aortic regurgitation because a physiologically significant murmur can be difficult to detect. In addition, echocardiography gives important information regarding both ventricular contractile function and ventricular size. Because many patients with aortic regurgitation are usually asymptomatic until marked left ventricular dilation occurs, careful evaluation for changes in ventricular size or function is important. The presence of these changes may constitute an indication to proceed with surgical intervention in the absence of significant symptoms.

## Pathophysiology

Aortic regurgitation increases left ventricular preload and causes left ventricular dilatation. Dilatation does not occur acutely; however, patients with acute aortic insufficiency are often severely symptomatic owing to a sudden increase in left ventricular end-diastolic pressure and a dramatic decrease in net forward cardiac output. Global left ventricular dysfunction caused by CAD also can contribute to left ventricular dilatation. Valve replacement relieves some of the preload but does not immediately result in improved left ventricular contractility. Revascularization of ischemic, hibernating myocardium in patients with AR and severe CAD may produce more immediate improved contractility as compared to patients with long-standing isolated aortic insufficiency.<sup>48,50</sup>

The indications for surgery in aortic regurgitation are reviewed in depth in the section on aortic valve disease. When CAD is also present, ischemic regional wall motion abnormalities can usually be distinguished from severe, global ventricular dilatation due to severe aortic valvular insufficiency. In patients with symptomatic AR who also have diffuse three-vessel CAD, however, assigning the primary cause of global left ventricular dysfunction to either ischemia or acute valvular-related ventricular dilatation is difficult. Attempting to distinguish between the relative impact of either valvular insufficiency or CAD on ventricular function is of paramount importance in the preoperative assessment and risk

stratification of these patients. This is because regional wall abnormalities due to CAD are more likely to immediately improve after myocardial revascularization, as compared to patients with global, severe ventricular dilation caused by long-standing AR. In difficult cases, an evaluation of myocardial viability (with thallium or PET scanning) may be helpful in evaluating candidates for surgery. Decisions about timing of aortic valve surgery in the presence of CAD are different from those in cases of isolated valvular disease, with the usual result that the valve is replaced earlier in the course of the valvular disease due to the pressing nature of symptomatic myocardial ischemia.

## Operative Management

The operation is conducted in a similar fashion to that described for AS and CAD. However, in the presence of significant aortic valvular insufficiency, antegrade cardioplegia in the aortic root is often less effective because a large portion of the cardioplegia solution leaks into the left ventricle due to valvular incompetence. As a result, retrograde cardioplegia through the coronary sinus is strongly recommended. However, since retrograde cardioplegia is recognized to be less effective in protecting right ventricular myocardium due to inconsistent venous anatomy, periodic delivery of antegrade cardioplegia using handheld catheters is advised. Technical operative details are essentially the same as those outlined earlier for AS operations.

Considerations in weaning from cardiopulmonary bypass are somewhat different from those described for AS. Patients with aortic regurgitation are more likely to have dilated ventricles that poorly tolerate increases in afterload. TEE has proved invaluable in successfully managing adjustments in preload and afterload during weaning from cardiopulmonary bypass. In patients with volume-overloaded ventricles caused by aortic insufficiency, vasodilatory inotrope infusions, such as milrinone and dobutamine, have an important role because they provide both inotropic support and ventricular unloading. In some circumstances, use of an intraaortic balloon pump may be necessary and beneficial in patients with marginal functional reserve. In rare instances, mechanical circulatory assistance with a ventricular assist device is required. Its use is generally reserved for younger patients without comorbid conditions in whom prompt improvement in ventricular function is anticipated.

## Results

Early results after operation for aortic regurgitation and CAD include an expected hospital mortality rate of less than 10%.<sup>36,42,48</sup> Incremental risk factors for hospital death are similar to those described previously, with advanced age and poor ventricular function, combined with the presence of diffuse CAD, having the greatest impact. Late survival after this operation is similar to that for AS and CAD (Fig. 45-3).<sup>48</sup> Despite the impression that patients with aortic insufficiency and CAD do not do as well as those with AS, aortic

insufficiency has not been an independent risk factor for early or late mortality.<sup>48</sup> As expected, recovery of ventricular ejection fraction does have a favorable impact on late mortality. Although some improvement of function can occur with elimination of the volume overload and revascularization in patients with combined valvular and CAD, when ventricular dilatation and dysfunction occur in the setting of chronic aortic regurgitation, these often are irreversible changes. Overall, recovery of ejection fraction and ventricular function in patients with aortic insufficiency is less when compared with AS when both are corrected in the later stages of the disease process. This observation is the primary reason that valve replacement is recommended for aortic valvular insufficiency before irreversible changes in ventricular morphology and function have occurred. However, although failure of recovery of ventricular function in this setting may have an impact on long-term survival, even patients with late stage aortic valvular insufficiency should tolerate valve replacement surgery.

## MITRAL REGURGITATION AND CORONARY ARTERY DISEASE

Successful management of patients with mitral regurgitation and CAD remains one of the most challenging and controversial topics in adult cardiac surgery.<sup>51</sup> This group of patients tends to be complex, and their surgical care is accomplished at higher risk.<sup>52-57</sup> This is almost certainly because of the complex interaction between the left ventricle and that of the mitral valvular apparatus. Normal mitral valve function depends on healthy supporting ventricular muscle to maintain proper alignment. Similarly, normal ventricular function depends on competence of the mitral valve. Abnormal valve function due to CAD occurs because of the impact of ischemia on the mitral valve apparatus, damaging subvalvular structural integrity including papillary muscle involvement. Remodeling of ischemic zones eventually leads to ventricular dilatation, and subsequent annular geometry.<sup>58</sup> Therefore, there is a unique, amplifying potential when CAD and mitral valve disease coexist, making patient management with this combination of pathophysiology more complicated, and the surgical management potentially more difficult.

In patients with preserved ventricular function, the pathophysiology and management strategies are not significantly different from those for treatment of isolated mitral regurgitation or CAD. Patients with acute onset of mild or moderate mitral insufficiency, in the presence of global ventricular dysfunction secondary to severe CAD, can be safely treated by coronary revascularization alone.<sup>59</sup> If it becomes necessary to include mitral valve annuloplasty to myocardial revascularization, the operation becomes more complex and longer.<sup>60,61</sup> Therefore, as described previously, a carefully conceived operative plan with special attention to myocardial preservation is important. However, the more interesting problems are in those patients with mitral insufficiency and CAD who do not have normal ventricular function. Often these patients present with recurrent ischemia, in addition to

previous myocardial infarction, that culminates with resultant regional wall motion abnormalities that produces mitral insufficiency.<sup>62</sup>

## Clinical Presentation

The spectrum of clinical presentation ranges from patients who are asymptomatic to those who are moribund in cardiogenic shock. The degree of mitral insufficiency involved can widely vary from mild insufficiency when associated with a limited ischemic event causing minor segmental wall motion abnormalities, to severe regurgitation and global left ventricular failure from acute ischemic rupture of a papillary muscle. Patients who present with acute syndromes are often related to myocardial infarction and demonstrate the sudden development of mitral insufficiency. These patients are extremely ill when they present in congestive heart failure, often presenting in profound cardiogenic shock. Management of these patients can be difficult and challenging. When faced with extreme mitral insufficiency and cardiogenic shock, immediate IABP support should be instituted for cardiac support and to provide valuable mechanical afterload reduction of the acutely injured left ventricle.

Findings on physical examination obviously relate to the nature of the presentation, and can range from signs of mild mitral insufficiency to severe congestive failure and cardiogenic shock. An electrocardiogram may show evidence of acute or chronic ischemia, and all patients should undergo echocardiography. TEE should be available for intraoperative use. Transesophageal echocardiogram is particularly useful because it gives information in regard to valvular function, left ventricular geometry and contractility, ventricular wall thickness, and associated regional wall motion abnormalities. Also the status of the other valves, particularly the tricuspid, can be quickly assessed to determine if they may require surgical attention as well. Cardiac catheterization is performed in these patients for the same reasons outlined for patients with aortic valve disease.

## Pathophysiology

A detailed understanding of the pathophysiology of functional mitral insufficiency is important for planning the operative approach. Limited regional wall motion abnormalities involving the papillary muscle and adjacent ventricular wall can produce dynamic changes that produce corresponding insufficiency of specific mitral valve regions. More global ventricular dysfunction from CAD can produce ventricular dilatation with profound mitral annular dilatation and progressive mitral insufficiency. The jet of ischemic mitral regurgitation typically is centrally or posteriorly directed on ECHO. Mitral regurgitation increases left ventricular preload and decreases afterload at the expense of cardiac output. Ischemic damage causes ventricular dilatation with decreased contractility and an increase in left ventricular filling pressures. These combined lesions cause synergistic decompensation, chronically leading to pulmonary hypertension with

secondary tricuspid regurgitation. Cardiac output may be very low, especially in patients with acute mitral insufficiency. Mitral insufficiency may occur in association with CAD, but often the CAD is the cause of functional mitral insufficiency. The pathophysiology of ischemic mitral insufficiency results in tethering or retraction of the valve leaflets, annular dilatation, geometric displacement of the subvalvular apparatus, or some combination of all of these. Correction of mitral insufficiency either by valve repair or valve replacement produces an instantaneous increase in left ventricular afterload. The ventricle no longer has the low-impedance left atrial chamber into which to eject blood and must overcome systemic afterload in systole. Even when myocardial ischemia is reversible, recruitment of hibernating myocardium may take time. These factors, in combination with the sudden increase in left ventricular afterload, contribute to the difficulty and increased risk of managing this entity. Secondary right ventricular failure may occur because pulmonary hypertension, if present, does not decrease immediately after mitral valve repair or replacement, and CAD also may affect right ventricular function.

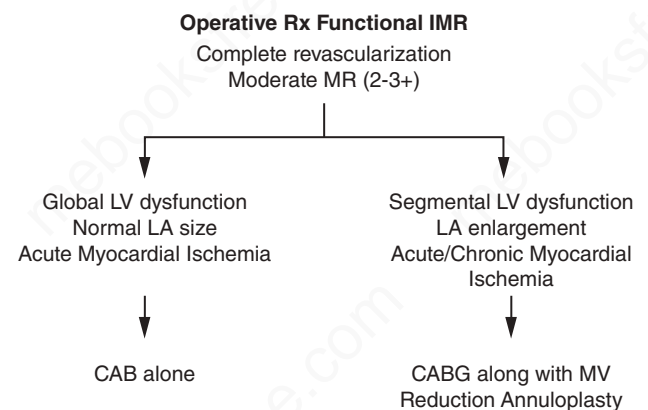

Symptomatic CAD in the presence of moderate or severe insufficiency in the setting of regional wall motion abnormality is the usual indicators for combined surgery. As noted, patients with acute illnesses may be in extremis and may benefit from temporizing measures.<sup>63</sup> Ventricular dysfunction is not a contraindication to surgery, especially if it is caused by reversible ischemia. Patients with global, irreversible, and severely dilated cardiomyopathy with severe mitral insufficiency, however, should not be operated on because the ventricle tolerates the increase in overload poorly and results are unsatisfactory. Severe diffuse CAD in which complete revascularization cannot be accomplished is a significant indication of extreme risk, as well. Estimation of the viability of the myocardium and demonstration of reversible ischemia using thallium or PET scanning therefore are important in stable patients. Left atrial enlargement in long-standing mitral valve insufficiency is common, and patients often present with atrial fibrillation. This condition also contributes to the reduction in cardiac output and ablation of the arrhythmia at the time of surgery may confer addition benefit.

## Operative Management

Preoperative decision strategies in patients with mitral regurgitation and CAD remains controversial.<sup>64,65</sup> The decision for the necessity of associated mitral valve intervention in this setting becomes critical because if moderate insufficiency is left untreated, the patient may be compromised. However, mitral regurgitation in the presence of acute CAD with regional ventricular decompensation that is caused by reversible myocardial ischemia can improve with isolated revascularization.<sup>66</sup> In many instances, however, residual significant mitral valve regurgitation may remain. It is important, therefore, to distinguish organic from functional mitral insufficiency as well as acute mitral insufficiency from ischemia as opposed to a more chronic mitral valvular pathology secondary to previous

ischemia and subsequent wall motion abnormality. Intraoperative TEE is an essential tool for assessment of mitral valve function in this setting, though the vasodilator effects of general anesthesia and subsequent decrease in afterload may minimize the appearance of the insufficiency.<sup>65</sup> Patients with no preoperative congestive heart failure, normal left atrial dimensions, normal pulmonary pressures, and mild to moderate mitral insufficiency by TEE after induction of anesthesia typically do not need mitral valve intervention.<sup>66,67</sup> Many of these patients will appear to have more mitral regurgitation and higher pulmonary pressures at catheterization or when they are ischemic than when they are under anesthesia. Furthermore, although mitral valve repair improves mitral valve regurgitation volume, it does not infer late mortality advantages over revascularization alone in large studies.<sup>67</sup> Complete myocardial revascularization alone may suffice for milder forms of initial valvular insufficiency (Fig. 45-4).

Despite a lack of consensus on the prognostic value of concomitant mitral valve repair at the time of revascularization, several recent studies suggest that the quality of modern surgical results justifies a more aggressive approach to valve repair in patients with moderate mitral insufficiency and CAD.<sup>51,63-65,67,68</sup> Most patients with ventricular enlargement and annular dilation secondary to CAD with functional mitral insufficiency determined to be significant may be managed with annuloplasty alone.<sup>69</sup> Restricted leaflet motion is frequently a complication of ischemic changes in ventricular shape and resultant papillary muscle displacement.<sup>70</sup> In patients with calcification, extensive fibrosis of the posterior leaflet, or severely restricted posterior leaflet motion, mitral valve replacement is warranted. Historically, results of mitral repair and CABG are superior to those of mitral valve replacement when repair is technically possible. Anesthetic considerations are similar to those described previously, although it must be recognized that these patients are generally quite compromised. As suggested earlier, intraoperative TEE is particularly important in this group of patients for pre- and post-operative assessment of valve and ventricular function. Setup for cardiopulmonary bypass is similar to that described earlier. The most common incision providing access to the mitral

**FIGURE 45-4** Complete myocardial revascularization alone may suffice for milder forms of initial valvular insufficiency.

valve is in the wall of the left atrium anterior to the right pulmonary veins. Preparative dissection (Sondegaard's maneuver) of the interatrial groove (Waterston's groove) facilitates exposure using this incision. Alternative approaches for valve exposure and their advantages have been described elsewhere.

As noted, patients with papillary muscle rupture caused by infarction usually require valve replacement. Some surgeons have reported success with reimplantation of the papillary muscle, but this strategy is risky in these patients because the operation must be both expeditious and effective. Multiple attempts to achieve mitral valve competence in this group of critically ill patients are poorly tolerated. A reimplanted, infarcted papillary muscle does not necessarily restore mitral valve competence and also may be subject to early or late breakdown.

As in combined aortic valve and coronary artery surgery, distal graft anastomoses are performed first. At this point, after the atrium has been opened, it may be prudent to undertake an arrhythmia ablation procedure in selected patients with atrial fibrillation. Radiofrequency or cryoablation probes can be used to create a standard lesion set within the left atria, as described in Chapter 55. The left atrial appendage should be oversewn. Valve repair or replacement is then carried out, followed by performance of the mammary artery anastomosis. Proximal graft anastomoses can be done either after release of the cross-clamp in place.

Weaning from cardiopulmonary bypass is similar to that in patients with aortic insufficiency and CAD. Again, in this

group of patients, afterload reduction using pharmacologic agents such as dobutamine and milrinone may be indicated. There should be a low threshold for insertion of the intra-aortic balloon postoperatively. Many of these patients, particularly when emergent, have severely compromised ventricular hemodynamics and may be quite tenuous for hours to days after surgery.

Strict attention must be paid to right ventricular function and intraoperative right ventricular myocardial protection in this group of patients. Right ventricular failure must be anticipated and correctly diagnosed and managed. The presence of a falling systemic blood pressure and cardiac output with rising pulmonary artery pressure, pulmonary capillary wedge pressure, and controlled venous pressure should prompt a search for right ventricular failure.

## Results

Hospital mortality for this group of patients is higher than that for most other forms of acquired heart disease. Early mortality rates range from 3% in good-risk patients to 60% in the sickest patients.<sup>64,65,67,68,71,72</sup> The higher mortality is seen in patients with acute ischemic mitral valve disease and severe ventricular dysfunction who require emergency surgery. Incremental risk factors for early death include age, functional class, ventricular function, elevated pulmonary pressures, and cardiogenic shock. Late survival in patients with this entity is 55 to 85% at 5 years and 30 to 45% at 10 years (Fig. 45-5).<sup>52-57,66,72-74</sup>

**FIGURE 45-5** Survival, mitral valve repair versus replacement, with and without CABG. (Reproduced with permission from Thourani VH1, Weintraub WS, Guyton RA, et al: Outcomes and long-term survival for patients undergoing mitral valve repair versus replacement: effect of age and concomitant coronary artery bypass grafting, *Circulation*. 2003 Jul 22;108(3):298-304.)

In general, patients who survive surgery have good relief of symptoms, although recurrent mitral insufficiency remains an issue for some patients who have undergone restrictive annuloplasty.<sup>66</sup> The risk factors for this complication remain incompletely identified, although abnormal ventricular morphology and regional function appear to play a role. Significant risk factors for late death include preoperative functional class, residual postoperative left ventricular dysfunction, and diffuse myocardial ischemia.

## MITRAL STENOSIS AND CORONARY ARTERY DISEASE

Patients with mitral stenosis and CAD usually have good left ventricular function and often are a relatively straightforward group of patients to care for because the mitral stenosis does not subject the left ventricle to abnormal hemodynamic loads. CAD may cause unexpected left ventricular dysfunction, but this is unusual, unless weakness, global ischemia coexists. A common concern in mitral stenosis patients is postoperative right ventricular dysfunction because pulmonary hypertension, with its potential to produce right ventricular failure and tricuspid insufficiency, is often encountered in patients with severe mitral stenosis.

### Clinical Presentation

As implied earlier, mitral stenosis is usually the dominant lesion in patients with mitral stenosis and CAD; therefore, symptoms are typically caused by the valvular lesion. Patients usually present with shortness of breath, orthopnea, and fatigue, despite normal left ventricular function. Atrial fibrillation is a common presenting symptom with mitral stenosis due to left atrial dilatation. Patients with mitral stenosis and CAD infrequently have angina as a presenting symptom. The electrocardiogram may show evidence of right ventricular strain and hypertrophy. TEE confirms the diagnosis of mitral stenosis and usually shows a small left ventricle with preserved contractile function. The right ventricle may be enlarged and hypertrophied. Cardiac catheterization further confirms the diagnosis by showing a gradient across the mitral valve. Other important information gleaned from invasive catheterization includes a measurement of the pulmonary artery pressures and central venous pressure. The degree of pulmonary hypertension is a marker of the severity and duration of mitral stenosis and alerts the surgeon to the potential for right ventricular failure postoperatively. An elevated central venous pressure is a potential sign that right ventricular decompensation has already occurred. Coronary angiography should be done in all patients with angina pectoris, and as noted before, in any patient greater than age 40 years in whom mitral valve surgery is anticipated.

### Pathophysiology

Unlike the other entities described, mitral stenosis and CAD do not have significantly synergistic pathologic effects on the

heart. CAD usually has more profound effects on the left ventricle, since left ventricular mass remains reasonably protected in patients with mitral stenosis until late in the disease. The right ventricle is the chamber most vulnerable to the effects of long-standing mitral stenosis due to increased transpulmonary pressure gradients. However, even with right ventricular hypertension, the potential impact of CAD on right ventricular function in adults is usually not prohibitive. In circumstances involving patients with diffuse CAD and significant ischemic cardiomyopathy, the risks of surgery are elevated, primarily because of global ventricular ischemic dysfunction.

The indications for surgery, not surprisingly, are usually determined by the severity of the mitral stenosis. Patients with significant heart failure symptoms and low cardiac output from mitral stenosis whose calculated valve area is less than 1 cm<sup>2</sup> should have a mitral valve operation, and associated bypass grafting if significant CAD is present. Patients with significant CAD but only mild mitral stenosis may arise, and these patients are well managed with CABG and mitral commissurotomy, if technically feasible. Another alternative in patients considered high risk for surgery, is the staged approach of percutaneous revascularization with stents and balloon mitral valvuloplasty. The number of patients suitable for the latter procedure is relatively small and thus far there are no definitive data supporting this kind of hybrid transcatheter approach to these lesions. These clinical situations are best managed within a multidisciplinary team on an individualized, patient-by-patient basis.<sup>5</sup>

### Operative Management

Monitoring, perfusion setup, and operative sequence are identical to those described for treatment of mitral regurgitation and CAD. TEE is useful to assess both the feasibility of mitral commissurotomy (or more extensive mitral repair) and the postoperative results of attempted valvuloplasty. In most patients with mitral stenosis, however, valve replacement is required because of irreversible calcific and fibrotic damage to the leaflets and subvalvular apparatus. A biological prosthesis is used most often due to a preponderance of advanced age patients, even if the majority of patients have chronic atrial fibrillation from left atrial enlargement. Although long-term anticoagulation is indicated in these patients, use of a biologic valve allows less aggressive anticoagulation regimens in patients often burdened with other comorbidities, and who are judged to be at significant risk for chronic anticoagulation. Particular attention must be directed to preservation of the right ventricle at regular intervals during the operation. In practice, this means that initial and subsequent doses of cardioplegia should be given antegrade, as well as retrograde, because the latter approach usually offers variable distribution of cardioplegia to the right ventricle, proximal inferior septal, and inferior left ventricular regions.

TEE is also an important adjunct in monitoring both right and left ventricular function postoperatively. The early differentiation between left and right ventricular failure is

facilitated by the use of this modality during weaning from cardiopulmonary bypass. If inotropic drugs are required, their selection should be based, in part, on the consideration that pulmonary hypertension and right ventricular failure might be important components of the clinical syndrome. Drugs such as isoproterenol, dobutamine, and especially milrinone (the latter often in combination with norepinephrine or other catecholamines to counteract profound peripheral vasodilatory effects from phosphodiesterase inhibition) may be indicated for their combined beneficial effects on right ventricular contractility and pulmonary vascular resistance. Judicious use of inotropic drugs and careful administration of fluid are usually sufficient to restore adequate cardiac output. The intraaortic balloon is rarely indicated in these patients because right ventricular problems predominate. Temporary support with either a right ventricular assist device or ECMO for acute pulmonary failure may be employed if the above measures are inadequate. Once the acute postcardiotomy failure resolves dramatic decreases in pulmonary artery pressures and subsequent recovery of right ventricular function allows for removal of extraordinary support.

## Results

Early mortality after combined surgery for mitral stenosis and CAD is approximately 8%.<sup>44-46</sup> This is not significantly different from results of surgery in lower-risk patients with mitral regurgitation and CAD. Long-term probability of survival is approximately 50% at 7 years and in one series was not significantly different from that for patients with ischemic mitral insufficiency.<sup>54-56</sup> Interestingly, long-term survival of patients with myxoid degeneration of the mitral valve and CAD (65%) was significantly better than survival of the patients with rheumatic or ischemic mitral valve disease and CAD in at least one series.<sup>52</sup> As implied, rheumatic valve pathology is a risk factor for late death, as is poor preoperative left ventricular function and the presence of ventricular arrhythmias. Interestingly, the use of a bioprosthesis without anticoagulants confers both a survival advantage and an event-free survival advantage in these patients. These data lend support to the hypothesis that biologic valves may be appropriate for mitral replacement in older patients and those with CAD, whose expected life span may be shorter than the anticipated durability of the replacement device.<sup>37</sup>

## AORTIC STENOSIS, MITRAL REGURGITATION, AND CORONARY ARTERY DISEASE

Patients with AS, mitral regurgitation, and CAD often present with AS as the predominant lesion. It is important to note that functional mitral regurgitation may improve after relief of AS with concomitant reduction in left ventricular systolic pressure. If the mitral valve is not intrinsically diseased, it may not require surgical intervention.<sup>75</sup>

## Clinical Presentation

Patients with these diseases often present identically with patients with AS and CAD, but may do so earlier because of the combined valvular lesions. Angina, congestive heart failure, and syncope may be presenting symptoms alone or together. It is relatively uncommon for symptoms resulting from mitral insufficiency to be predominant. Echocardiography is an extremely important tool in this disease combination. Careful evaluation of the mitral valve, often using TEE, is necessary to determine the degree of intrinsic mitral valve disease, because improvement in mitral insufficiency is expected after AVR and relief of left ventricular outflow obstruction.<sup>72</sup> It is critical to determine whether or not the mitral valve has anatomical abnormalities that might not reverse with aortic surgery alone.<sup>73,76</sup> Cardiac catheterization is required, as it is for the other disease entities described.

## Pathophysiology

Aortic stenosis increases left ventricular afterload and therefore can contribute to increasing the amount of mitral regurgitation. Because the combined lesions may cause patients to present earlier in the course of the disease, the left ventricle may be better preserved in this setting than in patients with isolated mitral insufficiency and CAD. Also as noted, the mitral valve may not be structurally diseased. Because of earlier presentation, pulmonary hypertension and subsequent right ventricular failure and tricuspid valve incompetence are usually not prominent features. Because relief of outflow obstruction helps left ventricular function immediately, these patients often do quite well.

The indications for surgery are usually the same as for AS and CAD. Critical AS, when documented, requires valve replacement; if significant CAD is present, CABGs are also done in the sequence previously described. Mitral valve repair is almost always appropriate with annular remodeling when mitral insufficiency is moderate to severe and reparable anatomical abnormalities of the valve are detected. End-stage ventricular dysfunction with ventricular dilatation and myocardial thinning are the primary cardiac contraindications to surgery.

## Operative Management

Anesthesia and perfusion setup are identical to those described for mitral valve and coronary artery surgery. Intraoperative transesophageal echocardiographic monitoring again plays an important role because the intraoperative assessment of mitral valve structure and function before and after bypass is critical. The choice of valve for aortic replacement is the same as described previously. In most situations, however, bioprosthetic valves should be considered, especially if the mitral valve is to be repaired.

Under almost all circumstances in which anatomical abnormalities of the mitral valve are detected, or in which mitral insufficiency is severe, mitral valve repair should be considered. Annuloplasty remodeling may be all that is required

if the mitral insufficiency results from annular dilatation and the insufficiency is symmetric and central. More complex disease may require more extensive repair, or even replacement of the mitral valve. When the decision is made not to operate on the mitral valve, TEE is done to assess residual mitral valve dysfunction following AVR and coronary artery bypass surgery. If moderate or severe mitral regurgitation remains, the valve should be repaired or replaced. This is technically more difficult after the aortic valve has been replaced, because the prosthesis in the aortic position hinders exposure of the mitral valve. Therefore, every effort must be made to assess mitral valvular morphology and function before starting cardiopulmonary bypass, and preferably prior to the induction of anesthesia.

As in the other entities described, distal graft anastomoses are performed first (Fig. 45-6). After these grafts are completed, the aorta is opened and the aortic valve is resected with appropriate annular debridement. Replacement of the aortic valve, however, is deferred until after the mitral valve operation because sutures used for mitral valve repair or replacement may become disrupted during later debridement of the aortic valve annulus. After resection of the aortic valve, the atrium is opened and the mitral operation is performed. The atrium is closed with a vent across the mitral valve. The aortic valve is then replaced and the aorta is closed. The internal mammary artery graft is done last. Proximal graft anastomoses can be done with the aortic cross-clamp in place. It is conceivable that at some point in the future high risk patients with this combination of lesions may undergo catheter-based coronary revascularization, catheter-based AVR, and catheter-based mitral valve repair particularly in high-risk patients.<sup>77,78</sup>

As noted, this group of patients may have preserved ventricular function, and weaning from cardiopulmonary bypass is often straightforward. Inotropic drugs and intraaortic balloon counter pulsation are used as indicated.

## Results

Early hospital mortality is 12 to 16%<sup>77,81</sup> Not surprisingly, predictors of early death include severe mitral regurgitation, lower ejection fraction with more severe symptoms of heart failure, and the presence of severe triple-vessel CAD. Late survival is approximately 60% at 72 months. Multivariate predictors of late mortality include advanced symptoms of heart failure and increased severity of mitral insufficiency.

## AORTIC AND MITRAL REGURGITATION AND CORONARY ARTERY DISEASE

Relatively few patients have insufficiency of both the aortic and mitral valves combined with CAD. Those patients who do usually have rheumatic heart disease and present early in the course of the valvular heart disease. Aortic regurgitation may be the predominant valve pathology in a patient with simultaneous significant CAD. The mitral valve pathology

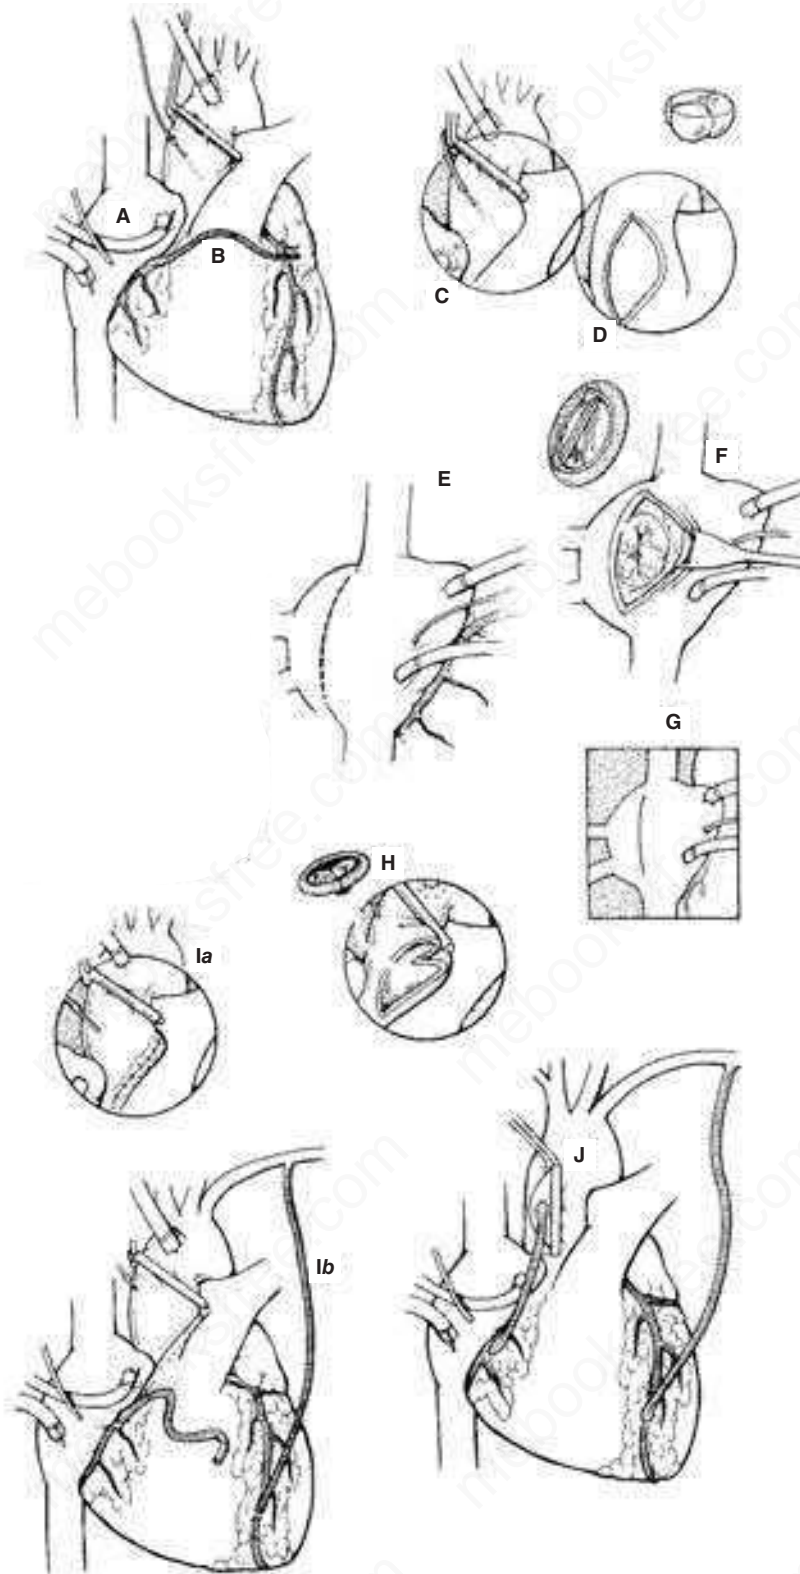

may be secondary to left ventricular dilatation from the aortic lesion and/or from ischemia resulting from the coronary obstructions. Morphologic mitral valve disease may not be present. Because of the interaction of the valve and coronary pathologies, assessment of left ventricular contractility may be difficult for the reason that both preload and afterload are altered. In addition, the presence of reversible ischemia may obscure accurate measurement of ventricular function and reserve. Therefore, assessment of myocardial viability in these patients is often important.

## Clinical Presentation

Most patients with this combination of cardiac lesions present with congestive heart failure. It is unusual to see a patient who has significant insufficiency of both the aortic and mitral valves present with angina as the primary symptom. Typical murmurs of aortic and mitral insufficiency are present, and the patient may have other signs of chronic congestive heart failure, including rales and peripheral edema. If myocardial infarction is a significant component of the pathophysiology and presentation of the disease, evidence of it may be seen on electrocardiogram and echocardiogram. On echocardiography, patients may have regional wall motion abnormalities if infarction has occurred, as well as global ventricular dilatation and dysfunction from the combined valvular lesions and/or diffuse CAD. Cardiac catheterization defines the coronary anatomy and helps to assess the severity of the valvular insufficiency and ventricular dysfunction. Accurate assessment of true left ventricular function is difficult in this entity. Mitral insufficiency may abnormally inflate visual measurements of ejection fraction because the ventricle can eject into the low-pressure pulmonary venous circuit. The misleading ejection fraction, with increased preload volumes due to insufficient aortic and mitral valves, when combined with the potential contribution of dysfunctional ischemic myocardium, make it very difficult to get an accurate estimation of preoperative left ventricular function. Thallium or PET scans may be useful to assess areas of dysfunctional myocardium that may be viable. Transesophageal ECHO may be extremely helpful, with special attention to left ventricular dimensions and bi-valvular anatomy.

## Pathophysiology

Symptoms and signs of left ventricular failure develop as the left ventricle dilates. In patients with rheumatic disease with both valves intrinsically damaged, ischemic disease may be minimal. In the setting of patients with aortic regurgitation and significant ischemia, mitral regurgitation is more likely to be secondary to both of these processes, and valve repair should be possible. Correction of aortic regurgitation reduces preload, whereas correction of mitral insufficiency increases afterload. The chronically dilated myopathic ventricle may not have sufficient reserves to maintain adequate output under these circumstances. Higher postoperative preload may need to be maintained while afterload is reduced. Any

**FIGURE 45-6** Operative sequence for aortic valve replacement, mitral valve replacement, and coronary artery bypass grafting. (A) Cannulation with cross-clamping of the aorta and administration of antegrade and retrograde cardioplegia. (B) Distal graft anastomoses are performed. (C) Aortotomy with standard oblique incision. (D) The aortic valve is resected but not replaced. (E) Standard left atriotomy after dissection in the interatrial groove. (F) Mitral valve repair or replacement with the prosthesis of choice. (G) Closure of the left atriotomy. (H) Aortic valve replacement with prosthesis of choice. (Ia and b) Closure of aortotomy and performance of distal anastomosis with the internal mammary artery. (J) Proximal graft anastomoses are performed. In this illustration, a partially occluding clamp has been applied to the aorta.

additional contractility as a result of revascularization should improve output further. However, because of the multiple, uncontrollable variables that inhibit preoperative assessment of ventricular function, prediction of expected improvement after this operation is difficult.

This consideration is extremely important, since patients with severe and irreversible ischemic myocardial disease and poor ventricular function will not do well with operative treatment. Therefore, preoperative assessments of myocardial viability and reversible ischemia are critical. It is also important to assess whether organic mitral valve disease is present. The best results in these patients are in those in whom no mitral operation, or at most annuloplasty, is required.

## OPERATIVE MANAGEMENT

Details of the operative technique are similar to those described previously. Because of the presence of aortic insufficiency, retrograde cardioplegia must be used in conjunction with handheld ostial cannulas to deliver cardioplegia antegrade. For the reasons enunciated, excellent myocardial protection is important in these patients. TEE is required in the operating room for the assessment of mitral valve function. Residual 1+ to 2+ mitral regurgitation may be acceptable in certain patients because relief of aortic regurgitation can be expected to reduce ventricular size, which may lead to improvement of mitral regurgitation as the ventricle remodels with time. Similarly, myocardial revascularization also may lead to ultimate improvement in ventricular and mitral valve function in those with mild mitral valve insufficiency.

In weaning from cardiopulmonary bypass, afterload reduction is extremely important because of the large preoperative volume overload of the heart. Drugs that reduce ventricular afterload, including vasodilators and inotropic drugs such as milrinone, may be particularly appropriate. The intraaortic balloon pump may be needed and helpful in the perioperative care of these difficult patients.

## Results

Early hospital mortality in this group of patients may be high, and if myocardial failure is severe, overall mortality rates exceed the range already noted for double-valve and coronary artery surgery.<sup>23,79,81</sup> Important determinants of risk in these patients are the familiar ones. In several series, predictors of hospital death and late events included severe mitral regurgitation, lower ejection fraction, more severe symptoms of congestive heart failure, and severe triple-vessel CAD.<sup>80</sup>

# Reoperative Valve Surgery

Julius I. Ejiogor • John G. Byrne • Marzia Leacche

The number of patients undergoing reoperation for valvular heart disease is increasing and will continue to increase as the general population ages.<sup>1</sup> These reoperations most commonly involve structural deterioration of a bioprosthesis or progression of native-valve disease after nonvalve cardiac surgery. Structural failure of a biologic valve should be considered a part of the natural evolution of tissue valves and should be fully appreciated by both the surgeon and the patient prior to implantation.<sup>2</sup> Reoperations are technically more difficult than primary operations because of adhesions around the heart with an associated risk of reentry, the presence of more advanced cardiac pathology, and the existence of more frequent comorbidities such as pulmonary hypertension. Perhaps most importantly, reoperative valve replacement operations often are performed in functionally compromised patients who tolerate complications poorly or who have little reserve.<sup>3</sup> As a consequence of these and other factors, reoperative valve surgery historically has been associated with a considerably higher operative mortality than primary valve surgery, particularly in patients who have had multiple prior replacements.<sup>4</sup> In the modern era, however, with the use of alternative surgical approaches and advanced perioperative care, there has been significant improvement in outcomes.<sup>5-9</sup>

Reductions in operative risk and postoperative morbidity after reoperative valve surgery have been made in the past few years through advances in myocardial protection, as well as alternative perfusion strategies such as the proper use of deep hypothermic cardiac arrest.<sup>10</sup> In addition, use of peripheral cannulation techniques to institute cardiopulmonary bypass (CPB) has become a relatively standard practice in reoperative cases.<sup>11-13</sup> Early institution of CPB prior to reentry prevents injury to the right ventricle (RV) or patent coronary artery bypass grafts during reoperative sternotomy.

Successful replacement of degenerated cardiac valves usually results in symptomatic and hemodynamic improvement. In this regard, improvements in valve design have mitigated but not eliminated primary bioprosthetic failure.<sup>14-16</sup> As such, the risk of re-replacement for bioprosthetic failure remains a significant factor to be considered in the selection of valve type for implantation.<sup>17</sup>

## MECHANICAL VERSUS BIOLOGIC VALVES

The most appropriate valve substitute for an individual patient remains a source of much controversy. This choice should be adapted to each individual patient depending on age, life expectancy, life style, valve size, and cardiac as well as noncardiac comorbidities.<sup>18</sup> Some studies comparing the long-term outcomes between biologic and mechanical aortic valve prostheses have yielded similar results with regard to overall valve-related complications.<sup>19-22</sup> However, most recent large studies have documented that anticoagulant-related bleeding with mechanical valves must be balanced against life expectancy and the risk of biologic valve re-replacement.<sup>23-25</sup> Bioprosthetic valves are known to undergo a time-dependent process of structural deterioration that results in freedom of reoperation of 80% at 15 years.<sup>20</sup> Consequently, structural degeneration of a bioprosthesis is the most frequent indication for reoperation in patients with tissue valves.<sup>19,26</sup>

Despite this, recently improved durability of tissue valves, as well as the availability of stentless valves and homografts, has led to surgeons placing bioprostheses in progressively younger age groups.<sup>18,27-30</sup> Contributing to this trend, many patients do not want to accept the risk of anticoagulant-related hemorrhage associated with mechanical valves: major events 0.5% per patient-year and minor events 2 to 4% per patient-year.<sup>31</sup> In addition, new concepts of valve-in-valve (VinV) interventions are suggesting to patients that there may be re-replacement of bioprosthetic valves in the future.

Mechanical prostheses usually are selected for younger recipients because of their proven durability over time. However, the risk of anticoagulant-related bleeding, as well as thromboembolic events (TEs), in these valves is not trivial and depends on valve design, structural materials, and host-related interactions.<sup>31</sup> In a 12-year comparison of Bjork-Shiley versus porcine valves, Bloomfield et al documented severe bleeding complications in 18.6 versus 7.1%, respectively.<sup>32</sup> Moreover, although endocarditis, dehiscence, perivalvular leak, and pannus formation are associated with both biologic and mechanical valves, acute prosthetic thrombosis is exclusively a complication of mechanical valves.<sup>33,34</sup> In considering

mechanical valve durability, these associated risks cannot be ignored and must be weighed against the anticipated rate of tissue-valve failure and the need for reoperation.

## RISK FACTORS IN REOPERATIVE VALVE SURGERY

In evaluating patients for reoperative valve surgery, certain factors are associated with added risk. For example, Husebye et al, in a review of their 20-year experience<sup>17</sup> with reoperative valve surgery, found specific issues to carry higher risk (see Table 46-1). Overall operative mortality was 7% for the second and 14% for the third reoperation. Operative mortality for the first reoperation (n = 530 patients) was 5.9% in the aortic position and 19.6% in the mitral position. In the aortic position, operative mortality was 2.4% for NYHA class I, 1.6% for NYHA class II, 6.3% for NYHA class III, and 20.8% for NYHA class IV emphasizing the significance of early referral. Regarding the urgency of surgery, the mortality for elective mitral valve reoperations was 1.4%; for urgent procedures, 8%; and for emergency procedures, 37.5%. Based on these findings, the authors have recommended that referral for reoperation be made when valve dysfunction is first noted, that is, before a significant decrement in myocardial function.<sup>17</sup> Similarly, Jones et al reviewed their experience with first heart valve reoperations in 671 patients between 1969 and 1998.<sup>6</sup> Their overall operative mortality for first-time heart valve reoperation was 8.6%, similar to the results published by Lytle et al<sup>35</sup> (10.9%), Cohn et al<sup>4</sup> (10.1%), Akins et al<sup>36</sup> (7.3%), Pansini et al<sup>2</sup> (9.6%), and Tyers et al<sup>37</sup> (11.0%). In the Jones and colleagues series, mortality increased from 3.0% for reoperation on a new valve site to 10.6% for prosthetic valve dysfunction or periprosthetic leak; mortality was highest (29.4%) for associated endocarditis or valve thrombosis. Concomitant coronary artery bypass grafting (CABG) carried a higher associated mortality (15.4%) than when it was not required (8.2%). Among the 336 patients requiring re-replacement of prosthetic valves, mortality was 26.1% for re-replacement of a mechanical valve

compared with 8.6% for re-replacement of a tissue valve. The authors concluded through multivariable analysis that significant predictors of mortality were year of reoperation, patient age, indication, concomitant CABG, and the replacement of a mechanical valve rather than a tissue valve.<sup>6</sup>

## PREOPERATIVE IMAGING IN REOPERATIVE VALVE SURGERY

Reoperative cardiac surgery is associated with higher morbidity and mortality than the first operation<sup>38-40</sup> partially related to the risk of surgical reentry. The main technical concern during surgical reentry is the risk of lethal injury to vital structures such as the aorta, RV, and patent coronary artery bypass grafts. The key to mitigating the risk of reentry is via careful planning of the surgical approach. This starts with knowing the exact proximity of the RV, aorta, and prior grafts to the posterior sternal table. The standard preoperative coronary angiography and chest x-ray is usually uninformative about the precise anatomic relationship of these vital structures with the sternum.

Retrospective electrocardiographic (ECG)-gated multidetector computed tomographic (MDCT) scanning has arisen as the modality of choice to assess not only the heart's location in relation to the sternum, but also graft's location and patency.<sup>41-43</sup> Use of ECG-gated MDCT meticulously evaluates the structures of interest to the surgeon, including sternum, mediastinal structures, bypass grafts, and their relationship to each other.<sup>44-46</sup> At our institution, all reoperative cardiac surgeries are preceded by a preoperative cardiac computed tomography (CT) scan assessment. For patients with prior valvular (non-CABG) surgeries in which assessment of bypass graft is not necessary, noncontrast CT scan is adequate. In 2010, the Appropriate Use Criteria of the American College of Cardiology rated this application of cardiac CT as an appropriate use of this technology.<sup>45,47</sup>

Preoperative CT scan will lead to a modification of surgical approach in 20% of patients undergoing redo cardiac surgery.<sup>41,44</sup> For example, if CT shows a distended RV adherent to the posterior sternum, it might be prudent to initiate CPB prior to attempting sternal reentry. In high-risk redo patients, MDCT is associated with a higher adoption of preventive maneuvers aimed at mitigating the risk of reentry.<sup>48</sup> There is evidence that preoperative MDCT reduces the risk associated with redo cardiac surgery<sup>49</sup> as well as shorter perfusion and cross-clamp time, shorter intensive care unit stays, and less frequent perioperative myocardial infarction (MI).<sup>50</sup>

## REOPERATIVE AORTIC VALVE SURGERY

Historically, aortic valve surgery typically involved the placement of a mechanical valve. In the past, there were only a few generally accepted indications to use a bioprosthesis for

**TABLE 46-1: Risk Factors for Reoperative Valve Surgery**

Advanced age
Impaired ejection fraction (EF), congestive heart failure (CHF), or advanced preoperative functional class (NYHA)
Urgency of operation or unstable status preoperatively
Preoperative shock
Concomitant coronary artery bypass graft (CABG) or the presence of previous bypass grafts
Prosthetic valve endocarditis
Surgery for perivalvular leaks, valve thrombosis, or prosthetic dysfunction
Renal dysfunction
Chronic obstructive pulmonary disease (COPD)

primary, isolated aortic valve replacement (AVR): (1) the presence of well-established contraindications to anticoagulation, (2) the inability to monitor prothrombin levels adequately, and (3) patients whose survival was limited and more dependent on nonvalve-related issues.<sup>18,26</sup> In recent years, however, the use of biologic valves in the aortic position has become more common.<sup>24,51</sup>

As mentioned, reoperations are technically demanding, and many patients present in a poor functional state that further increases their mortality, in some series up to 19%.<sup>32,52,53</sup> Generally, optimal planning for reoperation prior to deterioration to NYHA class III to IV levels and before unfavorable comorbid conditions have arisen is imperative to ensure good outcomes.<sup>9</sup> Following these guidelines in the modern era, elective re-replacement of malfunctioning aortic bioprostheses can be performed with results similar to those of the primary operation.<sup>18,23,54</sup> The Mayo Clinic, for example, recently reviewed its experience with 162 reoperative AVRs. Early mortality for reoperative AVR was not statistically different from that for primary AVR.<sup>55</sup> In light of recent lower operative mortality in reoperative valve surgery, a more conservative approach toward issues such as “prophylactic” AVR in patients with asymptomatic mild-to-moderate aortic stenosis (AS) at the time of CABG also may be more appropriate.<sup>56</sup>

In evaluating the reoperative patient, the presence of concomitant coronary artery disease and pulmonary hypertension has been shown consistently to be independent risk factors.<sup>18</sup> Patients with these risk factors therefore need careful surveillance once the probability of bioprosthetic dysfunction begins increasing (ie, 6 to 10 years after implantation).<sup>16</sup> Regarding valve surveillance and timing of reoperation, the following variables are relevant to the clinical management of patients with an aortic bioprosthesis: a history of endocarditis before the first operation, perioperative infectious complications, coronary artery disease acquired after the first operation, an increase in pulmonary artery pressure, and a decrease in left ventricular function during the interoperative interval.<sup>18</sup> Proper timing of the reoperation therefore is paramount because duration of clinical signs with a dysfunctional aortic bioprosthesis may be misleading. This is further supported by the fact that the need for emergency reoperation is the most ominous risk factor and consistently yields a high early mortality rate of 25 to 44%.<sup>57</sup>

## Reoperative Aortic Valve Surgery after Prior Coronary Revascularization

Reoperative valve surgery in patients with a prior patent left internal thoracic artery (LITA) to left anterior descending (LAD) graft is challenging for surgeons because of specific considerations for myocardial protection and prevention of patent graft injury. Unlike mitral valve surgery or CABG, in which cross-clamping of the aorta may be optional, aortic valve surgery mandates aortic cross-clamp unless hypothermic circulatory arrest is used. As such reoperative AVR in patients with a patent LITA graft presents a unique challenge of myocardial protection.

The incidence of LITA injury in the literature varies from 5 to 9%<sup>58-61</sup> and is associated with a 40% risk of perioperative MI<sup>59</sup> and 50% mortality rate.<sup>62-64</sup> This high morbidity and mortality rate warrants a preoperative decision concerning the most appropriate and safe surgical approach.

This is an area of recent controversy. The most traditional approach involves re sternotomy, dissection of the LITA graft, and occlusion of the patent graft with a small bulldog and then aortic cross-clamping. This strategy has the advantage of short CPB time, maximizing uniform myocardial protection without cardioplegia washout but with an obvious risk of LITA injury during dissection. Efforts to reduce the risk of LITA injury have led to the “no-dissection” surgical technique in which the graft is left unclamped with use of deep hypothermic cardioplegic arrest.<sup>58,65-67</sup> In this approach, the LITA graft is not dissected and myocardial protection is achieved by using moderate-to-deep hypothermic cardioplegic arrest. This has the advantage of minimizing (but not eliminating) graft injury and its main disadvantage is that an unclamped LITA graft can lead to poor/uneven myocardial protection because of cardioplegia washout from the LITA territory. Another disadvantage is poor visualization due to continuous flow through the LITA. Other less utilized and studied approaches involve supraclavicular or endovascular control of the patent LITA graft.<sup>68,69</sup>

It is worth mentioning that another strategy of handling patent LITA grafts involves deep hypothermic circulatory arrest without controlling the graft or aortic cross-clamping. This technique is occasionally indicated in patients with “porcelain” aortas.<sup>70</sup>

All these concerns reiterate the importance of meticulous preoperative assessment and planning, to determine the optimal surgical approach for each individual patient. The “no-dissection” technique with hypothermic cardioplegia is a preferred approach for redo AVR in patients with patent LITA graft. Several studies have documented the safety of this method without any increased risk of perioperative mortality.<sup>58,65-67</sup>

## Approaches and Techniques

### CONVENTIONAL RESTERNOTOMY

The evolution of cardiac surgery through the last few decades has led to the popularization of various surgical approaches. Thoracotomy, for example, once was used extensively to gain access to mediastinal structures. Then median sternotomy became the standard approach. In reoperative cases, however, repeating the sternotomy carries definite surgical risks. Before proceeding with a re sternotomy, the relationship between certain anterior mediastinal structures (eg, the RV and the aorta) and the posterior aspect of the sternum must be assessed carefully.<sup>71</sup> As described above, a CT scan with or without contrast is now the modality of choice.<sup>41,43,62</sup>

Exposure of the femoral vessels and preparation for emergency femoral-femoral CPB should be performed before re sternotomy. In cases of heightened concern for RV-graft injury or in cases in which a left internal mammary artery

(LIMA) graft is patent, the surgeon should consider the use of CPB before chest reentry. Sternal wires from the previous operation should be undone carefully but left in place as a posterior safeguard during initial sternal division. An oscillating (not reciprocating) bone saw can be used to divide the anterior sternal table. An Army-Navy retractor, placed inferiorly in-line with the sternotomy can be used to stent open the wound during opening of the posterior table. Most authors recommend dividing the posterior table using a combination of scissors and anterolateral rake retraction.<sup>62,71,72</sup> Following this, bilateral pleural spaces should be entered inferiorly, followed by careful dissection of other mediastinal structures. The pericardial dissection plane can be developed by starting at the cardiophrenic angle and advancing slowly cephalad and laterally on the surface of the right side of the heart. Cephalad dissection should start with freeing the innominate vein before spreading the retractor to avoid its injury. Further dissection then is carried down to the superior vena cava (SVC), being careful to note the location of the right phrenic nerve. An area of consistently dense adhesions is the right atrial appendage, and caution should be used here. In addition, great care should be taken to avoid “deadventilizing” the aorta. The area where the aorta apposes the pulmonary artery is another site of potential injury.

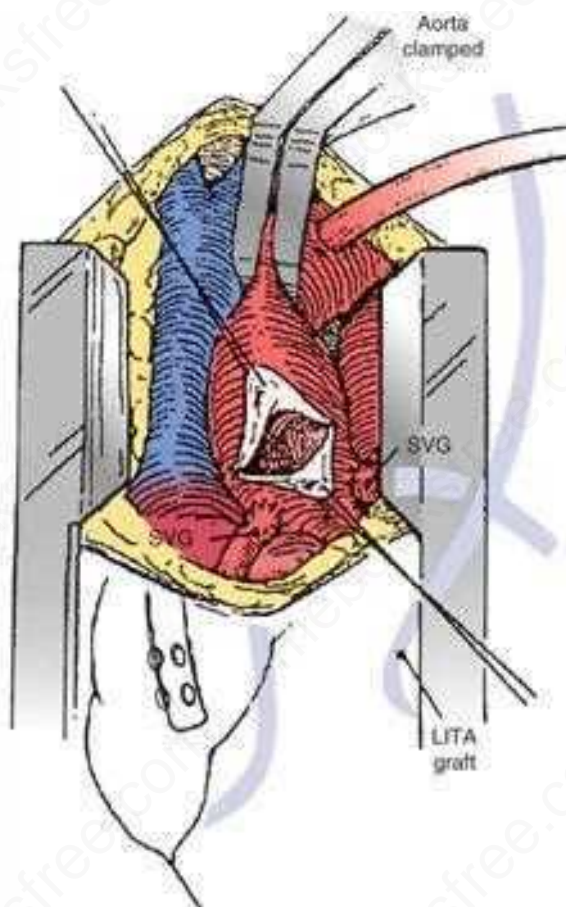

Repairing small ventricular or atrial lacerations should not be attempted before releasing the tension of the surrounding adhesions. Repair of great vessel injuries or severe RV injuries is best done on CPB.<sup>71</sup> Severe active hemorrhage during a second sternotomy usually is caused by adherence of the heart or great vessels to the posterior sternum. Prevention of this complication by interposition of pericardium or other mediastinal tissue at the time of the first operation has been suggested but has debatable relevance.<sup>62</sup> The incidence of re-sternotomy hemorrhage is between 2 and 6% per patient reoperation.<sup>73-75</sup> In a report of 552 patients who had undergone reoperative prosthetic valve surgery, 23 patients (4%) had complications related directly to sternal opening.<sup>17</sup> Of these, five patients had injury to the right atrium, seven patients had lacerated RVs, nine patients had injuries to the aorta, and two patients had a previously placed coronary artery graft divided. Nineteen of the 23 complications occurred during a first reoperation. Overall, there were two operative deaths related to re-sternotomy. The first death involved division of a previously placed coronary artery graft during reentry. The second death was caused by laceration of the aorta with subsequent exsanguination.<sup>17</sup> Of note, prior use of a right internal mammary artery (RIMA) graft can be particularly challenging because it frequently crosses the midline, and extreme caution must be used in first dissecting out this vessel.

Macmanus et al reviewed their experience with 100 patients undergoing repeat median sternotomy.<sup>74</sup> Eighty-one patients had one repeat sternotomy, whereas the others had undergone multiple sternotomies. All had had a previous valve procedure and were reoperated on for progressive rheumatic valvular disease or for complications related to the prosthesis. Complications included hemorrhage during reentry in eight patients, postoperative hemorrhage in

two, seroma in four, and dehiscence, wound infection, and hematoma in one patient each. There was one operative death directly related to re-sternotomy hemorrhage.<sup>74</sup> When major hemorrhage does occur on sternal reentry, attempts at re-sternotomy should be abandoned, and the chest should be reapproximated by pushing toward the midline. The patient should be heparinized immediately while obtaining femoral arterial and venous cannulation. Blood loss from the re-sternotomy should be aspirated with cardiotomy suction and returned to the pump. Once bypass has been established, core cooling should be commenced with anticipation of the need for circulatory arrest. Once cool, flow rates can be reduced briefly for less than a minute, and the remaining sternal division can be completed, followed by direct repair of the underlying injury.<sup>62</sup> Anticipating the possibility of this scenario, we frequently expose peripheral cannulation sites prior to beginning a re-sternotomy. In cases of heightened concern for RV or graft injury, or in patients with a patent LIMA to LAD artery graft, CPB and cardiac decompression may be initiated *before* sternal reentry. After safe sternal entry, the patient may be weaned from bypass for further dissection of adhesions to avoid prolonged pump times.

#### MINIMALLY INVASIVE REOPERATIVE AORTIC VALVE REPLACEMENT

Reoperative procedures are challenging owing to diffuse mediastinal and pericardial adhesions. A large incision that increases the operative exposure also has been associated with a higher risk of injury to cardiac structures and coronary artery bypass grafts and results in greater bleeding with its associated transfusion requirements.<sup>76-79</sup> A smaller incision with a limited sternotomy, on the other hand, reduces the area of pericardiolysis, thus mitigating these effects. The intact lower sternum that remains also preserves the integrity of the caudal chest wall, thereby enhancing sternal stability and promoting earlier extubation.<sup>80,81</sup> *Minimally invasive* valve procedures gradually have become more accepted as new technologies and instrumentation have been developed.<sup>80</sup> Reoperative procedures in which there is risk for graft injury are an area where minimally invasive strategies may be of direct benefit.<sup>82,83</sup> Our surgical approach in reoperative AVR is shown in Fig. 46-1.<sup>80</sup> In our series of patients, peripheral cannulation sites were exposed or cannulated before beginning the partial upper re-sternotomy. An external defibrillator is placed on the patient before draping for anticipated defibrillation as necessary. Transesophageal echocardiography (TEE) was used in every patient. A partial upper re-sternotomy was carried out to the third or fourth intercostal space depending on the estimated position of the aortic valve as documented by CT scan/TEE and then was “T’d to the right.”<sup>84</sup> The oscillating saw was used to divide the anterior sternal table, whereas the straight Mayo scissors, under direct visualization, was used to divide the posterior sternal table. In the setting of a patent LIMA-LAD graft or other anterior coronary artery bypass grafts, patients were placed on CPB before partial re-sternotomy. Mediastinal dissection was limited

**FIGURE 46-1** Partial upper re-sternotomy for reoperative AVR. The previous sternotomy incision is exposed to the third or fourth intercostal space depending on the position of the aortic valve, as documented by TEE. After dissection of the ascending aorta, paying particular attention to the position of coronary artery bypass grafts and their proximal anastomoses, cannulation is carried out. In this figure, the ascending aorta and innominate vein are cannulated. Frequently, however, other cannulation sites are required owing to space limitations in the chest. The ascending aorta is cross-clamped, and the aortic valve re-replacement is conducted in a standard fashion. (Reproduced with permission from Byrne JG, Karavas AN, Adams DH, et al: Partial upper re-sternotomy for aortic valve replacement or re-replacement after previous cardiac surgery, *Eur J Cardiothorac Surg*. 2000 Sep;18(3):282-286.)

to only the ascending aorta as was necessary for clamping and aortotomy. The right atrium was dissected only if it was cannulated. Although intrathoracic cannulation was preferred, we frequently used peripheral cannulation to avoid clutter in the chest. Retrograde cardioplegia, if necessary, was delivered via a transjugular coronary sinus catheter or with right atrial placement under TEE guidance. Vacuum assistance of venous drainage was used in the majority of patients. Once on CPB, all patients were systemically cooled to 20 to 25°C. Patients with patent LIMA-LAD grafts were cooled routinely to 20°C for additional myocardial protection and in so doing avoided the need and potential hazard of dissecting out the LIMA for clamping in an attempt to avoid cardioplegia washout. If flow

from the patent LIMA-LAD graft led to significant blood flow out of the coronary ostium and obscured the operative field, pump flows were turned down temporarily to allow visualization. Venting was accomplished by placing a pediatric vent through the aortic annulus. The aortic valve surgery then was performed based on patient indications. While closing the aortotomy, intracardiac air was removed by insufflating the lungs and decreasing flows on CPB. Carbon dioxide was used and flooded the operative field. Patients also were tilted from side to side to help with de-airing, and the ascending aortic vent was left open until separation from CPB. Temporary epicardial pacing wires were placed on the anterior surface of the RV while the heart was decompressed and before the aortic cross-clamp was removed. Two 32 French right-angled submammary chest tubes then were placed through the right pleural space, one angled medially into the mediastinum and one angled posterior into the pleural space. Decannulation and closure then were performed in the standard manner.

With our increasing experience in minimally invasive reoperative AVR, we have refined our technique as an alternative to conventional full re-sternotomy.<sup>80</sup> Technical details of the partial upper re-sternotomy approach are presented in Table 46-2. By following these guidelines, we have yet to

**TABLE 46-2: Twelve Technical Details for Successful Aortic Valve Replacement After Previous Cardiac Surgery by Use of Partial Upper Re-sternotomy**

1. Routine exposure of peripheral cannulation sites prior to partial upper re-sternotomy
2. Placement of Zoll (Zoll, Inc., Burlington, MA) defibrillator pads before prepping
3. Use of intraoperative transesophageal echocardiography for air removal and inspection of valve
4. In patients with patent left internal mammary artery to left anterior descending coronary artery (LIMA-LAD) graft, peripheral cannulation, and cardiopulmonary bypass (CPB) established before partial upper re-sternotomy
5. Mediastinal dissection limited to ascending aorta for clamping and aortotomy and atrium (RA), only if RA is cannulated
6. Use of peripheral cannulation to avoid clutter in the chest
7. Use of vacuum assistance on CPB
8. Use of retrograde cardioplegia (CP) delivered by transjugular retrograde CP catheter in addition to antegrade CP
9. Cooling to at least 25°C in all patients primarily for myocardial protection; if a patent LIMA-LAD graft is present, cooling to 20°C without isolation and clamping LIMA graft
10. If visualization is poor because of LIMA-LAD collaterals flowing from coronary ostia, temporary low flows on CPB to improve visualization
11. Venting with a pediatric vent placed through the aortic annulus
12. Placement of temporary pacing wires on the right ventricular free wall before aortic clamp removal

Reproduced with permission from Byrne JG, Karavas AN, Adams DH, et al: Partial upper re-sternotomy for aortic valve replacement or re-replacement after previous cardiac surgery, *Eur J Cardiothorac Surg*. 2000 Sep;18(3):282-286.

convert any patient to a full re-sternotomy. CT scan and/or TEE are helpful in locating the level of the aortic valve and determining the proximity of the aorta to the posterior aspect of the sternum.<sup>84</sup> Also, extension of the sternal incision laterally on both sides through the intercostal spaces helps to later reapproximate the sternum. We have tried to limit mediastinal and pericardial dissection primarily to the aorta, believing that this is the principal reason for decreased bleeding and transfusion requirements postoperatively.<sup>80,82,85,86</sup> The RV, which often is attached to the sternum, does not need to be dissected. Also, injuries to patent but atherosclerotic vein grafts can be reduced with this “no touch” technique.<sup>87</sup>

Arterial and venous cannulation sites can vary considerably, reflecting the individual choice of the operating surgeon and the sufficiency of intrathoracic space. Possible cannulation sites, other than standard ones, include the axillary artery, innominate vein, and percutaneous femoral vein.<sup>13,88</sup> Innominate vein or percutaneous femoral vein cannulation, as well as the use of TEE to place the retrograde cardioplegia catheter, has been extremely helpful in minimizing dissection of the right atrium. At present, we consider this approach to be useful for isolated, elective reoperative aortic valve surgery.<sup>80</sup>

#### REOPERATIVE AORTIC VALVE REPLACEMENT AFTER HOMOGRRAFT/ROOT/ALLOGRAFT

AVR with homografts and autografts was performed increasingly because of excellent freedom from thromboembolism, resistance to infection, and reasonable hemodynamic performance.<sup>27</sup> Although improved durability of current tissue valves has slowed this trend, autografts and, to a lesser degree, homografts remain popular in younger patients owing to durability and, in the case of autografts, the potential for growth.<sup>30,89</sup> Consequently, many patients will require aortic valve re-replacement for structural degeneration of their homograft or autograft valve.<sup>90</sup> It is expected that about one-third of patients younger than 40 years of age will require aortic valve re-replacement within 12 years of homograft placement. This is owing primarily to calcification and structural valve degeneration. As such, the issue of homograft or autograft durability is particularly pertinent in this subgroup of younger patients who are expected to live beyond 15 years from the time of operation.<sup>89</sup>

The incidence of patients with homografts or autografts in need of a second valve operation is expected to increase owing to the aforementioned recent popularity and availability of these conduits. Also, there is varied opinion as to the optimal surgical method of primary homograft AVR, with increased rates of aortic insufficiency (AI) in patients with the subcoronary implantation technique. Importantly, the selected technique of primary homograft operation may have relevance at reoperation because calcification or aneurysmal dilatation of the homograft may pose surgical challenges at reoperation. Despite these challenges, Sundt and others<sup>29,91,92</sup> have documented the feasibility of aortic valve re-replacement after full-root replacement with a homograft. In our own series of 18 patients, full-root, mini-root, and subcoronary techniques all were amenable to valve re-replacement.<sup>27</sup>

How to best approach the reoperative root scenario and which valve to reimplant, however, have been debated. At one extreme, Hasnat et al documented the results of 144 patients who underwent a *second* aortic homograft replacement with a hospital mortality rate of only 3.5%.<sup>90</sup> Although Kumar et al, in a multivariate analysis of reoperative aortic valve surgery, did not show that a previous homograft added significant risk,<sup>93</sup> the technical aspects of reoperative AVR in this patient population consistently have been found to be challenging owing to the heavy calcific degeneration that invariably occurs. With this in mind, and owing to the typical absence of the need for a second root operation, we and others<sup>94</sup> believe that a more simplified approach to reoperative aortic valve surgery in patients with previously placed homografts may be optimal. Our approach has been to perform aortic valve re-replacement using a mechanical valve or, less commonly, a stented xenograft while reserving a second homograft and root operation for specific indications such as endocarditis, associated root pathology, or a very young patient with contraindications to a mechanical valve.

An open valve-in-homograft approach involves resection of the degenerated or infected aortic homograft leaflets and a new valve is seated within the aortic homograft valve annulus without a need for root reconstruction.<sup>95</sup> The procedure is done via a median sternotomy, which is preceded by peripheral cannulation for CPB via femoral vein and artery or right axillary artery. The heart is dissected out, CPB is initiated, the patient is fibrillated and cross-clamped; antegrade (and occasional retrograde) cardioplegia is initiated.<sup>95</sup> The aorta is opened between the homograft root and the ascending aorta. If there is heavy calcification, a vertical or S-shaped aortotomy is made. The homograft leaflets are resected and the calcified annulus debrided with careful endarterectomy of the proximal ascending aorta. The endarterectomy is carried out starting at the annulus and coming up to allow stitches on in the softer aorta.<sup>95</sup> The valve prosthesis (bioprosthetic or mechanical) is then sized and implanted using interrupted noneverting 2.0 Ethibond (Ethicon, Somerville, NJ) pledgeted sutures. The valve is then seated and the sutures tied and cut. The aorta is then closed with a running 3-0 Prolene (Ethicon) suture. The cross-clamp is removed and the heart defibrillated into normal sinus rhythm.<sup>95</sup>

Homograft re-replacement nonetheless is performed but it is much less common, and hospital mortality varies widely across many centers, ranging between 2.5 and 50%.<sup>29,91,92</sup> David and colleagues, for example, recently reviewed their experience with root operations in 165 patients who previously had undergone cardiac surgery. Of these, 28 had a previous root operation. Overall, 12 operative (7%) and 20 late deaths (12%) occurred.<sup>96</sup> Variations in sample size, valve selection, surgical techniques, and patient factors, as well as the experience of the surgeons, may account for these wide differences.

#### AORTIC VALVE BYPASS SURGERY

Aortic valve bypass (AVB) surgery, also known as apical aortic conduit surgery, is an alternative for high-risk and “inoperable” reoperative patients with AS. It has been used

in patients with reduced LV function,<sup>97</sup> porcelain aorta,<sup>98</sup> severe patient prosthetic mismatch,<sup>99</sup> excessive comorbidities, and vulnerable functional grafts<sup>100</sup> leading to prohibitive risk for conventional reoperative AVR. AVB surgery works by shunting blood from the apex of the left ventricle to the descending aorta through a surgically placed valve conduit (Fig. 46-2). This approach avoids cross-clamping, cardioplegic arrest, potentially CPB,<sup>101</sup> debridement of the native valve, and injury to patent grafts because the procedure is performed through the left chest. Patient-prosthesis mismatch is also unlikely as the indexed effective orifice area (EOAi) is the sum of the valves in both the native position and conduit.

Contraindications to this procedure include moderate AI. Relative contraindications include a heavily diseased descending aorta or significant mitral valve regurgitation. However, Gammie et al showed that the degree of mitral regurgitation (MR) is reduced after placement of the conduit and moderate MR patients are still considered.

The procedure<sup>102,103</sup> is performed using a left ventricular apical connector with a silicon sewing ring and a heart valve (typically a stentless porcine valve with the coronaries over sewn) sewn to a Dacron graft at the beginning of the procedure. An 8-mm side branch off the Dacron graft may be used for direct inflow from the CPB machine if performed on pump. The patient is positioned in the right lateral decubitus position with a double lumen endotracheal tube. TEE is used

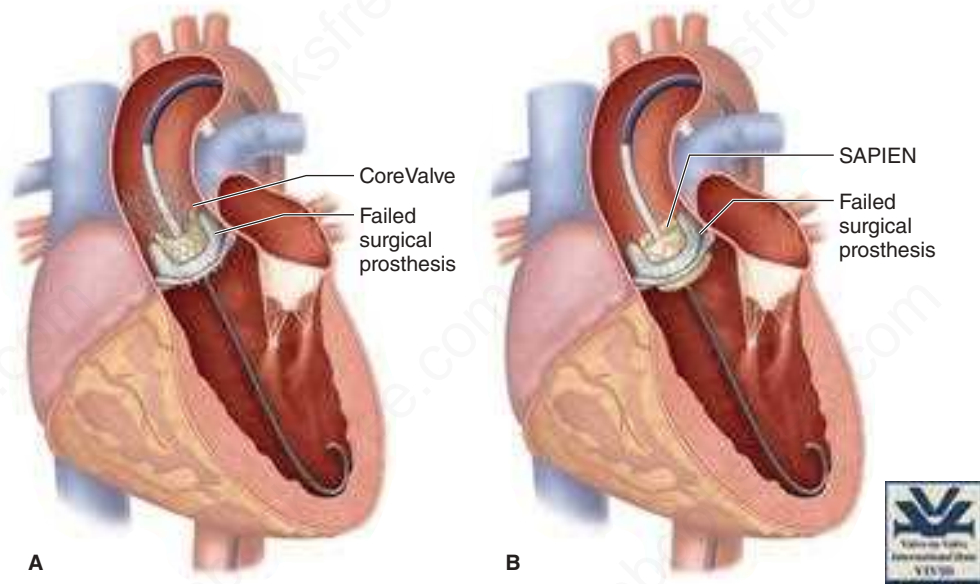

**FIGURE 46-2** Apical aortic conduit. Aortic valve bypass surgery performed via left thoracotomy avoids sternotomy in difficult reoperative cases. (Reproduced with permission from Gammie JS, Krowoski LS, Brown JM, et al: Aortic valve bypass surgery: midterm clinical outcomes in a high-risk aortic stenosis population, *Circulation* 2008 Sep 30;118(14):1460-1466.)

to exclude apical thrombus, calcification of the descending aorta, and ensure proper conduit positioning. If going on bypass an arterial and venous cannula are placed in groin. A fifth- to sixth-intercostal space thoracotomy is performed and the apex of the heart and descending thoracic aorta exposed. The valve conduit with apical connector is then oriented with connector aimed at the apex of the heart. After heparinization the distal anastomosis is performed after placement of a partial occluding clamp on the descending thoracic aorta. The clamp is removed and hemostasis achieved. Stentless valve competency will prevent blood flow out of the apical connector. The pericardium is then opened and tacked up and a mark is made 1 to 2 cm lateral to the true apex of the left ventricle: 2-0 monofilament pledgeted sutures are used in an interrupted fashion around this marked area with deep bites of nearly full thickness. These are then taken through the sewing ring of the apical connector. If CPB is to be initiated, it is done at this time. The patient is placed in steep Trendelenburg position and the ventricle is then paced at 200 beats/min to reduce ventricular ejection. A hole is made in the marked apical area and a 14 French Foley catheter is placed into the left ventricle. Tension is placed on the Foley catheter and a coring knife is used to remove a plug of apical myocardium. A coring knife 85% of the diameter of the apical connector is selected to ensure a proper fit and optimize hemostasis. The Foley catheter is then removed and the apical connector is placed in the left ventricle. The sutures are tied down. The graft is de-aired and the chest is closed. When complete blood flow from the left ventricle travels out of the native valve and the conduit where it will primarily travel distally in the aorta with some flow in the retrograde direction. Studies have shown that approximately one-third of the flow travels out the native valve, whereas two-thirds travel out the conduit.<sup>100</sup> The procedure has been shown to be highly efficacious, dropping the mean aortic valve gradients in one study from 43 to 10 mm.<sup>100</sup> The durability of the apical aortic conduit procedure is also apparent, with some patients now more than 25 years out from their operations.

## TRANSCATHETER AORTIC VALVES

The PARTNER trial was the first prospective randomized control study evaluating the safety and efficacy of transcatheter AVR (TAVR) in high-risk patients (cohort B) and “prohibitive” risk patients with severe AS. The study showed that in this “prohibitive” risk cohort, TAVR was better compared to medical therapy and in the high-risk cohort (cohort A) was noninferior to surgical AVR (SAVR).<sup>104,105</sup> Shortly after the successful results of the PARTNER trial was published in 2010, the US Food and Drug Administration approved TAVR. This ushered in the era of TAVR in the United States.

Today, the two types of TAVR approved in the United State are the Edwards SAPIEN XT (Edwards Lifesciences, Inc. [Irvine, CA]) and the Medtronic CoreValve (Medtronic, Inc., Minneapolis, MN). The Edwards SAPIEN XT uses a balloon-expandable stainless steel alloy tubular frame

**FIGURE 46-3** Transcatheter aortic valve-in-valve implantation in failed surgical bioprosthesis. (A) Showing the self-expandable CoreValve device and (B) the Balloon-expandable SAPIEN device. (Reproduced with permission from Dvir, D. In *Aortic Valve-in-Valve: Insights from the Global Registry on stented vs. stentless bioprostheses*, Transcatheter Cardiovascular Therapeutics (TCT), Washington D.C. 2014.)

within leaflets constructed from bovine pericardium while the Medtronic CoreValve uses a self-expanding nitinol (nickel-titanium alloy that is malleable at low temperature but rigid at body temperature) frame.<sup>106</sup> These devices can be implanted via percutaneous routes (transfemoral or sub-clavian/axillary), direct transapical or direct aortic access. For more on percutaneous AVR see Chapter 33.

### Transcatheter Aortic Valve-in-Valve Implantation

The wide success of TAVR in patients with severe native aortic valve stenosis has led to its application beyond native aortic valve disease. This initially led to several reports of off-label TAV implantation within failed surgically inserted bioprosthetic valves (VinV).<sup>107-110</sup> VinV was first reported by Wenaweser et al in 2007<sup>111</sup> and it has garnered widespread use. A VinV procedure involves percutaneous implantation of a valve inside an already implanted bioprosthetic valve (Fig. 46-3) and it is an alternative to open surgery in high-risk patients with a degenerate aortic bioprosthesis.

VinV implantation is relatively new, but technology and experience with its application are growing exponentially. The Valve-in-Valve International Data (VIVID) registry was established in 2010 to collect data on VinV procedures from 55 centers around the world. They recently published the outcomes of 459 high-risk patients who underwent VinV implantation, the largest series to date.<sup>112</sup> They reported a 30-day operative mortality of 7.6%, a 1.7% major stroke rate, and an 83.2% overall 1-year survival. Of those who survived to 1-year, 92.3% had good functional status (NYHA class I/II).

Although these initial results of VinV implantation are promising, it does come with a distinct set of technical challenges and early results have been marred by unique safety concerns. These safety concerns include device malposition, ostial coronary occlusion, and elevated postprocedural gradients.<sup>113</sup> The VIVID registry reported a high device malposition rate of 15.3%; a 3.5% rate of ostial coronary obstruction; and a 28.4% rate of postprocedural high gradients (mean  $\geq 20$  mmHg).<sup>113</sup>

Another area of uncertainty is the long-term durability of VinV implantation. There are currently no long-term data on this relatively new procedure with most studies only stating 1-year survivals.<sup>112-114</sup>

Conventional open redo AVR is still considered the standard of care for patients with failed implanted valves. Although VinV is appealing as an alternative for high-risk, “inoperable” patients, long-term follow-up data will be necessary to establish the true role of VinV implantation for failed, degenerate bioprosthesis.

### REOPERATIVE MITRAL VALVE SURGERY

Fundamental to a flawless surgical procedure is excellent and consistent exposure of the mitral valve.<sup>115</sup> Historically, the mitral valve has been exposed through a variety of surgical approaches, including median sternotomy, right thoracotomy, left thoracotomy, and transverse sternotomy.<sup>116</sup> The median sternotomy and right thoracotomy will be discussed in detail in the following; however, a brief description of the other approaches is warranted.

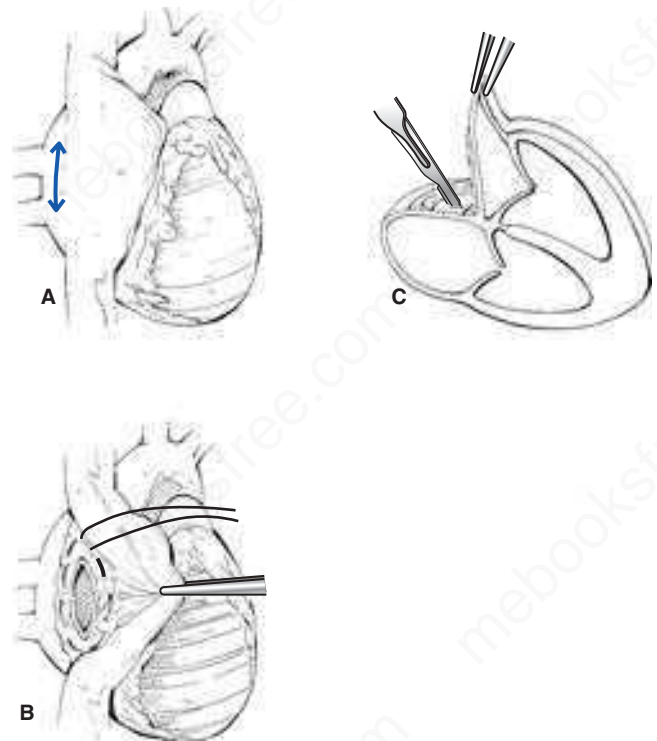

The *left* thoracotomy has been used in recent years to gain access to the mitral valve in situations in which a right thoracotomy is precluded (eg, mastectomy/radiation or pleurodesis). This incision is made through the fourth intercostal space, and the left pleural cavity is entered in the standard fashion.<sup>116</sup> Surgery is performed under fibrillatory arrest or with the beating-heart technique. Of importance, the mitral valve orientation is noted to be upside down with this approach, with the posterior annulus found anteriorly.<sup>117</sup> Thompson and colleagues recently reported their experience with the beating-heart left thoracotomy approach for reoperative mitral valve surgery. Of the 125 patients undergoing this technique, 86% were in NYHA class III or IV, and 28% had undergone two or more sternotomies. Thirty-day mortality was 6.4% with low complication rates.<sup>118</sup> Although occasionally useful, this approach provides limited access to the other cardiac chambers as well as poor visibility. This left-sided approach is rarely needed and typically reserved for patients in whom reoperative sternotomy or right thoracotomy is considered unacceptable. A bilateral anterior thoracotomy (ie, transverse sternotomy) carried out through the fourth intercostal space also has been described.<sup>117,119</sup> Rarely used today, this incision transects the sternum transversely, requiring ligation of both internal mammary arteries.

Regardless of the actual approach, once CPB has been established and the heart exposed, there are several incisions that can be employed to view the underlying mitral valve. The standard left atriotomy begins with blunt dissection of the interatrial groove (ie, Sondergaard's groove), allowing the right atrium to be retracted medially and anteriorly (see Fig. 46-4). The right superior pulmonary vein at its junction with the left atrium then is exposed, and the left atrium is opened at the midpoint between the right superior pulmonary vein insertion and the interatrial groove. This incision is extended longitudinally both superiorly and inferiorly to give enough exposure of the mitral valve. Care must be taken to avoid inadvertent injury to the posterior wall of the left atrium, and when closing, one must avoid including the posterior wall of the right pulmonary vein. The right atrial transeptal approach has become popular in recent years, especially in reoperative valve surgery. After opening the right atrium, the interatrial septum is incised starting at the fossa ovalis and moving vertically upward for a few centimeters (Figs. 46-5 and 46-6). This technique is especially helpful in reoperative surgery because it minimizes the amount of dissection required. Superior biatrial atriotomy, left ventriculotomy, and aortotomy all have been well described<sup>15,76,115,116,120,121</sup> as approaches to the mitral valve; each one has varying advantages and disadvantages.

## Approaches and Techniques

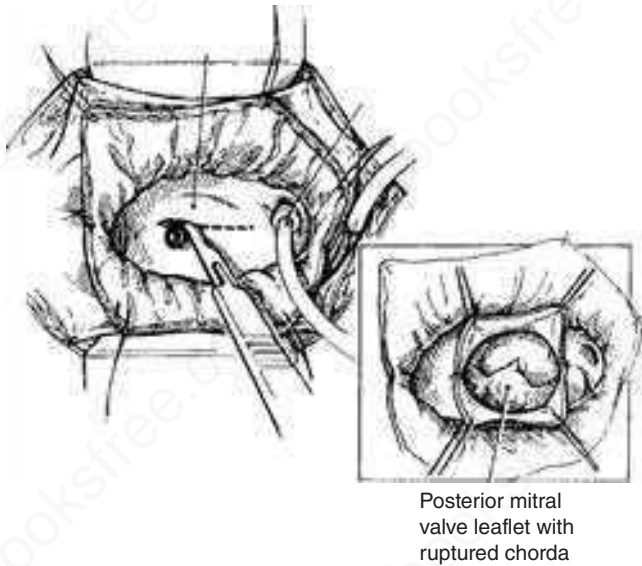

### RESTERNOTOMY

Resternotomy is still a common approach in reoperative mitral valve surgery. In many cases, this incision provides full and adequate exposure. This is especially true when concomitant procedures are necessary. However, reoperative median

**FIGURE 46-4** Sondergaard's groove approach. The left atrium enlarges to the right, increasing visualization from the right thoracotomy approach. The interatrial groove (Sondergaard's groove) is dissected approximately 1-cm deep, down to the left atrial wall. The purse-string suture is placed in the nondissected area. This prevents tearing of the dissected left atrial wall when the suture is tied down. Sagittal view shows location of the mitral valve in relation to the atriotomy. (Reproduced with permission from De DH, Pessella AT: Closed mitral commissurotomy utilizing right thoracotomy approach, *Asian Cardiovasc Thorac Ann* 2000;June:8(2):192-194.)

sternotomy has known risks, including injury to or embolism from prior grafts, sternal dehiscence, excessive hemorrhage, and inadvertent cardiac injury.<sup>122</sup> Patients with valvular heart disease may be especially prone to these complications because atrial dilatation can result in significant cardiomegaly, atrial thinning, and adherence of the heart to the posterior sternum. As discussed, patients undergoing prosthetic valve reoperation have a 4% incidence of complications directly related to sternal reentry that can result directly in intraoperative death.<sup>17,35</sup> Resternotomy also has been noted to be particularly hazardous in the presence of patent internal mammary grafts. Injury to a patent LIMA graft has an associated mortality rate approaching 50%.<sup>62,84</sup> Furthermore, manipulation of patent but diseased saphenous vein grafts can result in embolization into the native coronary circulation with resulting morbidity and mortality.<sup>122,123</sup> Patients with previous AVR can have difficult exposure of the mitral valve owing to anterior fixation and probably are best served by an anterolateral thoracotomy approach. In general, in the setting of reoperative surgery, the resternotomy is likely to be the most dangerous part of the operation.<sup>124</sup> In this situation, we also have employed techniques that avoid resternotomy, such as right thoracotomy.

**FIGURE 46-5** Atrial incision through the fossa ovalis. When the right atrium is incised, an incision is made in the atrial septum through the fossa ovalis. Retraction sutures on both the right atrium and the atrial septum of 2-0 silk then are used to elevate the septum and to keep the left atrium open. The mitral valve then will be exposed (*inset*). (Reproduced with permission from Byrne JG, Mitchell ME, Adams DH, et al: Minimally invasive direct access mitral valve surgery, *Semin Thorac Cardiovasc Surg.* 1999 Jul;11(3):212-222.)

**FIGURE 46-6** Closure. In the transseptal approach, the atrial septum is approximated with running 4-0 Prolene sutures and is left open until the aortic cross-clamp is removed and the air is evacuated. The left ventricle should be filled with fluid before removal of the cross-clamp to help dislodgment of intraventricular air. Once the cross-clamp has been removed, air is evacuated vigorously from the left atrium through the septum or the left atrium itself, and the sutures are tied. The right atrium is then closed with running 4-0 Prolene sutures in two layers. TEE has been very important in helping to monitor the clearing of air from the intracardiac structures. We consider it mandatory in the minimally invasive technique, in which access to the entire cardiac structure is limited. (Reproduced with permission from Byrne JG, Mitchell ME, Adams DH, et al: Minimally invasive direct access mitral valve surgery, *Semin Thorac Cardiovasc Surg.* 1999 Jul;11(3):212-222.)

## RIGHT THORACOTOMY

The right anterolateral thoracotomy approach was one of the first surgical approaches to the mitral valve, and it has become a safe alternative to re sternotomy for mitral valve replacement<sup>10,62,125,126</sup> (see Fig. 46-5). This approach provides excellent exposure of the valves (mitral and tricuspid) with minimal need for dissection within the pericardium. In our recent experience with this approach,<sup>124,127-131</sup> operations were performed in the supine position with the right side of the chest slightly elevated. We routinely prepped and draped the right groin to allow femoral cannulation, if necessary. Preoperative and intraoperative TEE was performed in all patients, as well as standard intraoperative cardiac monitoring and a pacing Swan-Ganz catheter. A 5-cm right anterolateral thoracotomy was made, and the chest was entered through the bed of the fourth or fifth rib.<sup>131</sup> Adhesions of the right lung to the chest wall or pericardium were divided by electrocautery. The pericardium was entered anterior to the phrenic nerve. Arterial cannulation was achieved peripherally via the femoral artery. Peripheral cannulation was mostly via the femoral artery and this route was utilized if by TEE the atheroma grade of the descending aorta or arch is less than grade III. However, if the atheroma grade is greater than III, arterial cannulation is done via the right axillary artery. Venous cannulation was performed via the femoral vein with the tip of the cannula positioned between the SVC and the right atrium. In cases requiring tricuspid valve surgery, an additional SVC cannula is used while the femoral venous cannula is advanced at the IVC into the right atrium. After systemic heparinization, CPB is initiated with vacuum-assisted drainage. Patients were then cooled to 28°C to induce fibrillatory arrest. If spontaneous arrest did not occur with cooling, the pacing Swan-Ganz catheter was used to pace rapidly the ventricle into fibrillation. Care is used to avoid left ventricular ejection by keeping the left ventricle empty (ie, maintaining laminar, nonpulsatile arterial line tracing). In the absence of AI, aortic cross-clamping usually was not required. Regurgitant flow through the aortic valve occasionally required temporary low pump flow at appropriate temperatures to avoid cerebral injury.<sup>131</sup> The mitral valve was then approached through the left atrium directly by dissection of the intra-atrial (Sondergaard's) groove (see Fig. 46-4) or through the right atrium via the atrial septum (see Fig. 46-6). As the valve procedure was completed, rewarming was initiated (Fig. 46-7). Carbon dioxide (CO<sub>2</sub>) can be continuously insufflated into the chest throughout the procedure to displace intracardiac air which reduces the time spent de-airing. In addition, perfusing blood via a cannula (eg, the left ventricular vent) positioned across the mitral valve and into the left ventricle will serve to displace residual air. A left atrial sump sucker was used to maintain a clear operative field. Upon completion of the procedure, patients then were placed in the Trendelenburg position and de-airing ascertained under TEE guidance. When core temperatures reached 37°C, the patient was weaned from CPB. Closure then was routine and at the conclusion of the procedure, patients were returned to the supine position.

**FIGURE 46-7** Right anterolateral thoracotomy through the fourth intercostal space and standard left atriotomy. (Reproduced with permission from Balasundaram SG, Duran C: Surgical approaches to the mitral valve, *J Card Surg.* 1990 Sep;5(3):163-169.)

The use of a small right anterior thoracotomy, femorofemoral bypass, and deep hypothermia has increased since our initial report in 1989.<sup>132</sup> Reduced blood use and decreased risk of LIMA or cardiac structural injury during sternal reentry make it a desirable approach for many complicated mitral reoperations. Deep hypothermia ( $\sim 20^{\circ}\text{C}$ ) and low-flow femorofemoral bypass perfusion, without the necessity of aortic cross-clamping, provide adequate myocardial protection.<sup>133</sup> CPB times, blood loss, blood product usage, and LIMA injury rates have been lower in reoperative patients undergoing right thoracotomy than in those with re sternotomy.<sup>35,118,120,129,133-136</sup>

Certain issues must be considered before the right thoracotomy approach is entertained. Patients who require simultaneous CABG generally will require a median sternotomy, although isolated right-sided grafting may be performed with a thoracotomy. Simultaneous replacement of the aortic valve is difficult from a thoracotomy approach and generally should be performed through a re sternotomy. Significant AI can make effective perfusion on CPB difficult because, after opening the left atrium, blood will be returned to the pump via the cardiectomy suction. Unless the ascending aorta is clamped, effective end-organ perfusion will not be achieved. Also, in the setting of AI, exposure of the mitral valve may be difficult owing to this regurgitant flow into the surgical field. Left ventricular distension and myocardial stretch injury also can occur with fibrillatory arrest in patients with and occasionally without AI. Patients with greater than minimal AI therefore should be either excluded from a right thoracotomy approach or expected to require aortic cross-clamping either with traditional clamping or rarely with balloon occlusion with delivery of cardioplegia and aortic root venting. Significant right pleural disease, especially scarring in the right hemithorax, previously has been a relative contraindication to a right thoracotomy, although our series includes two patients

with a previous right thoracotomy who did not represent an overwhelming challenge.<sup>137</sup>

Our experience with 90 patients undergoing reoperative mitral valve surgery via a minimally invasive right thoracotomy without aortic cross-clamping showed excellent results.<sup>136</sup> In that series, the 2% operative mortality was lower than the STS-predicted mortality of 7%. Three patients developed acute renal failure postoperatively with one patient requiring new hemodialysis. One patient (1%) developed a postoperative stroke and no patient suffered a postoperative MI.<sup>136</sup> This study confirmed that the minimally invasive right thoracotomy technique was safe and effective in reducing operative mortality in reoperative mitral valve surgery.<sup>136</sup>

### Minimally Invasive/Port Access Right-Sided Techniques

An alternative approach to reoperative mitral valve is with minimally invasive or port access techniques.

Some authors have noted that the distance to the mitral valve with the right thoracotomy approach at times can be limiting. Chitwood and colleagues recently reported use of a minithoracotomy aided by the voice-activated robotic camera AESOP.<sup>138</sup> Vleissis and Bolling also reported 22 patients who underwent a “minimally invasive” right thoracotomy approach to the atrioventricular valves.<sup>139</sup> The procedures performed included mitral valve repair ( $n = 12$ ), mitral valve replacement ( $n = 5$ ), prosthetic mitral valve re-replacement ( $n = 4$ ), repair of a perivalvular leak ( $n = 3$ ), tricuspid valve repair ( $n = 5$ ), and closure of an atrial septal defect ( $n = 7$ ). Mean bypass time was 109 minutes with a mean fibrillatory time of 62 minutes. Operative mortality in this group was 0%, and none of the patients experienced a wound complication. At follow-up, all reoperative patients thought that their recovery from this approach was more rapid and less painful than their original sternotomy.<sup>139</sup> Burfeind et al recently reviewed Duke University’s experience with the port access technique.<sup>140</sup> In their series of 60 patients, a 6 cm right anterolateral thoracotomy was used with standard port access technique. Forty-five percent of patients underwent cardiac arrest with the Endo Clamp technique, whereas ventricular fibrillation was used in 55% of patients. Femoral cannulation was used in all patients. When compared with concurrent cohorts of patients undergoing reoperative sternotomy or right anterolateral thoracotomy, patients undergoing the port access technique had lower mortality and decreased transfusion requirements but significantly longer CPB times. Although similar results have been found by other groups, one should be mindful of the potential hazards of the port access technique, namely, EndoClamp migration.<sup>141-144</sup>

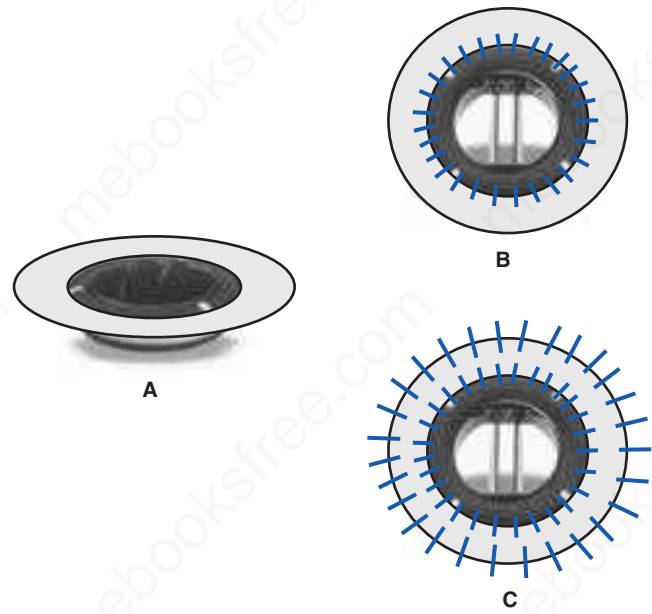

### Additional Techniques of Reoperative Mitral Surgery

A less common indication for reoperative mitral valve surgery but one that can be challenging is periprosthetic leak. The incidence of perivalvular leak for both mechanical and

biologic valves is about 0 to 1.5% per patient-year. Of note, perivalvular leak is slightly more common with mechanical than with tissue valves, possibly owing to differences in suture technique for each and sewing ring characteristics. The regurgitant flow across the perivalvular area frequently leads to hemolysis and, through denuding of the endocardium, endocarditis.

In evaluating patients with a periprosthetic leak, an assessment of valve function is important. If the valve itself is competent, direct repair of the leak avoids the hazards of valve replacement. Although pledgeted suturing may be attempted for smaller leaks, fibrotic tethering of surrounding tissue and the size of the defect may require a bovine or autologous pericardial patch. In cases of significant dehiscence or associated valvular dysfunction, removal of the valve is necessary. Replacement in this situation, however, is prone to leak recurrence because the annulus is partially intact, often calcified, and otherwise less than ideal for suture placement. In these cases, a bovine pericardial skirt can be fashioned and sewn to the sewing ring of the valve. Annular sutures then are placed in a typical fashion through the sewing ring, and the valve is seated. A running suture then can be used to sew this skirt to the left atrium (Fig. 46-8).

An additional risk of reoperative mitral valve replacement is atrioventricular disruption. Care must be used in removing the original valve sewing ring because it is frequently “socked in,” and inadvertent removal of excessive annular tissue may occur. Any evidence of disruption of the posterior annulus necessitates patch repair with pericardium (autologous or bovine) before placement of annular sutures.<sup>145</sup> When faced with less than ideal annular tissue, and in an attempt to ensure stability, bites must not be overly aggressive in depth. Left circumflex injury can occur and will lead to significant morbidity and mortality (Fig. 46-9). When removal of the old sewing ring will result in severe annular disruption, the ring may be left in place and used as a “neoannulus” for suturing.

**FIGURE 46-8** Pericardial skirt. Bovine pericardium can be fashioned as a skirt (A) and sewn to the sewing ring of the mitral prosthesis (B). Standard annular valve sutures are then taken through the sewing ring, the valve is seated, and the skirt is sewn to the left atrium with running technique (C). (Carbomedics mechanical valve shown.)

The benefits of preservation of the subvalvular apparatus have been clearly demonstrated during first-time mitral valve replacement.<sup>146</sup> Aside from improved contractile function, disruption of the posterior mitral annulus is avoided. David and colleagues found that preservation of the subvalvular apparatus is also important in reoperative patients.<sup>147</sup> Of 513 reoperative mitral valve replacements, preservation of the posterior subvalvular apparatus was accomplished in 103 (21%) patients, with anterior and posterior preservation occurring in 31 patients (6%). Gore-Tex neochochordal construction was performed in 135 reoperative mitral valve replacement

**FIGURE 46-9** Left circumflex artery injury. Preoperative (*left*) and postoperative (*right*) angiograms demonstrating excessive depth of annular sutures leading to left circumflex occlusion.

patients (26%). Perioperative mortality occurred in 3.6% of redo patients with a preserved subvalvular apparatus (native tissue and/or Gore-Tex reconstruction) versus 13.3% of redo patients without preservation ( $p < .001$ ). Attempts at preservation of the subvalvular apparatus in reoperative mitral valve patients therefore should be considered.

## REOPERATIVE TRICUSPID VALVE SURGERY

The need for reoperative tricuspid valve surgery most frequently occurs in high-risk patients. In a recent series of tricuspid valve replacements (TVR) by Filsoofi et al,<sup>148</sup> 72% (n = 58) were reoperations. The overall operative mortality in this group was 22% (n = 18). Risk factors for mortality included urgent/emergent status, age greater than 50 years, functional etiology, and elevated pulmonary artery pressure. Of the 60 survivors, 26 (43%) died during follow-up. The authors concluded that patients requiring TVR are at high risk, frequently at end-stage functional class. As such, serious consideration of the risks should occur before embarking on such procedures (Table 46-3).

Tricuspid valve endocarditis is most commonly the result of seeding of the tricuspid valve leaflets during sustained bacteremia.<sup>149</sup> Continued sepsis despite antibiotic therapy, heart failure owing to tricuspid insufficiency, and recurrent multiple pulmonary emboli are indications to intervene surgically in tricuspid valve endocarditis. Complete excision of the tricuspid valve (without subsequent replacement) was first advocated by Arbulu et al.<sup>149</sup> From an infectious disease standpoint, this surgical approach has the obvious advantage of complete extirpation of the infected tissue and avoids placement of any prosthetic material. Although it is tolerated initially, the extirpation procedure inevitably leads to late-onset right-sided failure in the majority of patients.<sup>149-151</sup> In a 20-year follow-up of the originally reported series of 55 patients with intractable right-sided endocarditis who underwent tricuspid valvectomy without replacement, two patients (4%) died in the postoperative period owing to right-sided failure. Six patients (11%) required prosthetic valve insertion 2 days to 13 years later for medically refractory right-sided heart failure. Of those who underwent reoperation (n = 6), four (66%) died. As such, severe hepatic congestion and the need for reoperative valve replacement have made this approach (without replacement) untenable to some practitioners. An alternative treatment option is to perform valvectomy followed by delayed valve replacement 3 to 9 months later.<sup>152</sup>

## FINAL POINTS

1. Reoperative valve surgery most commonly involves structural valve deterioration of a bioprosthesis or progression of native valve disease after nonvalve surgery.
2. Bioprosthetic valves are known to undergo a time-dependent process of structural deterioration that results in a freedom of reoperation of 80% at 15 years.

**TABLE 46-3: Technical Considerations for Reoperative Valve Surgery**

Consider reoperation before decline in functional status (NYHA class). Assess RV/aortic proximity to sternum preoperatively with CT scan
Consider alternate approaches (especially with patent bypass grafts)
Right thoracotomy for reoperative MVR
Mini-sternotomy for reoperative AVR
Consider alternate cannulation techniques to gain safe entry, eg, femoral, axillary
Address the LIMA-LAD graft if present
Dissect it out and clamp it, or
Cool and ignore it
Consider ease of implantation in valve choice, eg, mechanical in homograft
Use “no-touch” technique of bypass grafts
Use a conservative myocardial protection strategy
Antegrade and retrograde
Systemic cooling
Warm induction/final dose (“hot shot”)
If using hypothermic fibrillatory arrest, beware of AI leading to LV distension and/or obscuring operative field
Place external defibrillator pads
Consider the use of antifibrinolytic agents, eg, Amicar

3. Major risk factors in reoperative valve surgery include advanced age, impaired ejection fraction, congestive heart failure, urgency of operation, preoperative shock, concomitant coronary artery bypass surgery or presence of previous bypass grafts, prosthetic valve endocarditis, surgery for perivalvular leaks, valve thrombosis, or prosthetic dysfunction, renal dysfunction, chronic obstructive pulmonary disease, and pulmonary hypertension.
4. ECG-gated MDCT scanning is the preferred modality for preoperative assessment of vital structures in reoperative valve surgery.
5. Reoperative valve surgery after prior CABG with patent LITA graft presents unique challenges and the decision regarding intraoperative management of the patent graft must be made during the preoperative planning phase.
6. Reoperative aortic valve surgery after homograft or root replacement can be difficult and should be simplified by replacement with a mechanical valve when possible. Reoperative root operations should be avoided if not indicated.
7. AVB surgery is an alternative for reoperative AVR in extremely difficult reoperative cases.
8. TAVR is now an established technique of reoperative valve replacement in high-risk patients and VinV implantation is the next frontier of percutaneous valve implantation.
9. The right thoracotomy approach to reoperative mitral and tricuspid valves provides excellent exposure with minimal need for dissection while also avoiding prior

bypass grafts. Significant AI and the need for bypass grafting preclude this approach when aortic clamping and cardioplegic myocardial arrest are used.

10. Most commonly, periprosthetic leaks should be patched, rather than treated with valve replacement if the valve is functioning normally.
11. Reoperative tricuspid valve surgery occurs in high-risk patients with pulmonary hypertension with variable degrees of right heart failure. As such, this operation should be carefully considered.

# Aortic Dissection

Ravi K. Ghanta • Carlos M. Mery • Irving L. Kron

Thoracic aortic dissection occurs when an intimal tear allows redirection of blood flow from the aorta (true lumen) through the intimal defect into the media of the aortic wall (false lumen). A dissection plane that separates the intima from the overlying adventitia forms within the media. The acute form of aortic dissection is often rapidly lethal; whereas, those surviving the initial event go on to develop a chronic dissection with more protean manifestations. The purpose of this chapter is to review the etiology and pathogenesis of aortic dissection, examine current diagnostic algorithms, and provide detailed descriptions of contemporary surgical techniques for treatment. Additional information regarding follow-up and the subsequent management of these patients is presented to provide a comprehensive understanding of a clinical entity that has challenged physicians and surgeons for centuries.

## HISTORY

Sennertus is credited with the first description of the dissection process, but the earliest detailed descriptions of the clinical entity appeared in the seventeenth and eighteenth centuries, during which time Maunoir named the process aortic “dissection.” Laennec defined the propensity of the chronically dissected aorta to become aneurysmal. Aortic dissection was exclusively a postmortem diagnosis until the first part of the twentieth century, but in 1935 Gurin attempted surgical intervention with the first aortic fenestration procedure to treat malperfusion syndrome.<sup>1</sup> In 1949, Abbott and Paulin advanced surgical treatment by theoretically preventing aortic rupture by wrapping the aorta with cellophane. Other attempts at surgical treatment over the years met with limited clinical success, although certain concepts regarding surgical management are still in use today.<sup>2</sup> With the advent of cardiopulmonary bypass, DeBakey et al forever altered the natural history of aortic dissection by successfully performing primary surgical repair using techniques not remarkably different from contemporary procedures.<sup>3</sup> Investigators such as Wheat et al made substantial contributions by defining physiologically based medical management algorithms to complement surgical correction.<sup>4</sup> There is still considerable

controversy regarding surgical versus medical treatment of certain forms of acute thoracic aortic dissection.

## CLASSIFICATION

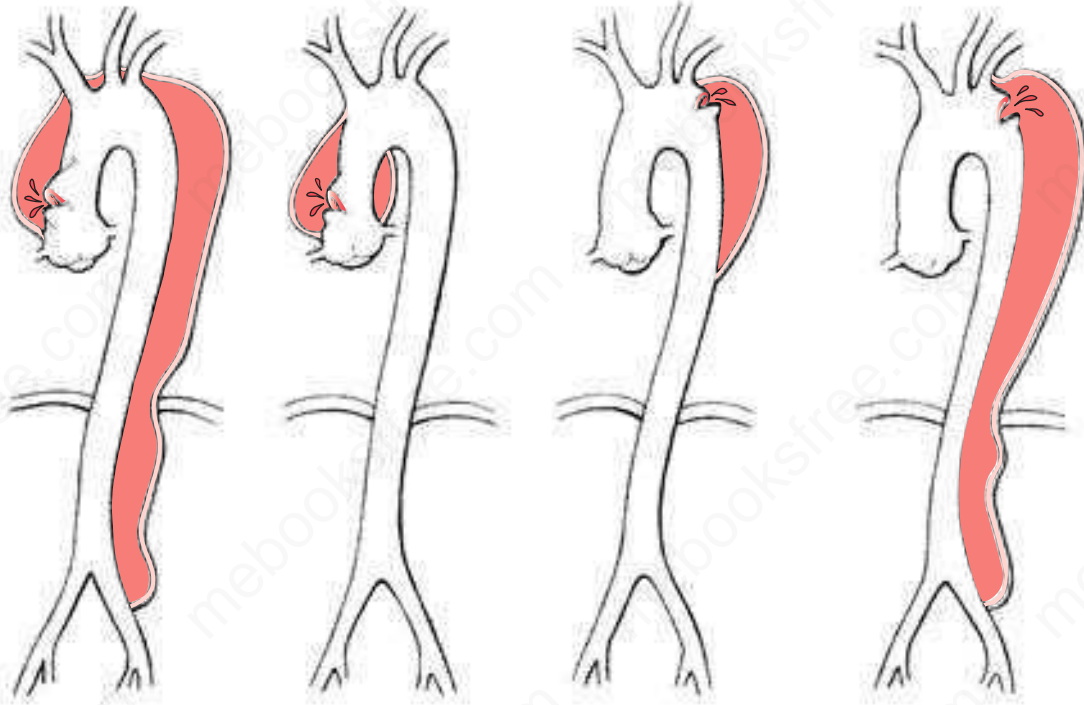

The classification systems used for aortic dissection are based on the location and extent of dissection. The particular type is then subclassified based on the timing of dissection. Acute dissection has traditionally been used to describe presentation within the first 2 weeks, whereas the term *chronic* is reserved for those patients presenting at more than 2 months after the initial event. The more recently added subacute designation is sometimes used to describe the period between 2 weeks and 2 months.

Two classification systems are most frequently used in clinical practice: the DeBakey and the Stanford systems (Fig. 47-1). The DeBakey system differentiates patients based on the location and extent of aortic dissection.<sup>5</sup> The advantage of this system is that four different groups of patients with different forms of aortic dissection emerge. This structure provides the greatest opportunity for subsequent comparative research. In contrast, the Stanford system proposed by Daily et al is a functional classification system.<sup>6</sup> All dissections that involve the ascending aorta are grouped together as type A, regardless of the position of the primary tear or the distal extent of the dissection. Proponents of the simpler Stanford system contend that the clinical behavior of patients with aortic dissection is essentially determined by involvement of the ascending aorta. Critics, however, suggest that individual patients in the type A classification may be quite different from one another depending on the distal extent. Drawing clinical conclusions from such a potentially heterogeneous patient population has inherent limitations. However, because of its simplicity, practicality, and widespread use, the Stanford system is used throughout this chapter.

## INCIDENCE

Aortic dissection is the most frequently diagnosed lethal condition of the aorta. Dissection occurs nearly three times as frequently as rupture of abdominal aortic aneurysm in the

**FIGURE 47-1** Classification of aortic dissection. DeBakey type I and Stanford type A include dissections that involve the proximal aorta, arch, and descending thoracic aorta. DeBakey type II only involves the ascending aorta; this dissection is included in the Stanford type A. DeBakey type III and Stanford type B include dissections that originate in the descending thoracic and thoracoabdominal aorta regardless of any retrograde involvement of the arch. These are subdivided into subtypes a and b, depending on abdominal aortic involvement.

United States.<sup>7</sup> There is an estimated worldwide prevalence of 0.5 to 2.95 per 100,000 per year; the prevalence ranges from 0.2 to 0.8 per 100,000 per year in the United States, resulting in roughly 2000 new cases per year.<sup>8</sup> These figures are only an estimate. In one autopsy series, the antemortem diagnosis was made in only 15% of patients, revealing that many immediately fatal events go undiagnosed.<sup>9</sup> Clinically, type A dissections occur with an overall greater frequency (Table 47-1).

**ETIOLOGY AND PATHOGENESIS**

Several hypotheses exist regarding the etiology of the intimal disruption (primary tear) that permits aortic blood flow to create a cleavage plane within the media of the aortic wall. This was originally viewed as a consequence of a biochemical abnormality within the media on which normal mechanical forces in the aorta acted to create an intimal tear. The link between the abnormal media, termed *cystic medial necrosis* or *degeneration*, and the primary tear has not been scientifically established. In fact, medial degeneration is found in only a minority of patients with acute aortic dissection, and most are children.<sup>10</sup> This theory has lost support over the years.

Alternatively, there are data supporting a relationship between aortic dissections and intramural hematoma. Advocates of this theory suggest that bleeding from vasa vasorum into the media creates a mass that results in localized areas

**TABLE 47-1: Clinical Characteristics of Patients Presenting with Acute Type A and B Thoracic Aortic Dissections**

	Type A	Type B

Peripheral pulse deficit	Upper and lower extremities	Lower extremities

of increased stress in the intima during diastole. These areas then permit intimal disruption. In fact, between 10 and 20% of patients thought to have acute aortic dissection are found to have intramural hematoma, suggesting that it may be a precursor to dissection.<sup>11</sup> Penetrating atherosclerotic ulcers have been implicated as the source of intimal disruption in some cases; thus many centers treat penetrating ulcers of the ascending aorta similar to true dissections.<sup>12</sup> Although it may apply to certain patients, enthusiasm for the penetrating ulcer mechanism causing all dissections has waned. The pattern of atherosclerotic involvement of the thoracic aorta resulting in penetrating ulcer and the frequency of dissection throughout the aorta do not support this theory.

Although no single disorder is responsible for aortic dissection, several risk factors have been identified that can damage the aortic wall and lead to dissection (Table 47-2). These include direct mechanical forces on the aortic wall (ie, hypertension, hypervolemia, derangements of aortic flow) and forces that affect the composition of the aortic wall (ie, connective tissue disorders or direct chemical destruction). Hypertension is the mechanical force most often associated with dissection and is found in greater than 75% of cases.<sup>8</sup> Although the role of increased strain on the aortic wall is intuitive, the mechanism by which hypertension actually leads to dissection is unclear. Similarly, hypervolemia, high cardiac output, and an abnormal hormonal milieu certainly contribute to the increased incidence of dissection in pregnancy, but the mechanism is unclear. Atherosclerosis is not a risk factor for aortic dissection except in preexisting aneurysms or in the case of atherosclerotic ulceration. Iatrogenic trauma

**TABLE 47-2: Risk Factors for Type A and B Thoracic Aortic Dissection**

to the aortic intima may result in dissection. Catheterization procedures, aortic root and femoral artery cannulation for cardiopulmonary bypass, aortic cross-clamping, surgical procedures performed on the aorta (aortic valve replacement and aortocoronary bypass grafting), and placement of intra-aortic balloon pumps have all been reported to result in dissection. Aortic transection as a result of trauma rarely results in excessive dissection and deserves differentiation from the process of aortic dissection. This process is usually limited to the aortic isthmus and in addition to the risk of rupture may present as a circular prolapse of the intima and media producing aortic obstruction referred to as "pseudocoarctation" (Fig. 47-2).

Once a cleavage plane exists in the media, the aortic wall floating within the lumen is termed the *dissection flap* and is composed of the aortic intima and partial-thickness media. The primary tear is usually greater than 50% of the circumference of the aorta. Full aortic circumference is rarely involved, but may carry a worse prognosis. The primary tear in type A dissection is usually located on the right anterior aspect of the ascending aorta and follows a somewhat predictable course, spiraling around the arch and into the descending thoracic and abdominal aorta on the left and posteriorly. The dissection may propagate in a retrograde fashion for a variable distance as well to involve the coronary ostia; this occurs in roughly 11% of all dissections.<sup>11</sup> Myocardial ischemia or aortic rupture into the pericardium is the cause of death in as many as 80% of mortalities from acute dissection. Often the distal false lumen communicates with the true lumen through one or more fenestrations within the dissection flap. The false lumen may also end blindly in as many as 4 to 12% of patients, in which case blood in the false lumen frequently thromboses. The false lumen may also penetrate the adventitia, causing rupture and death. Regardless of whether the true and false lumens communicate, perfusion of aortic side branches may be compromised by the dissection,

**FIGURE 47-2** Axial image of CT arteriogram showing a nearly circumferential dissection flap (*arrowhead*) as a result of acute traumatic aortic dissection.

**FIGURE 47-3** Diagram of aortic dissection. (A) An intact dissection membrane compresses the true lumen and causes malperfusion of a branch artery. (B) Rupture of the dissection membrane that may or may not restore blood flow to the branch.

resulting in end-organ ischemia (Fig. 47-3). If these acute complications are avoided, the weakened outer aortic wall, composed of partial media and the adventitia, may dilate over time, resulting in aneurysm formation. This evolving dilatation is the reason for operation in the majority of chronic dissections regardless of type.

The remaining adventitia provides most of the tensile strength of the aortic wall with minimal contribution from the media. The media is composed of concentrically arranged smooth muscle interposed with connective tissue proteins such as collagen, elastin, and fibrillin within the ground substance. Abnormal constituents of the media, as in certain connective tissue disorders such as Marfan's disease and Ehlers-Danlos syndrome, are associated with aortic dissection. Marfan's syndrome is an autosomal dominant inherited disorder in which a point mutation in the fibrillin-1 gene (FBN1) located on the long arm of chromosome 15 results in an abnormal media. The incidence of Marfan's syndrome is approximately 1 per 5000 live births.<sup>13</sup> There are, however, many incomplete forms of the disease, and as many as 25% may be sporadic in which no known fibrillin abnormalities are observed. Type IV Ehlers-Danlos syndrome is a connective tissue disorder of the pro $\alpha$ 1(III) chain of type III collagen with an incidence of 1 in 5000.<sup>14</sup> The structurally abnormal media is susceptible to dissection. Of note, there are also familial aggregations of dissection without discernable biochemical or genetic abnormalities.<sup>7</sup>

## CLINICAL PRESENTATION

### Signs and Symptoms

As many as 40% of patients suffering from acute aortic dissection die immediately. Those surviving the initial event may be stabilized with medical management, and it is these

patients in whom subsequent therapeutic intervention on aortic dissection has altered the natural history of the disease. The clinical outcome is eventually determined by dissection type and timing of presentation, patient-related factors, and the quality and experience of the individuals and institution providing care.

The initial evaluation of a stable patient with suspected aortic dissection includes a detailed history and physical examination focusing on those elements likely to rule in the diagnosis. Most importantly, the diagnosis of aortic dissection requires a high level of suspicion. Up to 30% of patients ultimately diagnosed with acute dissection are first thought to have another diagnosis. Aortic dissection should always be considered in the setting of severe, unrelenting chest pain, which is present in most patients. Patients usually have no previous episodes of similar pain, which often causes anxiety. Pain is usually located in the midsternum for ascending aortic dissection, while in the interscapular region for descending thoracic aortic dissection (see Table 47-1). The location of maximum pain tends to change as the dissection extends in an antegrade or retrograde direction. Such "migratory pain" should arouse clinical suspicion. The character of the pain is often described as "ripping" or "tearing." The pain is constant with greatest intensity at the onset. Although painless dissection has been described, it usually occurs in the setting of an existing aneurysm in which the pain of a new dissection may not be differentiated from chronic aneurysm pain. Patients may also present with signs or symptoms related to malperfusion of the brain, limbs, or visceral organs. These findings confuse the true diagnosis, as the obvious signs of ischemia distract the historian from a less apparent initial episode of pain.

Elements of the past medical history such as primary hypertension, presence of aneurysmal disease of the aorta, or familial connective tissue disorders are useful as risk

factors to help establish the diagnosis. Illicit drug use is an increasingly important predisposition to ascertain during the initial evaluation. The differential diagnosis of chest pain as a result of aortic dissection includes diagnoses such as myocardial ischemia, aortic aneurysm, acute aortic regurgitation, pericarditis, musculoskeletal pain, and pulmonary embolus. It is essential to consider aortic dissection in each case, as specific therapy (eg, thrombolytic therapy for acute myocardial infarction) may impact the survivability of acute dissection.

Patients suffering acute dissection appear ill. Tachycardia is usually accompanied by hypertension in the setting of baseline essential hypertension and increased catecholamine levels from pain and anxiety. Hypotension and tachycardia may result from aortic rupture, pericardial tamponade, acute aortic valve regurgitation, or even acute myocardial ischemia with involvement of the coronary ostia. An abnormal peripheral vascular examination is present in a minority of patients with acute aortic dissection, but when present an abnormal pulse exam may indicate the type of dissection. Absence of pulses in the upper extremity suggests ascending aortic involvement, whereas pulse deficits in the lower extremities speak to involvement of the distal aorta. These findings are subject to change as the dissection progresses or reentry into the true lumen occurs. Auscultation of the heart may reveal a diastolic murmur consistent with acute aortic regurgitation or an S3, indicating left heart volume overload. Physical exam findings such as jugular venous distention and a pulsus paradoxus are signs of pericardial tamponade that should be identified in any unstable patient to initiate the correct diagnostic and treatment algorithms. Unilateral loss of breath sounds, usually the left, may indicate hemothorax as a result of aortic leak or rupture with hemothorax. Alternatively, a pleural effusion may exist secondary to pleural inflammation related to the dissection. This finding requires additional evaluation before treatment.

A complete central and peripheral neurologic exam is critical in that abnormalities are present in up to 40% of acute type A dissections. Involvement of the brachiocephalic vessels with loss of brain perfusion may result in transient syncope or stroke. Syncope may also result from rupture into the pericardium and is an ominous sign. Stroke rarely

improves with restoration of blood flow and may even cause hemorrhage and brain death, yet surgery is indicated in such patients. Fortunately, stroke is a presenting feature in fewer than 5% of patients with acute type A dissection. Loss of perfusion to intercostals or lumbar arteries may result in spinal cord ischemia and paraplegia. Peripheral nerve ischemia as a result of malperfusion may yield findings similar to spinal cord malperfusion and should be discerned as these patients often improve with restoration of blood flow. Acute aortic dissection may also cause superior vena cava syndrome, vocal cord paralysis, hematemesis, Horner's syndrome, hemoptysis, and airway compression as a result of local compression and mass effect.

Malperfusion of aortic branch vessels may occur from the coronary ostia to the aortic bifurcation and may dominate the presentation of certain patients. Although autopsy series yield a greater percentage of patients with evidence of malperfusion, clinical series reveal that dissection is not infrequently complicated by malperfusion of at least one organ system (Table 47-3).<sup>15</sup> Compression of the true lumen by the false lumen is the mechanism by which aortic branch vessel occlusion occurs in the majority of cases. Branch vessels may also be completely sheared off the true lumen and perfused to various degrees by the false lumen.

Chronic aortic dissection is usually asymptomatic. It may be incidentally discovered following an asymptomatic acute dissection, most often in patients with a preexisting aortic aneurysm. Some patients eventually require surgical treatment for chronic dissection and most do so as a result of aneurysmal dilatation of a chronically dissected aortic segment. Presenting complaints often include intermittent, dull chest pain, or even severe skeletal pain from erosion into the bony thorax with large or rapidly expanding aneurysms. Aortic insufficiency may develop with chronic type A dissection and present with typical features of congestive failure, including fatigue, dyspnea, and mild, dull chest pain. Infrequently, chronic dissection may result in paralysis/paraplegia from loss of vital intercostal arteries or even distal embolization of thrombus or atheroma from the false lumen. Malperfusion syndrome is an uncommon presentation for patients with chronic dissection given the likelihood that the true and false lumens communicate.

**TABLE 47-3: Frequency and Location of Malperfusion in Acute Type A and B Thoracic Aortic Dissection**

Vascular system	Frequency (%)
Renal	23-75
Extremities (upper and lower)	25-60
Mesenteric	10-20
Coronary	5-11
Cerebral	3-13
Spinal	2-9

## Diagnostic Studies

Routine diagnostic studies including blood tests, chest x-ray, and electrocardiogram (ECG) should be obtained, but are often not sufficient to establish the diagnosis of acute aortic dissection. ECG often reveals no ischemic changes. Obvious ischemic changes are present in up to 20% of acute type A dissections, whereas only nonspecific repolarization abnormalities are present in nearly one-third of patients with coronary ostial involvement. The ECG may also reveal left ventricular hypertrophy in those patients with long-standing hypertension. The chest x-ray is abnormal in 60 to 90% of patients with acute dissection (Fig. 47-4). Although most patients have at least one, if not several abnormal findings,

**FIGURE 47-4** Plain chest x-ray exhibiting many features of acute type A dissection, such as a widened mediastinum, rightward tracheal displacement, irregular aortic contour with loss of the aortic knob, an indistinct aortopulmonary window, and a left pleural effusion.

a normal chest x-ray does not rule out the diagnosis. Blood should be drawn and sent for complete blood count, serum and electrolytes, creatine kinase with myocardial isoenzymes, troponin, and blood type and screen. These tests obtained at the time of initial observation are usually unremarkable. There is frequently a mild to moderate leukocytosis. Anemia may result from sequestration of blood or hemolysis. Liver function tests, serum creatinine, myoglobin, and lactic acid may all be abnormal in the setting of certain malperfusion syndromes.

### Diagnostic Imaging

Diagnostic imaging is essential to clarify the anatomy of an acute aortic dissection, regardless of clinical certainty of diagnosis or the acuity of the patient. The diagnosis should be made rapidly with minimal distress for the patient. Two imaging modalities currently meet these criteria and are used to diagnose acute aortic dissection: computed tomography (CT) and echocardiography. Magnetic resonance imaging (MRI) and aortography, with or without intravascular ultrasound (IVUS), are used to diagnose acute aortic dissection but are second-line modalities for various reasons. The benefits, disadvantages, and diagnostic accuracy of each are useful when choosing the most appropriate study for a particular clinical situation (Table 47-4). Each test provides disruption, reentry points, whether there is flow or thrombus in the false lumen, status of the aortic valve, the presence and nature of myocardial ischemia, and brachiocephalic and aortic branch vessel involvement. Specific data may be necessary for operative planning and subsequent management to define the imaging study most appropriate for a particular patient. In a recent review, an average of 1.8 imaging studies was used to diagnose correctly acute aortic dissection.<sup>9</sup>

Helical CT scanning is widely available and is now the most frequently used test to diagnose acute aortic dissection. It requires intravenous contrast medium that may limit its

**TABLE 47-4: Sensitivity and Specificity of Various Imaging Modalities Useful for the Diagnosis of Thoracic Aortic Dissection**

Imaging study	Sensitivity (%)	Specificity (%)
Aortography	80-90	88-93
Computed tomography	90-100	90-100
Intravascular ultrasound	94-100	97-100
Echocardiography		
Transthoracic	60-80	80-96
Transesophageal	90-99	85-98
Magnetic resonance imaging	98-100	98-100

use in certain clinical situations but generates images familiar to most practitioners and has a high sensitivity and specificity. This technique can be performed quickly, fulfilling the requirements for use in the early management of acute dissection. Additional structures such as the pleural and pericardial spaces are imaged. When performed and formatted as an arteriogram, aortic branch vessels may also be evaluated: Involvement of the brachiocephalic vessels is identified with nearly 96% accuracy. The diagnosis of dissection requires two or more channels separated by a dissection flap (Fig. 47-5). For operative planning, a CT scan with arterial phase contrast of the chest, abdomen, and pelvis to the level of the femoral arteries is ideal. Transaxial two-dimensional images can be reconstructed to display three-dimensional images of the aorta that not only aid in diagnosis but also are useful for operative planning.

Transesophageal echocardiography (TEE) is currently the second most frequently used study for making the diagnosis of

**FIGURE 47-5** Axial image of CT arteriogram of acute type A dissection showing a dissection flap in the mid-ascending aorta.

**FIGURE 47-6** Transesophageal echocardiogram showing the dissection membrane (arrowheads) in the short (left panel) and long (right panel) views of a type A dissection.

acute aortic dissection. It is widely available, requires no intravenous contrast or radiation, and generates dynamic images of the aorta from which the diagnosis can be made (Fig. 47-6). It requires operator expertise both to acquire the necessary images and to conduct the examination safely. Although the safest setting in which to perform TEE is the operating room under general anesthesia, it can be performed in a monitored setting using topical anesthesia and light sedation. Patient comfort is paramount in this situation as rupture has been reported during difficult studies and a complete examination of the entire aorta is necessary to exclude the diagnosis of acute dissection. Absolute contraindications to TEE include esophageal abnormalities such as varices, stricture, or tumor. A full stomach or recent meal is a relative contraindication, but recognition of these conditions permits safe examination with few complications in the vast majority of patients. Criteria for making the diagnosis of acute aortic dissection include visualization of an echogenic surface separating two distinct lumens, repeatedly, in more than one view, and that can be differentiated from normal surrounding cardiac structures. The true lumen is identified by expansion during systole and collapse during diastole. Communication of the false lumen is found by identifying distal tears in the flap and flow in the false lumen with the addition of color Doppler. Similarly, the absence of flow indicates false lumen thrombosis. TEE additionally may provide high-quality images of the aortic valve and pericardial space. The coronary ostia are directly evaluated and regional left ventricular function may be assessed to identify myocardial ischemia indirectly. Color flow Doppler reliably quantifies aortic regurgitation and may be used to assess for additional valvular abnormalities. The pericardium and pleural space are also visualized and therefore effusions may be identified.

Transthoracic echocardiography (TTE) provides images of the ascending aorta and sections of the aortic arch that may yield the diagnosis but with much less sensitivity than transesophageal imaging. As such, transthoracic imaging may prove useful but is generally insufficient to establish reliably the diagnosis. Transthoracic evaluation is additionally limited by patient-related factors including body habitus,

emphysema, and mechanical ventilation. A negative transthoracic study should be complemented by a transesophageal study, which provides greater detail of the entire aorta.

Aortography was the first study used to diagnose acute dissection in 1939 and until recently was considered the gold standard for diagnosis. It is an invasive test requiring nephrotoxic contrast media in which the aorta is visualized in multiple two-dimensional projections. The diagnosis of dissection depends on visualization of the intimal flap, two distinct lumens, or compression of the true lumen by flow through an adjacent false lumen (Fig. 47-7). Indirect signs of

**FIGURE 47-7** Aortogram of acute type B dissection illustrating differential contrast enhancement of the true and false lumens in the descending thoracic aorta. The intimal flap (arrowhead) can be seen separating the two lumens.

dissection include the presence of branch vessel abnormalities and abnormal intimal contour on injection of the false lumen. The status of the aortic valve may be evaluated and coronary angiography in the setting of type A dissections is possible only with this diagnostic test. However, coronary angiography is not recommended given that the coronary ostia are involved in 10 to 20% of acute type A dissections and are easily evaluated at the time of surgery. Coronary atherosclerosis is present in 25% of all patients with acute aortic dissection, but even in those patients repair of the dissection should take precedence. Aortography is sometimes useful in acute type B dissections with evidence of mesenteric ischemia or oliguria and in type A dissections with signs of malperfusion because catheter-based intervention may be possible. Aortography can have a high false-negative rate secondary to thrombosis of one lumen or when contrast equally opacifies each lumen, impairing distinction of a separate true and false lumen.<sup>9</sup> The diagnosis of intramural hematoma may also be difficult given the absence of intimal disruption, whereas penetrating atherosclerotic ulcer is usually easily visualized. Visualization of the dissection variants is best accomplished with either CT scanning or MRI (Figs. 47-8 and 47-9). One major limitation to the use of aortography in the acute setting is the need for skilled personnel. The time required to assemble this team varies with each institution, rendering aortography less useful when compared with other immediately available diagnostic tests. Aortography also requires arterial access, which can be painful and precipitate rupture or dissection extension.

IVUS is a catheter-based imaging tool that provides dynamic imaging of the aortic wall and an intimal flap in patients with aortic dissection. It is particularly useful in delineating the proximal and distal extent of dissection and

**FIGURE 47-8** Axial image from a CT arteriogram showing an intramural hematoma of the descending thoracic aorta (*arrowhead*).

**FIGURE 47-9** Sagittal contrast-enhanced MRI of penetrating atherosclerotic ulcer of the ascending aorta (*arrowhead*).

for identifying the true and false lumens in questionable cases during aortography. High-resolution images of the normal three-layered aortic wall are differentiated to identify the abnormally thin wall adjacent to the false lumen. Because the aortic wall itself is imaged, intramural hematoma and penetrating atherosclerotic ulcers may also be identified. Currently, as an isolated imaging study, it is time consuming and requires skilled personnel, as with aortography, and generally is not useful as an initial study in the acute setting. It may be most useful in combination with aortography when the initial imaging studies are negative, yet there remains a high clinical suspicion of dissection.

MRI and the newer contrast-enhanced magnetic resonance angiography (MRA) generate superior images reliably demonstrating aortic dissection (Fig. 47-10). MRI/MRA offers detailed anatomy as CT does but does not require radiation. Moreover, MRI may be particularly useful in pregnant patients. Dissection is identified as an intraluminal membrane separating two or more channels (Fig. 47-11). MRI provides detailed images of the entire aorta, the pericardium, and pleural spaces similar to those obtained with CT. Cine imaging may also be used to evaluate left ventricular function, the status of the aortic valve, and flow in aortic branch vessels as well as flow in the false lumen. It is, however, not widely available and the presence of ferromagnetic metal contraindicates its use. Another disadvantage of MRI is that artifact is identified in up to 64% of studies, which underscores the need for expert radiologic interpretation of the images. These factors account for its infrequent use in the acute setting.

**FIGURE 47-10** Sagittal contrast-enhanced MRI of a chronic type B dissection. The dissection flap (*arrowhead*) is clearly identified and the false lumen appears to extend the entire length of the thoracic and abdominal aorta (*darker posterior lumen*).

### Diagnostic Strategy

The evaluation of suspected acute aortic dissection begins with a determination of the clinical likelihood that the diagnosis is correct and an evaluation of the hemodynamic stability of the patient. The unstable patient with a high suspicion for acute aortic dissection should be transferred immediately to the operating room. Medical management may be initiated as soon as the diagnosis is suspected. It is our practice to intubate and mechanically ventilate such patients while essential monitoring lines are placed. A TEE is then performed. If TEE fails to reveal acute aortic dissection, a hemodynamically unstable patient will then have a protected airway and invasive monitoring lines for subsequent evaluation of alternative diagnoses and continued resuscitation. If acute dissection is suspected despite a negative TEE, CT arteriogram (CTA) or aortography (potentially with IVUS) is the next study of choice.

Clinically stable patients permit a more detailed history and physical examination with imaging decisions tailored to specific aspects of the presentation. At the University of Virginia, all stable patients with a suspected dissection are evaluated with a CTA, as this study is definitive and provides valuable anatomic information for procedural planning. If dissection is identified on other studies, such

**FIGURE 47-11** Axial (A) and sagittal (B) contrast-enhanced MRI of a chronic type A dissection.

as a TTE, our preference is to obtain a CTA of the chest, abdomen, and pelvis provided the patient is stable prior to proceeding to the operating room. Detailed anatomic information from CTA is valuable for operative planning and postoperative management, especially in cases with abdominal malperfusion.

Diagnostic imaging of chronic aortic dissection is usually performed for surveillance, but may also be necessary in patients with symptoms attributable to dissection and for operative planning. Routine follow-up for acute dissection occurs on a scheduled basis and is usually done with either CT or MRI. We prefer CT scanning for patients with normal renal function and no contrast allergy because CT is usually the original imaging study obtained during the acute dissection. The improved accuracy that comes with comparing similar studies combined with the availability, cost, and patient satisfaction makes CT favorable for this purpose. MRI is used mostly as a follow-up study for patients with renal insufficiency, but is the study of choice to provide precise anatomical detail for operative planning. TTE is useful to follow chronic type A dissection when there is aortic insufficiency. It can provide cross-sectional images of the ascending aorta, but generating images useful for comparison to previous studies is highly dependent on the skill of the operator. For that reason, we use echocardiography to follow patients with aortic insufficiency but also obtain a CT scan to assess ascending aortic diameter. Aortography is used primarily for operative planning. Patients older than 50 years and those with risk factors for coronary artery disease routinely undergo coronary arteriography before operation, and images of the aorta are obtained at that time. Aortography is especially useful to determine the origin of aortic branch vessels for operative planning when noninvasive imaging is inadequate (Fig. 47-12).

## MANAGEMENT OF ACUTE TYPE A AORTIC DISSECTION

### Natural History

Acute type A aortic dissection is impressively morbid. Fifty percent of patients suffering acute type A aortic dissection are dead within 48 hours if untreated.<sup>16</sup> Data such as these suggest that acute type A dissection carries a “1% per hour” mortality for missed diagnoses. More contemporary data reveal a different prognosis such that medical management may be considered in certain high-risk groups. In one such study in octogenarians, type A dissection was managed medically in 28% of patients for various reasons with a 58% in-hospital mortality.<sup>8</sup> Regardless, because of the extreme mortality with medical management, patients surviving acute type A aortic dissections must be aggressively diagnosed and treated with surgical intervention.

### Initial Medical Management

The high morbidity of acute type A aortic dissection dictates that management should precede confirmation of diagnosis in highly suspicious cases. The initial patient encounter centers on making the diagnosis while identifying factors that require immediate treatment. The site of this initial evaluation and resuscitation is determined primarily by the hemodynamic stability of the patient. The unstable patient belongs in the operating room, whereas a more detailed diagnostic approach and subsequent management can be undertaken in stable patients. Therefore, the hypotensive patient, whether from hemorrhagic shock or tamponade, requires the aforementioned evaluation and resuscitation on transfer to the operating room. It is preferable to avoid procedures such as TEE

**FIGURE 47-12** Coronal view of contrast-enhanced MRI (A) demonstrating chronic type B dissection with renal arteries (*arrowheads*) separated by the dissection flap (*arrow*). Aortogram (B) of the same patient revealing that each renal artery is perfused exclusively by either the true or false lumen. Such tests are often complementary and may influence surgical strategy.

or central line placement on an awoken patient outside the operating room because hypertension resulting from patient discomfort may precipitate aortic rupture or propagation of dissection. However, as in any patient with potential aortic rupture, anesthetic induction remains dangerous in patients compensating for impaired preload, whether from pericardial fluid or hypovolemia. The operating room must be prepared for prompt decompressive pericardiotomy and/or initiation of cardiopulmonary bypass.

In the hemodynamically stable patient, blood pressure is measured in both arms and both legs. These dissections can propagate in either direction, but proximal propagation can quickly destabilize the situation. In general, the goals of hypertension management in acute aortic dissection, regardless of anatomy, are twofold.<sup>4</sup> First, transmural aortic wall stress is diminished by decreasing the systolic blood pressure, which reduces the possibility of rupture. Second, shear stress on the aorta is decreased by minimizing the rate of rise of aortic pressure to decrease the likelihood of dissection propagation, so-called anti-impulse therapy. Specifically, the immediate goal for this situation remains to achieve a target systolic blood pressure between 90 and 110 mm Hg with a target heart rate of less than 60 beats per minute.

Pain control is important to reduce catecholamine release and decrease the risk of rupture. Therefore, therapy begins with pain control using narcotic analgesics. The drugs most commonly used for anti-impulse therapy are beta-blockers and peripheral vasodilators. In most cases, beta-blockers such as esmolol should be used first because adequate heart rate control may be difficult if the blood pressure is controlled by peripheral vasodilators first and because vasodilators may increase ventricular ejection and aortic shear stress if used unopposed. Short-acting beta-blockers should be titrated to a heart rate less than 60 beats per minute. After beta-blocker treatment has been initiated, vasodilators such as sodium nitroprusside are used for further blood pressure control. Sodium nitroprusside is a direct arterial vasodilator with a short onset and duration of action, which makes it ideal to achieve rapidly the target systolic blood pressure. Loading doses for esmolol and sodium nitroprusside should be avoided to prevent hypotension. Alternative beta-1 blocking drugs such as propranolol or metoprolol, and the combined alpha- and beta-blocker labetalol are appropriate in the subacute phase. Calcium channel blockers may be necessary to reduce systolic blood pressure in those patients with a contraindication to beta-blocker use. A commonly used alternative to nitroprusside is nicardipine. This is also a calcium channel-blocker devoid of any cardiac effects which is easily titrated to a goal blood pressure.

## Operative Indications

The goals of surgery in acute type A dissection are to prevent or treat an aortic catastrophe while restoring blood flow to the true lumen of the aorta. Aortic catastrophe includes aortic rupture into the pericardium or pleural space, dissection and occlusion of the coronary ostia, and progression

**TABLE 47-5: Operative Indications for Acute and Chronic Type A and B Thoracic Aortic Dissection**

Dissection type	Operative indication
Acute	
Type A	Presence
Type B	Failure of medical management (persistent or recurrent pain, medically uncontrolled hypertension)
	Expanding aortic diameter
	Progressive dissection
	Impending or actual rupture
	Malperfusion
Chronic	Impending or actual rupture
	Symptoms related to dissection (congestive heart failure, angina, aortic regurgitation, stroke, pain)
	Malperfusion
	Aneurysm $\geq 5.5$ cm (type A), $\geq 6.5$ cm (type B)
	Aortic expansion $> 1$ cm/year

to aortic valvular incompetence. The presence of ascending aortic involvement is therefore an indication for operative management in all but the highest-risk patients (Table 47-5). The difficulty arises in determining which patients are at high risk and which additional factors should affect the management algorithm. Patient age, for example, is not regarded as an absolute contraindication to surgery. However, this factor should be considered given the relative worse outcomes of operative treatment for acute type A dissection for patients greater than 80 years of age. Neurologic status at the time of presentation can also affect the decision to operate. Although most agree that obtunded or comatose patients are unlikely to improve with surgical repair, complications such as stroke or paraplegia at the time of presentation are not contraindications to surgical correction. It must be acknowledged that dissection repair will most likely not improve neurologic condition, and may even make it worse. Neither the distal extent nor the thrombosis of the false lumen obviates the need for surgical repair because the risk of developing an aortic catastrophe remains. Similarly, patients with subacute type A dissection who present or are referred after 2 weeks of dissection onset require operation. Scholl et al demonstrated that these patients have avoided the early complications of dissection and may safely undergo elective operation rather than emergency repair.<sup>17</sup>

Important surgical considerations for Type A aortic dissection include extent of aortic repair, establishment of cardiopulmonary bypass, temperature management, cerebral protection, myocardial protection, and management of aortic insufficiency and end-organ perfusion during and after completion of surgery. Technical considerations for establishment of cardiopulmonary bypass, cerebral protection, and

temperature management are discussed in depth below. An important component to any surgical strategy includes identification and correction of end-organ malperfusion. Patients who present with abdominal pain or tenderness and lactic acidosis may require additional endovascular procedures, such as fenestration or mesenteric stenting either immediately after or in select cases, prior to, ascending aortic repair.

## ANESTHESIA AND MONITORING

Anesthesia used during the repair of aortic dissections is often narcotic based with inhalational agents for maintenance. Single-lumen endotracheal tubes are used for procedures performed through a median sternotomy, whereas double-lumen endotracheal tubes are useful but not mandatory for procedures performed through a left thoracotomy. Monitoring lines often include central venous access with a pulmonary artery catheter and one or more arterial pressure monitoring lines specific to the operation performed. Preparation must be made for all possibilities in these cases, most importantly for the possible need for hypothermic circulatory arrest. Arterial monitoring should be tailored to both the anatomy of the dissection and the method of cannulation. One or two radial arterial lines and at least one femoral line may be required to ensure adequate perfusion of the upper and lower body. If antegrade cerebral perfusion via a right axillary or innominate artery cannulation is planned, right arterial line placement (in addition to femoral and/or left radial) is useful to measure perfusion pressure. All patients require a TEE probe. Core body temperature is monitored in the bladder using a Foley catheter and in the esophagus using a nasopharyngeal probe. A wide skin preparation to include the axillary and femoral arteries is essential to provide all possible cannulation options.

Neurologic monitoring is available, but its utility remains controversial even in elective cases. Advocates of both cerebral and spinal cord monitoring argue that these monitors are able to detect injury to neurons before irreversible cellular injury.<sup>18</sup> Thus, this warning allows for detection of imminent injury and subsequent evasion of injury. Opponents argue that there is a significant learning curve and that the injury has already occurred once these monitors can identify ischemic neurologic changes. The optimal type of monitoring depends on the location of the dissection and the resultant details of required vascular control. Manipulation of the ascending aorta and arch can affect cerebral perfusion. In these cases, transcranial Doppler (TCD) or near-infrared spectroscopy (NIRS) has been used. Intraoperative TCD monitoring is used to identify malpositioned cannulas or document the need for adjustment of retrograde perfusion.<sup>19</sup> Opponents of TCD argue difficulty with low baseline flow and poor signal in patients with thick temporal bones, which confuses interpretation of the results and the response to them. Continuous noninvasive NIRS can be used to monitor cerebral oxygenation, marker of cerebral blood flow. Although the role of NIRS in aortic dissection has not been elucidated, advocates extrapolate use from studies on carotid endarterectomy and coronary bypass.

NIRS can be used for identification of regional oxygenation changes during the case, which may be particularly useful during normothermic periods of these cases.<sup>18</sup> Somatosensory evoked potentials (SSEP) is argued to be useful in identifying neurologic injury ranging anywhere from the peripheral nerve to the brain. These studies may even identify ischemic cerebral injury during hypothermic circulatory arrest earlier than electroencephalography (EEG).<sup>20</sup> SSEP can also be useful in the detection of spinal cord ischemia to identify crucial spinal cord vasculature requiring reimplantation. The use of SSEP at some centers has led to reduced intraoperative and postoperative paraplegia in retrospective studies.<sup>21</sup> Neurologic monitoring remains a relatively new technology that is operator dependent, but probably is useful in experienced hands.

## HEMOSTASIS

Open aortic dissection repair is commonly associated with significant blood loss caused by weak tissues and coagulopathy from bleeding or hypothermia. Strict blood conservation is an important aspect of the operation. At least one cell-saver device should be available. Packed red blood cells, platelets, and fresh-frozen plasma should be in the operating room at the start of the operation. Coagulopathy as a result of the preoperative status of the patient, cardiopulmonary bypass, and deep hypothermic circulatory arrest contribute to excessive blood loss. Antifibrinolytic drugs can be useful hemostatic adjuncts. Patients will often require transfusion of fresh-frozen plasma, platelets, and possibly cryoprecipitate. Fibrin glues and hemostatic materials such as Surgicel and Gelfoam are useful as systemic coagulopathy is corrected.

## CARDIOPULMONARY BYPASS

Cannulation for type A dissection repair requires thoughtful evaluation of the dissection anatomy while taking into consideration the extent of the repair to be undertaken. The crucial point is to provide arterial flow into the true lumen of the aorta with proof of sufficient end-organ perfusion, in particular as dynamic flaps may alter perfusion. Some flexibility regarding arterial access should be exercised. In certain situations, a patient may require multiple cannulation sites to perfuse adequately the entire body. Various options for cannulation exist, but the optimal choice of cannulation in aortic dissection requires tailoring to the combination of surgeon preference with dissection anatomy.

Venous cannulation remains relatively straightforward. Venous cannulation is obtained commonly through the right atrium using a two-stage venous cannula, whereas bicaval cannulation is used for certain cases in which retrograde cerebral perfusion is used during hypothermic circulatory arrest. A left ventricular vent is necessary in the setting of aortic valve incompetence and is easily placed through the right superior pulmonary vein or rarely through the left ventricular apex wall. Cardioplegia is administered in a retrograde fashion through a coronary sinus catheter with additional protection via direct cannulation of the undissected coronary ostia.

Arterial cannulation requires a much more thoughtful process. Right axillary artery, femoral artery, and direct ascending aortic cannulation are the three most common techniques. The optimal site of cannulation should be tailored based on the combined goals of surgery and the specific anatomy of the patient, with contingency plans for evidence of malperfusion.

Historically, femoral cannulation was the site of choice for arterial cannulation for type A dissection. The most favorable side of femoral cannulation has been debated in the past, but as long as there is perfusion into the true lumen, the side most likely does not matter. Reports from the University of Virginia, among others, have also shown that the dissected ascending aorta itself can be cannulated safely with echocardiographic guidance.<sup>22</sup> This technique involves confirming access to the true lumen of the aorta with echocardiography of the descending aorta. Then, using the Seldinger technique, a percutaneous cannula can be properly positioned. Direct cannulation should be avoided through areas with evidence of hematoma. Proper perfusion of the true lumen must be confirmed with ultrasound or echocardiography. A potential salvage maneuver involves cannulation of the ventricular apex with advancement of the cannula through the aortic valve and into the true lumen of the aorta. This technique also requires confirmation of true lumen perfusion. Aortic cannulation of either the dissection area or the apex mandates cannulation of the graft after repair in most cases.

Increasingly, the right axillary artery is being utilized for cannulation during dissection repair and is the first choice cannulation site at many institutions.<sup>23</sup> The right axillary artery provides direct access to the right carotid artery for selective antegrade perfusion. This can be done by sewing a graft to the artery or directly cannulating it. However, direct axillary cannulation appears to cause more morbidity than graft cannulation, including further dissection, brachial plexus injury, and limb ischemia. Axillary cannulation may be suboptimal in cases in which the axillary, right common carotid, or innominate artery are dissected. Similar techniques have been described in cannulation approaches to the innominate artery.

No matter the preferred site of arterial cannulation, the surgeon must be cognizant of whole body perfusion. Patients that are not cooling properly or show other signs of malperfusion may require more than one arterial cannulation sites for cardiopulmonary bypass. Routine confirmation of blood flow in the carotids as well as the descending aorta can be critical to avoid malperfusion.

## CEREBRAL PROTECTION

Type A dissection repair involving the arch disrupts blood flow to the brachiocephalic arteries during a period of circulatory arrest. Cerebral protection during that period is critical to neurologic outcome. Cerebral protection is optimized through deep hypothermia with or without potential neuroprotective adjuncts. Straight hypothermia during circulatory arrest was the first method used to perform operations on the aortic arch and remains an effective method for shorter

procedures. Two alternative primary end points for cooling are employed: goal temperature or EEG silence.

The published temperature goals vary widely, namely anywhere from 14 to 32°C. The ischemic tolerance of the brain improves with colder temperatures. However, cooling to a temperature below 14°C can result in a form of nonischemic brain injury and is therefore not recommended. The neurologic protection from straight hypothermic circulatory arrest can be very good, especially for short ischemic times. Most data suggest that straight hypothermic circulatory arrest up to 20 minutes is safe. However, increased ischemic time is directly related to increased incidence of neurologic deficits.<sup>24</sup> Proponents of straight hypothermic circulatory arrest have suggested in elective patients that longer times can be used safely without significant adverse cognitive outcomes but circulatory arrest should be limited to as short a time as possible.<sup>25</sup>

For these cases, temperature is being used as a proxy for metabolic function. Unfortunately, nasopharyngeal and tympanic temperature may be imperfect estimates of brain temperature. Moreover, temperature does not directly relate to neurologic activity. For these reasons, some groups use EEG silence to determine the appropriate point at which to discontinue cooling and perfusion. The patients are cooled until EEG silence is obtained. After 5 minutes at this temperature, the circulatory arrest period can be initiated, usually at a temperature between 15 and 22°C. Using this technique, the group from the University of Pennsylvania achieved EEG silence in 90% of patients after 45 minutes of cooling and had a postoperative stroke rate of less than 5%.<sup>26</sup> As a result, in the absence of EEG monitoring, they cool for at least 45 minutes in almost all cases to optimize brain protection. Although EEG is attractive in theory, it is not always available when patients with dissections are taken to the operating room. We typically cool for 45 minutes to achieve a goal temperature of 18 to 21°C.

Continued cerebral perfusion during the period of circulatory arrest is an alternative technique for cerebral protection, especially for circulatory arrest times greater than 20 minutes. Utilizing cerebral perfusion, some groups have moved progressively to more moderate hypothermia (24–28°C) during dissection repair.<sup>27</sup> Cerebral blood flow may be delivered in a either retrograde or antegrade fashion. The technique for retrograde cerebral perfusion depends on the venous cannulation strategy. If bicaval cannulation is used, reversing flow through the superior vena caval cannula with a proximally placed tourniquet is simple and effective. Use of retrograde flow with dual-stage venous cannulation requires placement of a retrograde “coronary sinus” catheter into the superior vena cava through a purse-string suture. The superior vena cava is then occluded with an umbilical tape to direct flow toward the head. Retrograde cerebral perfusion has the added benefit of flushing atherosclerotic material and air from the brachiocephalic vessels. A flow rate necessary to produce a superior vena caval pressure of 15 to 25 mm Hg is considered optimal.

Selective antegrade cerebral perfusion has gained popularity, particularly when extended aortic arch surgery is planned.

This can be performed by clamping the base of the innominate artery with a right axillary or innominate arterial cannulation, allowing for cerebral perfusion via the right carotid artery. This also can be performed once the aortic arch is open by encircling the innominate artery with a vessel occluder and cannulating the lumen with a retrograde "coronary sinus" cannula. Bilateral antegrade perfusion can be performed by similarly cannulating the left carotid artery lumen. With the left subclavian artery occluded, flow rates are slowly increased to achieve perfusion pressures of 50 to 70 mm Hg at the desired circulatory arrest temperature. These cannulae are then removed just before completing the anastomosis of the brachiocephalic vessels to the vascular graft, at which time cardiopulmonary bypass may be reinstated.

A few basic principles apply to all approaches. During cooling on cardiopulmonary bypass, a maximum temperature gradient between perfusate and patient of less than 10°C is ideal. The head is then packed in ice to maintain a low brain temperature. To ensure maximal protection, the goal temperature should be maintained for 5 minutes before initiation of hypothermic circulatory arrest. Similarly, the body should be reperfused for 5 minutes at the colder temperature before beginning the rewarming process. Rewarming too early can exacerbate neurologic injury. Rewarming proceeds without exceeding a 10°C perfusate-patient temperature gradient to at least 37°C as core body temperature often falls briefly after cessation of active warming and separation from cardiopulmonary bypass.

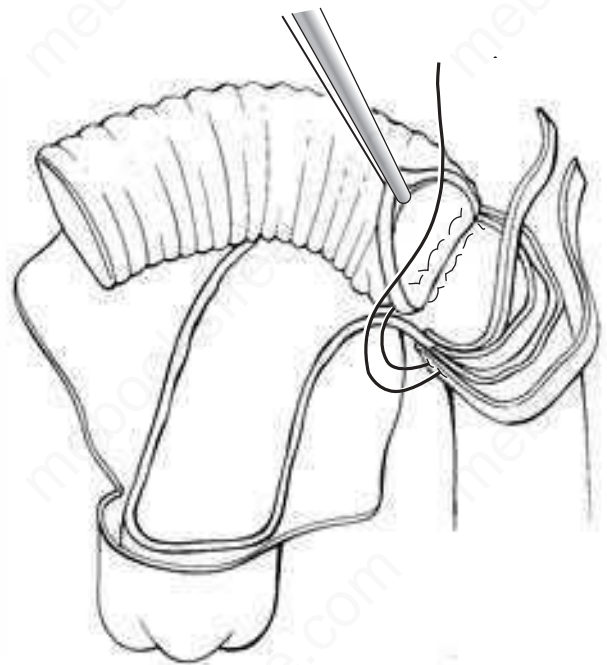

Pharmacologic adjuncts are believed by some to decrease metabolic rate with hopes of reducing injury. Although methylprednisolone continues to be used in these cases by many, barbiturate administration during cooling has fallen mostly out of favor. If used, methylprednisolone should be given early, as the steroid effects require incorporation into the cell nucleus. Others give lidocaine and magnesium before the arrest period to stabilize the neuronal cell membrane. Furosemide and mannitol can be administered to initiate diuresis and promote free radical scavenging after circulatory arrest. The results of all these techniques are not fully substantiated yet.

## OPERATIVE TECHNIQUE

The exposure for procedures performed on the ascending aorta and proximal arch is through a median sternotomy. This can be modified with supraclavicular, cervical, or trapdoor incisions to gain exposure to the brachiocephalic vessels or descending thoracic aorta. When dissecting the distal arch, it is important to identify and protect both the left vagus nerve with its recurrent branch and the left phrenic nerve. Replacement of the ascending aorta in type A dissections is best performed by an open distal anastomosis technique if the arch is involved (30%) or if arch involvement is unknown. Once the patient is placed on cardiopulmonary bypass and cardioplegia catheters are in place, the mid ascending aorta is clamped, producing cardiac arrest via administration of antegrade and/or retrograde cardioplegic solution. The dissected ascending aorta proximal to the clamp is then opened. Evaluation and

surgical correction of the aortic valve is ideally performed at this time while systemic cooling continues. If the dissection does not involve the aortic root, the aorta is transected 5 to 10 mm distal to the sinotubular ridge. When the dissection involves the sinotubular ridge, the proximal aorta is reconstructed by reuniting the dissected aortic layers between one or two strips of Teflon felt using either 3-0 or 4-0 Prolene suture. Safi et al use a technique of interrupted pledgeted horizontal mattress sutures as compared with the felt sandwich technique.<sup>28</sup> In their experience, this provides superior stabilization and decreases the potential for subsequent aortic stenosis. The University of Pennsylvania has described aortic reconstruction using felt as a neomedia giving a stable platform to sew the graft to otherwise friable tissue.<sup>26,29</sup>

Once the temperature reaches 18 to 21°C, perfusion is discontinued during a brief period of circulatory arrest. When using antegrade or retrograde cerebral perfusion, the selected perfusion is initiated at this time. The aortic clamp is released and the intima of the aortic arch is inspected and repaired accordingly (Fig. 47-13). If the intima is intact, the distal anastomosis is performed and the graft is cannulated, deaired, and clamped for resumption of cardiopulmonary bypass with systemic warming. If the intima of the arch is violated, then a hemiarch reconstruction is performed (Fig. 47-14). We have only rarely found it necessary to perform a complete arch resection for an acute dissection. If a complex aortic root procedure is required, it is often useful to repair the aortic root with one vascular graft and use a separate graft to create the distal aortic anastomosis. The two grafts are then measured, cut, and anastomosed to provide the correct length and orientation for aortic replacement.

**FIGURE 47-13** The false lumen of the distal aorta is closed and the aortic wall is reconstructed with inside and outside felt strips.

**FIGURE 47-14** (A) The type A dissection extends into the proximal aortic arch. (B) The distal dissected aortic wall is reconstructed with inside and outside felt strips to replace part of the arch and ascending aorta.

If the ascending aorta cannot be cross-clamped or the surgeon prefers not to clamp the dissected aorta, the patient is first cooled to 18 to 21°C with subsequent circulatory arrest. The distal aortic reconstruction is performed first in this circumstance, at which time the graft is cannulated and proximally clamped with resumption of cardiopulmonary bypass and systemic rewarming. Cannulation of the graft for antegrade systemic perfusion and rewarming is associated with improved neurologic outcomes compared with retrograde perfusion and should be performed whenever possible. Proximal ascending aortic repair is completed during the

period of rewarming. Because a cross-clamp is not applied with this technique, the left ventricle must be decompressed once fibrillation starts during systemic cooling to prevent distention and irreversible myocardial injury. In cases of severe aortic insufficiency, ventricular distention may occur despite appropriately positioned vent catheters. In this, manual cardiac decompression or aortic cross-clamping will be required.

An alternative to the open distal technique is possible when the dissection is limited to the ascending aorta or the proximal arch away from the origin of the brachiocephalic vessels. Antegrade arterial perfusion is achieved through distal arch or right subclavian artery cannulation; retrograde perfusion via cannulation of a femoral artery has traditionally provided acceptable results. An aortic cross-clamp is applied tangentially just proximal to the innominate artery. The ascending aorta is resected to include the inferior aspect of the arch. The layers of the dissected aorta proximal to the clamp are then reunited if necessary and the ascending aorta replaced with an appropriately sized, beveled vascular graft. The proximal reconstruction and anastomosis may then be created and the entire procedure performed without requiring deep hypothermia and circulatory arrest.

Isolated dissection of the aortic arch is rare. Classified as a type A dissection, it requires resection of the arch at the site of intimal disruption and aortic replacement. Surgical management of the brachiocephalic vessels is determined by the integrity of the adjacent intima. If intact, the brachiocephalic vessels are reimplemented as a Carrel patch into a vascular graft after repair (Fig. 47-15). If the dissection involves individual

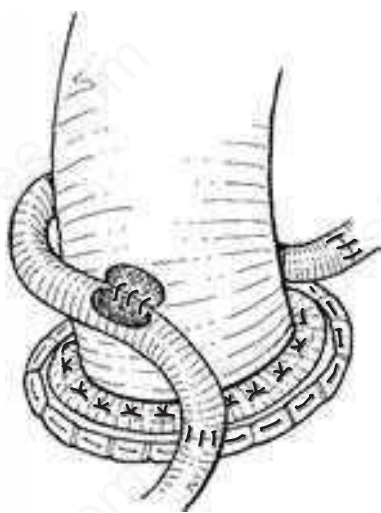

**FIGURE 47-15** Brachiocephalic vessels can be reattached to an arch graft as a unit if the inner cylinder of origin of each vessel remains intact. (A) The arch vessels are excised as a unit from the superior surface of the dissected aortic arch. (B) The separated layers of the brachiocephalic patch are reunited using inner and outer felt strips and continuous suture. (C) A corresponding hole is cut in the aortic graft and the continuous brachiocephalic unit is sutured into place.

**FIGURE 47-16** The brachiocephalic vessels are separated from the true lumen by the dissected false lumen (*left panel*). If individual brachiocephalic vessels are also damaged beyond repair, short interposition grafts are added to reconnect each artery to the aortic graft (*right panel*).

vessels, each may require repair and reimplantation individually into the graft used for arch replacement (Fig. 47-16).

Aortic root dissection often fails to violate the intima of the coronary ostia. Repair of the ascending aorta at the sinotubular junction is therefore sufficient to reunite the aortic root layers and provide uninterrupted coronary blood flow. Minimal disruption of the coronary ostial intima should be repaired primarily with 5-0 or 6-0 Prolene suture. If, however, the ostium is circumferentially dissected and an aortic root replacement is necessary, an aortic button should be excised and the layers reunited with running 5-0 Prolene suture, glue, or both. Coronary buttons are then reimplanted into the vascular graft or to a separate 8-mm vascular graft as part of a Cabrol repair (Fig. 47-17). Aortocoronary bypass

**FIGURE 47-17** Illustration showing the attachment of the coronary ostia to the graft using the Cabrol technique. The ends of a 60-mm Dacron graft are sewn end to end to each coronary ostium. A side-to-side anastomosis is made between the intercoronary tube graft and the aortic graft.

grafting is performed only when the coronary ostium is not reconstructable and as a last resort.

Acute type A dissection is complicated by aortic valve insufficiency in up to 75% of patients. Fortunately, preservation of the native valve is successful nearly 85% of the time. The mechanism of aortic insufficiency in most cases is the loss of commissural support of the valve leaflets. This is repaired using pledgeted 4-0 Prolene sutures to reposition each of the commissures at the sinotubular ridge (Fig. 47-18). The dissected aortic root layers are then reunited using 3-0 Prolene suture and either one or two strips of Teflon felt to recreate the sinotubular junction and reform the sinuses of Valsalva. Aortic valve preservation must always be performed using intraoperative TEE to assess the valve postoperatively. No more than mild aortic insufficiency should be present. In addition to commissural resuspension, techniques exist to spare the aortic valve and replace the aortic root in acute type A dissection, but the experience is early and the number of patients few. This topic is covered in greater detail in the section on surgical techniques for chronic type A dissection. If the aortic valve cannot be spared, replacement of the ascending aorta and valve should be performed using a composite valve graft or homograft. The composite valve graft is implanted using horizontal mattress 2-0 Tycron sutures to encircle the annulus and to seat the valved conduit (Fig. 47-19). The previously excised and reconstituted coronary buttons are reimplanted into the vascular graft with running 5-0 Prolene suture (Fig. 47-20). The left coronary button is implanted first, at which time the graft is clamped and placed under pressure to define the proper orientation and position of the right coronary button. The aortic homograft is similarly implanted using horizontal mattress 2-0 Tycron sutures, except that a generous margin of aortic root below the coronary buttons is retained for a second hemostatic suture line of running 4-0 Prolene. This is an ideal solution for individuals who have a contraindication to anticoagulation or for young females. The Ross procedure (pulmonary autograft) is not applicable

**FIGURE 47-18** Resuspension and preservation of the native aortic valve in a type A dissection. (A) The dissected layers are approximated at each commissure with double-pledgeted mattress sutures. (B) The aortic valve commissures are completely resuspended. (C) Thin felt strips (8- to 10-mm wide) are placed inside and outside from the circumference of the aorta. The coronary ostia are not compromised. (D) The aortic walls are sandwiched between the felt strips with a horizontal mattress. (E) A vascular graft is sutured to the reconstructed proximal aorta.

in those patients with connective tissue disorders and not recommended in acute dissection.

Some centers have extended repairs into the descending thoracic aorta utilizing thoracic aortic endografts to potentially decrease the risk of malperfusion, reduce distal aortic aneurysmal degeneration and rupture, and decrease late distal aortic reoperation.<sup>30,31</sup> This hybrid repair, commonly referred to as a “frozen elephant trunk,” is performed during the circulatory arrest period. A guidewire is introduced into the open true lumen and positioned in the mid-descending aorta. An endograft is then introduced over the guidewire, positioned under direct vision just distal to the left subclavian artery, and then deployed. The proximal extent of the endograft is then secured with suture to the native aorta. Institutions with hybrid operating rooms with integrated fluoroscopy may also utilize fluoroscopy to guide final endograft placement. They may also perform completion angiography and correct

**FIGURE 47-20** The coronary ostia are attached to the graft by the button technique using continuous 5-0 polypropylene suture.

any distal malperfusion with endovascular fenestration and peripheral arterial stenting. At present these techniques are not widely performed and techniques are evolving.

### POSTOPERATIVE MANAGEMENT

Invasive hemodynamic monitoring is used to ensure adequate end-organ perfusion with a target systolic blood pressure between 90 and 110 mm Hg. Early postoperative blood pressure control begins with adequate analgesia and sedation using narcotics and sedative/hypnotic agents. The patient should, however, be allowed to emerge from general anesthesia briefly for a gross neurologic examination. The patient is then sedated for a period to ensure continued hemodynamic stability and facilitate hemostasis. Coagulopathy is aggressively treated with blood products and antifibrinolytic agents as necessary, and by warming the patient. Hematocrit, platelet count, coagulation studies, and serum electrolytes are obtained and corrected as necessary. An ECG and chest radiograph are used to assess for abnormalities and to serve as baseline studies. A full physical exam, including complete peripheral vascular exam, is performed on arrival. Despite adequate repair of the dissection, perfusion of the false lumen may persist; therefore, malperfusion syndrome remains possible. If an abdominal malperfusion syndrome is suspected postoperatively, this should be aggressively evaluated with ultrasound and subsequent angiography if positive. A strong clinical suspicion is enough to warrant this evaluation given the consequences of failed recognition. Exploratory

laparotomy should be performed early if bowel ischemia is suspected. The patient can be extubated once extubation criteria are met if the patient has been hemodynamically stable without excessive bleeding and the results of a neurologic exam are normal. Management is routine from that point forward.

### LONG-TERM MANAGEMENT

Surviving the operation for acute dissection represents the beginning of a lifelong requirement for meticulous medical management and continued close observation. It has been estimated that replacement of the ascending aorta for type A dissection obliterates flow in the distal false lumen in fewer than 10% of patients. As a result, the natural history of repaired dissection may involve dilatation and potential rupture of the chronically dissected distal aorta. This was the reason for the late death in nearly 30% of DeBakey's original series in 1982 and is currently the leading cause of late death following surgical repair.<sup>32</sup> Often a multidrug antihypertensive regimen including beta-blocking agents is required to maintain systolic blood pressure below 120 mm Hg. There are some data indicating that blood pressure control within a narrow range may alter the natural history of chronic dissection by diminishing the rate of aneurysmal dilatation. The long-term durability of the aortic valve after supracoronary reconstruction is quite good with freedom from aortic valve replacement of 80 to 90% at 10 years. Progressive aortic insufficiency of the native valve is possible and should be followed with TEE in some patients.

Follow-up diagnostic imaging is required to monitor aortic diameter in patients after repair. Spiral CTA and MRI are the imaging studies of choice. MRI and ultrasound are useful in patients with renal insufficiency and those requiring only imaging of the abdominal aorta. Echocardiography is useful for imaging the ascending aorta and provides additional information regarding the aortic valve. It is important to recognize the resolution limitations of each imaging modality and inherent imprecision of comparing different imaging modalities to evaluate changes. In general, measurements should be made at the same anatomical level with respect to reproducible anatomical structures (ie, the sinotubular ridge, proximal to the innominate or left subclavian arteries or at the diaphragmatic hiatus). It is important to recognize that the false lumen should be included in measurements of aortic diameter whether it is perfused or not. Three-dimensional reconstruction of spiral CT and MRI scans minimizes the error introduced by aortic eccentricity when comparing imaging studies and has simplified following this patient population. The current recommendations are to obtain a baseline study before hospital discharge and at 6-month intervals during the first year. If the aortic diameter remains unchanged at 1 year, studies are obtained yearly. Aortic enlargement of more than 0.5 cm within a 6-month period and greater eccentricity on comparison of three-dimensional reconstruction images are high-risk changes for which the interval is decreased to 3 months if surgery is not indicated.

## Results

The operative mortality for repair of acute type A aortic dissection has fallen since DeBakey's original 40% mortality was reported in 1965. Improved ICU and floor care of these patients, earlier recognition of dissection through improved imaging modalities, development of hemostatic vascular graft material, more effective hemostatic agents, and improvements in the safety of cardiopulmonary bypass are likely responsible. In the last two decades, most centers consistently report an operative mortality for acute type A dissection of between 10 and 30%. The high early mortality in acute dissection parallels the number of patients who present profoundly hypotensive and in shock. The mode of death is stroke, myocardial ischemia/heart failure, aortic rupture, or malperfusion in most cases.

The International Registry of Acute Aortic Dissections (IRAD) recently reported on the results of 526 patients with acute type A aortic dissection who underwent surgical treatment in 18 large tertiary centers.<sup>33</sup> Surgery in these patients included replacement of the ascending aorta in 92%, aortic root in 32%, partial arch in 23%, complete arch in 12%, and descending aorta in 4%. Overall in-hospital mortality was 25%; 31% for hemodynamically unstable patients; and 17% for stable patients. Causes of death were aortic rupture (33%), neurologic complications (14%), visceral ischemia (12%), tamponade (3%), or nonspecified (42%).

Age is not an absolute contraindication to surgical treatment of type A aortic dissections. However, operative mortality increases with age. Retrospective series show that operative mortality increases from 20 to 30% for patients younger than 75 years of age to greater than 45 to 50% for those 80 years or older.<sup>34</sup>

The published results for long-term survival following surgically treated acute type A aortic dissection over the last decade is roughly 71 to 89% at 5 years and between 54 and 66% at 10 years.<sup>35-37</sup> Survival for patients who are discharged alive from the hospital after surgical repair of type A aortic dissection carries a survival rate of 96% at 1 year and 91% at 3 years.<sup>38</sup>

## MANAGEMENT OF ACUTE TYPE B AORTIC DISSECTION

Type B aortic dissections account for approximately 40% of all acute aortic dissections.<sup>8</sup> Their natural course is more benign than that of acute type A dissections.

Most patients with acute type B aortic dissections survive the acute and subacute phases with medical management alone. Approximately 20 to 30% of patients present with complicated type B dissection, which require urgent operative (surgical or endovascular) intervention. Complicated dissection can be defined as imminent or actual aortic rupture, aortic expansion, hemodynamic instability, persistent pain despite medical management, drug-resistant hypertension, and malperfusion syndrome.<sup>8,39</sup> The most frequent causes of

death in acute type B dissection are aortic rupture and visceral malperfusion.

The relative success with medical management has relegated surgical treatment for acute type B dissections to patients with complicated dissections or those with progression of the disease (see Table 47-5). Medical therapy of uncomplicated type B aortic dissection confers a relatively good short-term prognosis with in-hospital survival of approximately 90%.<sup>39</sup> Medical management in these patients has survival rates of approximately 85% at 1 year and 71% at 5 years.<sup>40</sup>

On the contrary, patients with complicated dissections that require open surgical intervention have a 30-day mortality of approximately 30%.<sup>8</sup> More recently though, endovascular techniques have been used in these complicated dissections with reduced perioperative mortality and morbidity. Endovascular treatment of acute type B dissections was first described in 1999 by Dake et al<sup>41</sup> and Nienaber et al.<sup>42</sup> As endovascular treatment of complicated dissections has expanded, the results have improved, with studies now reporting a mortality of around 5%.<sup>43</sup>

## Medical Management

Historically, the mortality of open surgical approaches for type B aortic dissections exceeded 50%, whereas medical management carried a mortality risk of 30% or less. Therefore, medical management has played a pivotal role in the management of these patients. Medical management is identical to that described in the initial management of the acute type A aortic dissection. The goals are control of the heart rate and blood pressure to decrease the shear stress on the aorta and limit expansion of the false lumen and propagation of the dissection.

Medical management initially requires an adequate airway and intravenous access. Patients with suspected or confirmed type B aortic dissection should be admitted to the intensive care unit for close monitoring. Pain control is important to reduce catecholamine release and is best achieved with narcotic medications, in particular morphine sulfate. Management is initiated with beta-blockers such as esmolol or propranolol.<sup>9</sup> These medications should be titrated to achieve optimal blood pressure (ie, systolic pressure of 100 to 120 mm Hg) and heart rate while allowing for adequate renal, gut, and brain perfusion. Heart rate control to a goal of less than 60 bpm has been shown to decrease the risk of secondary adverse events such as aortic expansion, recurrent dissection, and aortic rupture.<sup>44</sup>

Vasodilators such as sodium nitroprusside can be used as an adjunct to beta-blockers if blood pressure is still not adequately controlled. Vasodilators can increase the force of ventricular ejection and aortic shear stress and should therefore be only used concurrently with beta-blockade. Calcium channel blockers can also be used to control blood pressure, especially in patients intolerant to beta-blockers. However, their use has not been appropriately studied in patients with aortic dissection. Patients with normal or decreased low blood pressure at presentation, without evidence of cardiac

tamponade or heart failure, may benefit from judicious intravenous volume administration.

Once the patient with uncomplicated type B aortic dissection has been stabilized, blood pressure medications should be transitioned to an oral regimen. The patient can then be discharged from the hospital with close follow-up, including imaging and clinical assessment in 3 months and every 6 months thereafter.

## Operative Indications

Operative management of acute type B aortic dissection, either by endovascular or by open surgical techniques, is currently limited to the prevention or relief of life-threatening complications.<sup>9,45</sup> Operative treatment is indicated for patients with persistent or recurrent pain, medically uncontrolled hypertension, rapidly expanding aortic diameter, progression of dissection despite maximal medical management, signs of impending or actual aortic rupture (ie, periaortic or mediastinal hematoma), or malperfusion to limbs, kidneys, or gut (see Table 47-5).

## Endovascular Therapy

### GENERAL CONSIDERATIONS

Given the poor outcomes of open surgical approaches, endovascular therapy has transitioned to the frontline of therapy

for complicated type B dissections. Endovascular treatments can include placement of thoracic endovascular graft prostheses, endovascular creation of flap fenestrations, and/or placement of uncovered stents in affected branch vessels to treat malperfusion. Because of the relative simplicity and recent improvements in outcomes, endovascular grafts have become the preferred endovascular technique for treatment of aortic dissections.

The goals of endovascular graft therapy in complicated acute aortic dissection are to restore flow to the true lumen and perfusion to the distal aorta and branch vessels. Coverage of the primary tear is frequently necessary to achieve these goals, especially if the tear is in the proximal descending aorta. Obliteration of the false lumen is desirable as well because it improves the prognosis, but it is not always possible. Endoluminal treatment of these cases usually requires coverage of the entire descending thoracic aorta because of the presence of multiple tears in the intima. The optimal outcome occurs when the prosthesis covers the primary tear, reapposes the dissected layers of the aorta, and prevents blood flow into the false lumen, therefore leading to thrombosis of the false lumen, expansion of the true lumen, and restoration of branch vessel patency (Fig. 47-21).

An alternative technique used to treat branch malperfusion from aortic dissection is percutaneous fenestration with or without stenting of the malperfused branch vessels. According to this technique, a communication is created between the true and the false aortic lumens so as to

**FIGURE 47-21** Endovascular stent grafting in a 77-year-old male with an acute type B aortic dissection. *Upper panel:* CTA at initial presentation showing a long dissection flap involving the descending thoracic aorta. *Lower panel:* CTA on the same patient one year after placement of an endovascular stent graft showing aortic remodeling with obliteration of the false lumen. (Used with permission from John Kern.)

provide flow to both of them. Percutaneous fenestration is performed by pulling an inflated balloon or a fenestration knife through the dissection flap to create communication between both lumens. An uncovered stent can then be placed in the true lumen at the region of the affected branch vessel or vessels to alleviate dynamic obstruction (occlusion of the branch by prolapse of the dissection flap into the branch vessel).<sup>46</sup> If static obstruction (extension of the dissection into

the branch vessel with reduction of the true lumen) is also present, a stent is deployed directly into the branch vessel (Fig. 47-22). The major limitation of percutaneous fenestration for treatment of aortic dissection when compared with endovascular grafting is that it does not induce thrombosis of the false lumen. False lumen thrombosis has been shown to induce aortic remodeling and decrease the long-term risk of aortic dilatation and rupture.<sup>47</sup>

**FIGURE 47-22** Endovascular treatment of visceral ischemia with fenestration and stenting of the aortic true lumen and the superior mesenteric artery (SMA) on a 40-year-old man with type B aortic dissection. (A) Near-total aortic true lumen collapse of the proximal descending aorta. (B) Dynamic compromise of the celiac artery origin. (C) Collapsed true lumen and dissection flap within the SMA suggesting both dynamic and static obstructions of this vessel. (D) Angiogram showing the dissection flap extending into the SMA. (E, F) Follow-up imaging at 1 month after percutaneous fenestration, true lumen stenting of the aorta at the level of the celiac artery, and placement of a stent into the SMA shows a patent fenestration tear in the dissection flap and a patent vessel. (Reproduced with permission from from Patel HJ, Williams DM, Meerkov M, et al: Long-term results of percutaneous management of malperfusion in acute type B aortic dissection: implications for thoracic aortic endovascular repair, *J Thorac Cardiovasc Surg.* 2009 Aug;138(2):300-308.)

Percutaneous fenestration and stenting can also be used as an adjunct to endovascular grafting when closure of the primary tear fails to improve distal malperfusion. Another technique that can be used to improve malperfusion after endovascular grafting is the PETTICOAT (provisional extension to induce complete attachment) technique.<sup>48</sup> According to this technique, a bare metal stent is placed as a distal extension of the previously implanted stent graft in order to expand the true lumen.

### PREOPERATIVE PLANNING

The endovascular treatment of aortic dissections requires meticulous preoperative planning. The anatomy of the aorta and the actual dissection should be studied in detail with the use of imaging technology.

Preoperative imaging for endovascular repair of aortic dissections is accomplished with either computed tomographic arteriogram (CTA) or MRA. Three-dimensional sagittal and coronal reconstructions are useful to assess details of the anatomy of the aorta. Preoperative imaging allows the surgeon to size the aorta for selection of the device, ascertain the presence of adequate proximal and distal landing zones for adequate apposition of the graft, and assess the femoral and iliac vessels to plan the delivery of the device.

The left subclavian artery may be occluded in certain situations without the need for revascularization. Exclusion of the left subclavian artery without concomitant revascularization should be avoided in patients with a patent left internal mammary artery coronary bypass, those with an incomplete posterior cerebral circulation, a dominant left vertebral vessel, or a stenosed or occluded right vertebral artery.<sup>49</sup> Left subclavian revascularization should also be considered in those patients in whom a long segment of the aorta is being covered or those with a history of prior aortic surgeries because of the increased risk of spinal ischemia. Left subclavian revascularization is usually accomplished with the creation of a left carotid to subclavian bypass, or less commonly, left subclavian artery transposition. To assess the cerebral circulation, a head and neck CTA should be performed preoperatively in every patient in whom left subclavian exclusion is a possibility. In our experience, the left subclavian artery is covered in approximately 50% of the cases, with 25% of these patients requiring revascularization because of concerns of cerebral circulation or arm claudication.<sup>50</sup>

Adequate vascular access for delivery of the device is an important requirement for endovascular therapy of the aorta. Both iliofemoral systems are evaluated preoperatively with CTA or MRA with particular attention to size, tortuosity, and presence of calcification that may preclude safe delivery of the device. The minimum size required for the access vessels is determined by the outer diameter of the introducer sheath. Current devices require insertion through a vessel of at least 6 to 8 mm in diameter (equivalent to ~20 French delivery device). When the femoral vessels have an adequate caliber, no tortuosity, and minimal calcification, total percutaneous access is possible, using automated percutaneous closure devices to seal the entry point. Alternatively, an open

approach to control the common femoral arteries may be used. If the caliber of the femoral vessels is not appropriate for insertion of the device, retro-peritoneal exposure of the iliac artery with placement of a 10-mm tube graft may be necessary as a surgical conduit for insertion of the device.

Endovascular stenting of the aorta is associated with a risk of paraplegia in recent series of 0 to 3.4%.<sup>39,51</sup> Preoperative insertion of a lumbar catheter for drainage of cerebrospinal fluid (CSF) may decrease the risk of permanent paraplegia. In our institutions, we perform selective preoperative placement of lumbar catheters at the discretion of the surgeon, taking into account the region and length of planned aortic exclusion, and previous history of aortic surgery.<sup>49</sup> If there is no evidence of paraplegia postoperatively, these drains are usually discontinued 48 to 72 hours after surgery.

### Operative Technique

The endovascular stenting procedure can be performed either in the angiography suite or an operating room with advanced imaging capabilities. At our institutions, the procedure is performed in the angiography suite by a team of cardiovascular surgeons and interventional radiologists. The procedure is usually performed under general anesthesia, although local or epidural anesthesia can also be used, depending on the comorbidities and clinical status of the patient. Monitoring lines are placed, including a radial arterial line in the right upper extremity. A lumbar drain for CSF drainage is placed preoperatively at the discretion of the surgeon, as stated. Antibiotic prophylaxis is administered.

In most cases, bilateral iliofemoral arterial access is used for the procedure. The larger side with less calcification and tortuosity is chosen for the delivery of the device. The other side is used for percutaneous insertion of a 5 French pigtail catheter for diagnostic contrast injection. If only one side is appropriate for use, the diagnostic pigtail catheter may be inserted through one of the brachial arteries.

If there is significant calcification of the vessel or the surgeon does not feel comfortable with the use of a percutaneous vascular closure device, the femoral artery is surgically exposed and controlled. In our experience, approximately 20% of patients have femoral vessels of an inadequate caliber to accommodate the delivery device. In these patients, a flank incision is performed and the retroperitoneal common iliac artery is exposed. A 10-mm polyester surgical conduit is then anastomosed to the common iliac artery and used as access for delivery of the device.

The pigtail catheter is inserted percutaneously and advanced to the arch of the aorta. Aortography or IVUS is then used to confirm the location of the catheter within the true lumen, define the anatomy, localize the entry tear, and create a roadmap for the procedure. The confirmation of the device being in the true lumen cannot be overemphasized. Many centers use only IVUS for these procedures. From these images, the decision is made regarding the site of deployment. The left subclavian artery may need to be covered to ensure an adequate proximal landing zone and completely exclude the

primary tear. The proximal landing zone is usually visualized best at a fluoroscopic angle of approximately 45 to 75 degrees left anterior oblique (LAO).

A super-stiff wire is then inserted through a sheath placed into the iliofemoral vessel previously chosen for device delivery, and advanced into the aortic arch. The patient is heparinized to an ACT of greater than or equal to 200 seconds. The appropriate sheath is advanced into the abdominal aorta under direct fluoroscopic visualization. The device is then advanced to the selected point of delivery. Placement of the sheath and the device into the aorta are probably the most dangerous parts of this procedure. Before the deployment of the device, blood pressure and heart rate should be pharmacologically controlled so as to avoid undue strain on the heart and migration of the endograft on deployment. The device is then deployed. The optimal placement of the prosthesis is confirmed by angiography or IVUS. Although the device may need to be ballooned for full opening and apposition to the aortic wall, this maneuver has inherent risks given the weakness of the aortic wall and the pressure required to expand the stent grafts.

It is important to confirm the correct placement of the device, the absence of endoleaks, and the resolution of malperfusion to branch vessels at the end of the procedure. For this purpose, an angiogram is performed through the diagnostic pigtail catheter. If there is evidence of persistent malperfusion, adjunctive therapies should be considered such as percutaneous fenestration or deployment of additional bare-metal stents on the distal aspect of the prosthesis to expand the true lumen (PETTICOAT technique). Branch vessel stenting may also be necessary to relieve static obstruction.<sup>46</sup> In case of a ruptured dissection, the endovascular prosthesis should cover both the site of the primary tear and the site of rupture. Furthermore, in patients with significant hemothorax the dissection should be treated before draining the chest, as this may be tamponading the rupture.

## Surgical Therapy

### GENERAL CONSIDERATIONS

Open surgical intervention for type B aortic dissections is performed under general anesthesia with narcotic and inhalational agents. Double-lumen endotracheal intubation allows for lung isolation, which is critical in exposure of the thoracic aorta. Central venous access, right radial and femoral arterial lines, and in selected cases a pulmonary artery catheter, are inserted before the procedure. Core body temperature is usually measured with the use of a temperature probe in the Foley catheter and/or an esophageal probe. Antibiotic prophylaxis is administered.

Spinal cord ischemia resulting in paraplegia or paraparesis is a recognized complication of acute dissection repair that may be partially preventable and even reversible. The incidence of spinal cord ischemia is between 19 and 36% after repair of acute type B dissection.<sup>52,53</sup> Whereas various strategies exist to prevent spinal cord ischemia during repair of a chronic dissection, very few are feasible in the acute setting.

Pharmacologic agents such as steroids, free radical scavengers, vasodilators, and adenosine are promising adjuncts to prevent spinal cord ischemia but presently have little to no proven clinical utility. We presently use left atrial to femoral artery bypass and reimplant key intercostals arteries and selectively use CSF drainage as outlined by Safi et al.<sup>54</sup>

### OPERATIVE TECHNIQUE

The patient is positioned in right lateral decubitus. The pelvis is canted posteriorly to allow access to both femoral vessels. A posterolateral thoracotomy in the fourth intercostal space provides sufficient access to the aorta; notching the fifth and sixth ribs posteriorly can facilitate wider exposure of the thorax. A thoracoabdominal incision may be required to access the abdominal aorta in the case of visceral malperfusion. This may be performed through either a transperitoneal or a retroperitoneal approach. The left hemidiaphragm is divided in a radial fashion while marking adjacent sites on each side of the division with metal clips for later reapproximation.

The ideal open acute type B aortic dissection repair involves replacement of as little of the descending thoracic aorta as necessary. The extent of replacement rarely exceeds the proximal third, which includes the primary tear in most cases. Such a strategy optimizes perfusion of the spinal cord by preserving more intercostals arteries.<sup>52</sup> This point is controversial, however, and some groups advocate replacement of the entire thoracic aorta. Any less extensive aortic replacement leaves dissected aorta with the potential for late aneurysmal dilation when there is perfusion of the false lumen. The ideal strategy to minimize spinal cord malperfusion yet resect all involved aorta has not been proved.

Once the thoracic aorta has been exposed, the operation continues with division of the mediastinal pleura between the left subclavian and the left common carotid arteries. It is essential that the left vagus and recurrent laryngeal nerves are identified and preserved during the course of the dissection. The left subclavian artery is encircled with an umbilical tape and Rummel tourniquet. Ultimately, the entire distal arch must be free enough to place an aortic clamp between the left common carotid and left subclavian arteries. Next, the proximal descending thoracic aorta is circumferentially mobilized, dividing intercostal arteries in the segment to be excised.

The formerly popular "clamp and sew" technique used for repair of acute type B dissection has largely been replaced by the use of partial left heart bypass. To institute left heart bypass, the left inferior pulmonary vein is dissected and a 4-0 Prolene pursestring suture placed posteriorly for cannulation. Arterial cannulation sites for this technique include the distal thoracic aorta for limited dissections of the proximal descending thoracic aorta or the femoral artery for those extending into the abdomen. It is important to assure that distal perfusion during cannulation is directed into the true lumen. Following the administration of 100 U/kg of intravenous heparin, 14 French cannulae are inserted into the left inferior pulmonary vein and either a normal-appearing area of descending thoracic aorta or percutaneously into

either femoral artery. Bypass is then initiated with flow rates between 1 and 2 L/min.

The left subclavian artery is controlled and vascular clamps are placed on the aorta proximal to the left subclavian artery and distally on the mid-thoracic aorta. Right radial artery pressure is measured to maintain proximal aortic systolic pressure between 100 and 140 mm Hg and mean femoral artery pressure greater than 60 mm Hg.<sup>53</sup> The aorta is then opened longitudinally and bleeding from intercostals arteries is controlled by suture ligation. Transection of the aorta distal to the origin of the left subclavian artery provides a site for the proximal anastomosis. This is performed using 3-0 Prolene suture and may require external reinforcement with Teflon felt strips.

The graft inclusion technique is another procedure in which the posterior aspect of the proximal aorta is not fully transected. The proximal anastomosis is then created to the intact posterior aspect of the aorta. We do not recommend this technique because one cannot be certain of including all layers of the aorta in the anastomosis.

The size of the vascular graft is based on the diameter of the distal aorta and beveled to match the aorta proximally. This anastomosis may include the origin of the left subclavian to treat dissection in this vessel. A separate 6- to 8-mm Dacron graft can be used if there is intimal disruption involving the proximal segment of the left subclavian artery. Once the proximal anastomosis is completed, the proximal clamp is released and repositioned on the vascular graft to inspect the anastomosis. The distal anastomosis is then completed, the clamps are released, and partial left heart bypass is terminated. Percutaneously placed femoral artery cannulae 14 French or smaller may be removed without direct repair of the vessel. When cannulae 15 French or larger are required, open surgical repair of the femoral arteriotomy is indicated.

Rupture of the thoracic aorta before or during repair is a catastrophic event often leading to operative death. Successful management requires immediate cannulation of the femoral artery and vein for cardiopulmonary bypass and eventual deep hypothermic circulatory arrest. Assisted venous drainage through the femoral vein is often adequate, but direct cannulation of the right ventricle through the pulmonary artery may also be performed. A left atrial vent is placed through the left inferior pulmonary vein once the heart begins to fibrillate; the left ventricle may be vented as well directly through the apex. Once the nasopharyngeal temperature reaches 15°C, the vent is occluded and cardiopulmonary bypass is stopped. The head is placed down and the aorta opened for repair under circulatory arrest. The distal aorta should be clamped to minimize blood loss. Once the proximal anastomosis is performed, the proximal clamp is moved onto the graft and the graft cannulated to resume cardiopulmonary bypass.

Malperfusion of intra-abdominal viscera or lower extremities may be apparent at the time of presentation or may follow surgical repair of aortic dissections. Proximal repair of the dissection is a standard treatment and may be sufficient to treat the malperfusion syndrome. However, if malperfusion

presents or persists after surgical repair, percutaneous or surgical fenestration may be necessary. As specified, percutaneous fenestration is accomplished by using a balloon or a percutaneous knife to create a communication between the false and the true lumens. Surgical fenestration is performed through a midline laparotomy or left flank incision to provide exposure of the infrarenal aorta (Fig. 47-23). Occasionally, fenestration of intra-abdominal aortic branch vessels may be required if the intima is violated beyond the ostia. If the dissection flap cannot be completely excised, the distal vessel layers must be reunited. Consideration should be given to patch angioplasty to prevent narrowing when closing smaller vessels. In the event that perfusion is not reestablished, extra-anatomic bypass may be required.

Obstruction of the terminal aorta or malperfusion of the lower extremities following operative repair is best treated with percutaneous fenestration. Surgical fenestration remains an option if percutaneous techniques fail to reestablish blood flow. In the event that surgical fenestration fails, the best solution is femoral-femoral bypass grafting in the setting of unilateral malperfusion or axilla-femoral and femoral-femoral bypass if bilateral lower extremity malperfusion exists.

**FIGURE 47-23** Fenestration of the abdominal aorta for visceral malperfusion. A transverse incision is made into the aorta, preferably into a nondissected aorta. The proximal dissection membrane is incised and then excised to decompress the false lumen as far proximally as possible. The dissected layers are reconstructed with Teflon felt or glue and the aortotomy is closed directly.

## Results

Medical management remains the mainstay of treatment for acute uncomplicated type B aortic dissections. Early medical management alone is an adequate treatment in approximately 68 to 85% of patients presenting with acute type B dissection and leads to a 30-day survival rate of 89 to 93%.<sup>39,55</sup> The long-term outcomes of medical management are not as favorable. In the IRAD series, only 78% of 189 patients discharged alive from the hospital after medical management of type B dissections were alive at 3 years.<sup>38</sup> Predictors of follow-up mortality were female gender, history of prior aneurysm, history of atherosclerosis, in-hospital renal failure, pleural effusion, and in-hospital hypotension or shock. In a separate series of patients, 87% of patients managed medically were alive at 5 years, with 25% of patients requiring aortic-related interventions.<sup>56</sup> Similarly, in a series of 122 patients with type B aortic dissections managed medically over 36 years, Umana et al reported survival rates of 85% at 1 year and 71% at 5 years, with reoperation rates of 14% at 5 years.<sup>40</sup>

These outcomes have prompted some authors to consider operative treatment of uncomplicated dissections in an attempt to prevent long-term aortic-related complications. The rationale for this consideration also comes from the fact that endovascular stenting induces thrombosis of the false lumen in 75% of cases<sup>43</sup> and false lumen patency is associated with long-term aortic-related complications and mortality.<sup>57</sup>

Xu et al recently reported a series of 63 patients with type B aortic dissections (59 uncomplicated) treated with endovascular grafting.<sup>58</sup> The authors delayed the intervention in uncomplicated patients until 2 weeks after presentation so as to allow fibrosis and increased stability of the intimal flap. The perioperative mortality was only 3% with morbidity including stroke in one patient, renal failure in two, and retrograde aortic dissection in two. No patients developed paraplegia. Complete thrombosis of the false lumen was achieved in 98% of patients at 1 year, and the 4-year survival was nearly 90%.

Two European randomized clinical trials have been designed to answer the question of whether uncomplicated type B dissections should be treated with endovascular grafting or with medical management alone. The results of the first trial, the INSTEAD (INvestigation of STEnt Grafts in Aortic Dissection) trial, have been recently published.<sup>59</sup> This trial randomized 140 patients with subacute or chronic type B aortic dissection (>14 days but <1 year) to either elective stent graft placement or optimal medical management alone. Survival was not significantly different between both groups with 2-year survival rates of 96 and 89% after optimal medical therapy and endovascular stenting, respectively. There were also no differences in the rates of a combined end point, including aortic-related deaths or reinterventions. Complete thrombosis of the false lumen was more common among patients with endovascular stenting (91% with stenting vs 19% with medical management). Aortic expansion to greater than 6 cm was also more common in the group with medical management, requiring crossover to stent grafting in 16% of cases and conversion to open surgery in 4%. All crossover

patients had uneventful outcomes and no deaths. Therefore, the trial supported the use of optimal medical management for treatment of uncomplicated type B aortic dissections and reserving endovascular interventions for those patients that develop complications or other indications for intervention. A recent landmark analysis of the INSTEAD trial, however, demonstrated that at 5 years aorta associated mortality was decreased with endovascular stenting (6.9 vs 19.3%).<sup>60</sup> The second trial, the ADSORB (Acute Uncomplicated Aortic Dissection Type B) trial has been designed to study patients with acute uncomplicated dissection (<14 days) by randomizing them to optimal medical management or endovascular stenting.<sup>61</sup> In 61 randomized patients, endovascular stenting increased true lumen size, decreased false lumen size, and reduced overall aortic diameter.<sup>62</sup> These short- and mid-term results appear to support that endovascular stenting is safe and potentially leads to favorable aortic remodeling in uncomplicated dissections. At present, medical management remains the standard of care for *uncomplicated* type B aortic dissection, however indications for endovascular stenting remains evolving. Longer term data are required to determine the utility and timing of intervention in uncomplicated type B aortic dissection.

Approximately 20% of patients with acute type B aortic dissection present with complications requiring intervention.<sup>39</sup> In the past, surgical intervention was the only therapy available for these patients. The development of endovascular techniques has provided an additional treatment option that is now preferred in the majority of cases.

Surgical treatment of aortic dissection was traditionally poised with dismal outcomes. Even though morbidity and mortality remain high, outcomes from surgical management have improved over the last few decades, from as high as 50% in the 1960s to as low as 13% in more recent times.<sup>63</sup> In a series of 76 patients treated emergently with surgery for acute complicated type B aortic dissection including 22% patients with aortic rupture, Bozinovski and Coselli reported an in-hospital mortality of 22% with a risk of stroke of 7%, paraplegia of 7%, and renal failure of 20%.<sup>64</sup> Similarly, as part of the IRAD series, 82 patients surgically treated for acute type B aortic dissection had an in-hospital mortality of 29% with a risk of stroke of 9%, paraplegia of 5%, and acute renal failure of 8%.<sup>65</sup>

Because of the unfavorable outcomes of open surgical therapy for acute complicated type B aortic dissection, endovascular therapies have been increasingly used in this patient population. Table 47-6 summarizes the current experience with endovascular therapy for treatment of type B aortic dissections.<sup>39,41,42,46,50,51,58,66-74</sup>

A recent meta-analysis of 39 studies involving 609 patients using endovascular repair of aortic dissections between 1999 and 2004 showed a procedural success of 98% with emergency surgical conversion of 1%. In-hospital complications occurred in 14% of patients including neurological complications in 3%, retrograde dissection in 2%, and a perioperative mortality of 5%.<sup>45</sup> Survival rates at 2 years were 89% with a risk of aortic rupture at follow-up of 2%.

**TABLE 47-6: Selected Retrospective Series with Endovascular Treatment of Type B Aortic Dissection**

Study	N	Type of dissection	Technique	Technical success (%)	Perioperative mortality (%)	Morbidity	Permanent paraplegia (%)	Endoleak (%)	Median follow up (month)	Long-term survival (%)	False lumen thrombosis (%)

\*Patients presented preoperatively with paraplegia.

Most of these studies have used endografts, rather than percutaneous fenestrations, as the endovascular treatment of choice. In one of the largest series of percutaneous fenestration for treatment of type B aortic dissection, Patel et al reports the experience from the University of Michigan from 1997 to 2008.<sup>46</sup> During this period, 69 patients with type B aortic dissection and malperfusion by angiography were treated with endovascular flap fenestration and/or branch vessel stenting. Overall technical success for flow restoration was 96% with an early mortality of 17%. Complications included stroke in 4%, acute renal failure requiring dialysis in 14%, and permanent spinal cord ischemia in two patients that presented initially with paraplegia from their dissection. However, despite these encouraging outcomes all-cause mortality at follow-up was as high as 36% with 7% risk of aortic rupture, likely related to the obligate persistence of the false lumen as part of the fenestration procedure.

Despite the multiple isolated series reporting outcomes after different treatment strategies for acute type B aortic dissection, there are currently no randomized controlled trials addressing this issue. The most recent retrospective report by IRAD comparing the different strategies included 571 patients with acute complicated or uncomplicated type B aortic dissection between 1996 and 2005. Of these, 390 patients (68%) were treated medically and 125 required intervention for complicated dissection; 59 (10%) underwent open surgical procedures and 66 (11%) had endovascular treatment with either stent grafts or percutaneous fenestration. In-hospital mortality was significantly higher for patients that underwent surgery (34%) when compared to those that had endovascular procedures (11%) (Fig. 47-24). In-hospital complications

occurred in 40% of patients undergoing surgical treatment and in 21% of those undergoing endovascular therapy. These findings remained true even after comparing patients with similar comorbidities. Interestingly, in-hospital mortality was similar for those patients that underwent endovascular therapy and those that were treated medically, and significantly better than in those that underwent surgery. The low mortality risk of patients treated medically is obviously related to the fact that most of these patients presented with uncomplicated disease and were deemed eligible for medical management. However, the data suggest that endovascular therapies may improve outcomes of patients with *complicated* type B aortic dissection to the rate of those with uncomplicated dissections managed medically. The data have to be interpreted with caution though, because part of these findings may be associated to selection bias in treatment modality based on patient characteristics not accounted for, or in differing treatment strategies in different institutions.

## MANAGEMENT OF CHRONIC AORTIC DISSECTION

Chronic type A dissection develops in patients who fail to undergo immediate surgical treatment of the acute dissection. Patients with chronic type B aortic dissection include those that have been successfully managed medically after an acute dissection and those with repaired type A aortic dissections that have retained segments of dissected descending thoracic aorta.

Patients with a history of acute aortic dissection, especially those with retained dissected segments, require close surveillance indefinitely. Our preference for follow-up imaging in patients with normal renal function and no contrast allergy is CTA. CTA provides good imaging, is cost effective, and is usually the technique used for the original acute dissection, making it ideal for longitudinal comparison of studies. MRA is utilized mostly as a follow-up study for patients with renal insufficiency but is the study of choice to provide precise anatomical detail for operative planning.

Many patients treated for aortic dissection, especially those with persistent communication between true and false lumens, can progress to develop aneurysmal dilatation of the aorta. They carry similar risk for aortic rupture that of atherosclerotic aneurysms. Chronic dissections have an annual rate of expansion of 0.9 to 7.2 mm per year.<sup>75-77</sup> Despite appropriate medical management and close follow-up, approximately 20 to 40% of patients have aortic enlargement during follow up.<sup>75,78</sup> This number is probably even higher in those patients with connective tissue disorders. In one study of 50 patients over a period of 40 months, 18% had fatal rupture and another 20% underwent surgical repair because of symptoms or aneurysm enlargement, emphasizing the need for diligent follow-up care.<sup>75</sup> Risk factors for rupture of chronic type B dissection include older age, chronic obstructive pulmonary disease (COPD), and hypertension. Chronic beta-blocker treatment reduces the rate of aortic

**FIGURE 47-24** Survival curves for patients with type B aortic dissection managed with medical, endovascular, or surgical treatment according to the IRAD. (Reproduced with permission from Fattori R, Tsai TT, Myrmet T, et al: Complicated acute type B dissection: is surgery still the best option? A report from the International Registry of Acute Aortic Dissection, *JACC Cardiovasc Interv.* 2008 Aug;1(4):395-402.)

dilatation as well as the incidence of dissection-related hospital admissions and procedures.<sup>78</sup>

The presence of a patent false lumen is a significant predictor of aortic enlargement and is associated with a higher incidence of aortic-related complications and death.<sup>57,76</sup> In a study of 101 patients followed after medical management for type B uncomplicated dissections, the most important risk factors for aortic enlargement were a maximum aortic diameter of 4 cm or more and a patent false lumen.<sup>79</sup>

## Operative Indications

The operative indications for chronic type A and B dissection are shown in Table 47-5. Chronic type A dissection is rarely symptomatic yet a minority of patients will present with chest pain as a result of aneurysm expansion or heart failure related to aortic regurgitation. Chronic type B dissection may present with intermittent dull chest or back pain, or infrequently, with malperfusion syndrome. Although each of these findings is an indication for intervention, the most common indications for operative management are aneurysmal dilatation of the aorta, rapid expansion, or aortic rupture. The size criteria for intervention in aortic dissection are controversial, but the one generally used is similar to that for general thoracic aortic aneurysms. Based on these criteria, aortic intervention is indicated at a size of 5.5 cm for type A dissections and 6.5 cm for type B dissections, or slightly less if there is a family history or physical stigmata of a connective tissue disorder.<sup>80</sup> Similarly, aortic expansion greater than 1 cm per year should be considered an indication for repair.

Recent retrospective studies from Japan have shown that patients with aortic diameters greater than or equal to 4 cm and a patent false lumen have a high likelihood of aortic-related complications (up to 50% in 6 months).<sup>79,81</sup> Based on these findings, it has been suggested that these patients should be considered for early repair depending on their operative risk. This issue is controversial and further studies are required before making more definitive recommendations.

## Techniques for Chronic Type A Aortic Dissection

Chronic type A dissection, with or without aneurysmal enlargement, is treated using similar operative techniques described for acute dissection. The particular operation performed depends on the specific pathology involving the aortic root, status of the aortic valve, distal extent of dissection, and brachiocephalic vessel involvement. The pathology of each of these components can be very different in a chronic dissection as compared with the acute process. These differences underlie the need for surgical techniques appropriate to each unique abnormality. In general, the ascending aorta is replaced using a vascular graft to include the entire diseased segment as in acute dissection, but surgical treatment of the aortic valve and creation of the distal anastomosis differ.

Whereas the aortic valve can be repaired in most cases of acute type A dissection by simple commissural resuspension, the rate of aortic valve replacement is much higher in patients with chronic dissection. Preservation of the aortic valve is complicated by morphologic changes in the valvular apparatus such as leaflet elongation and annuloaortic ectasia, which render the valve irreparable in as many as 50% of cases. More severe grades of preoperative aortic regurgitation portend a lower probability of valve preservation. In cases in which the aortic valve cannot be preserved with simple commissural reattachment, three options exist to treat aortic insufficiency: composite root replacement, aortic valve replacement with separate ascending aortic replacement, and finally, valve-sparing aortic root repair. The technical aspects of composite valve-graft repair were covered under the surgical management of acute type A dissection. Separate aortic valve and ascending aortic replacement are appropriate when there is an operative indication to repair the ascending aorta in the setting of a normal aortic root and structural aortic valve disease. Note that this operation is not appropriate for patients with connective tissue disease. In this situation, aortic root replacement is required.

Several methods for aortic valve preservation have been described for cases affecting the aortic root. One such technique is performed by reimplanting the valve commissures into an appropriately sized vascular graft, which is secured to the left ventricular outflow tract using multiple horizontal mattress sutures.<sup>82</sup> Another elegant yet time-consuming technique requires resection of the sinuses of Valsalva leaving a 5-mm rim of aorta circumferentially around the leaflets.<sup>83</sup> Scallops are then created in the vascular graft to resuspend the commissures and remodel the aortic root. David et al advocate Teflon felt reinforcement of the aortic annulus to prevent late annular dilatation and recurrent aortic insufficiency for the remodeling technique.<sup>84</sup> The mid-term outcome of such operations revealed a freedom from reoperation rate of 97 to 99% at 5 years and a 5-year survival for the aortic dissection subgroup of 84%. Cochran and Kunzelman devised a similar technique to recreate the sinuses of Valsalva, which may be more important than previously recognized and contribute to improved long-term valve durability.<sup>85</sup> Such data in patients with chronic dissection are lacking. These techniques appear appropriate for patients with Marfan disease and in those with congenitally bicuspid aortic valves.

Treatment of the distal aorta in chronic type A dissection is somewhat controversial. Some advocate obliteration of flow in the false lumen with distal aortic repair, whereas others purposely maintain flow into both the true and false lumen using distal resection of the intimal flap. Those who reunite the chronically dissected aortic layers to perfuse only the true lumen maintain that false lumen perfusion continues through distal reentry tears in greater than 50% of cases. There is a theoretical concern that important side branches arise exclusively from the false lumen and perfusion may be interrupted with this technique. Our practice at the University of Virginia is to resect the distal chronic dissection flap as far as possible to obviate such concerns. The distal

anastomosis is therefore made to the outer wall of the aorta, which has been strengthened over time. Malperfusion of the brachiocephalic vessels as a result of chronic type A dissection is treated with resection of the dissection flap from the arch. Infrequently, the chronic dissection flap extends into more distal branch vessels and may present as transient ischemic attacks or stroke. In such cases it is often necessary to resect the dissection flap into the branch vessel or reunite the layers distally before reimplantation.

Infrequently, chronic type A dissection results in extensive aneurysmal dilatation of the aorta extending from the ascending aorta through the arch and into the descending thoracic aorta. Surgical treatment of such extensive disease has traditionally been performed as a staged procedure in which the ascending aorta and arch are replaced first through a sternotomy. The second stage of the so-called elephant trunk procedure is performed 6 weeks later through a left thoracotomy for replacement of the descending aorta using a second vascular graft. Originally described by Borst et al, this technique has been used extensively with good results.<sup>86</sup> In some cases, the aorta distal to the left subclavian artery may be so large as to preclude the use of a two-stage repair. Kouchoukos et al have described a single-stage repair performed through a bilateral anterior thoracotomy in which the arch is repaired first during a brief period of circulatory arrest. Right subclavian and femoral artery cannulation for cardiopulmonary bypass provide proximal and distal perfusion during the subsequent ascending and descending aortic replacement. The hospital mortality was 6.2% and there were no adverse neurologic outcomes in the small series.<sup>87</sup> Postoperative and long-term management of these cases are identical to the acute repairs, but with an emphasis on monitoring for evidence of malperfusion.

## Techniques for Chronic Type B Aortic Dissection

### ENDOVASCULAR THERAPY

Endovascular therapy has been recently used for management of chronic type B aortic dissections<sup>42,50,51,58,69,70</sup> (see Table 47-6). The goal of endovascular therapy is to seal any dissection entry points, promote thrombosis of the false lumen, induce aortic remodeling, and prevent further aneurysmal dilatation, rupture, or malperfusion.

The general considerations, preoperative assessment, and operative technique for endovascular therapies in chronic dissection are similar to the ones described for acute type B dissection. Although percutaneous fenestrations may be used in cases of malperfusion, most chronic dissections require treatment for aneurysmal dilatation and aortic expansion because of the persistence of a false lumen, an obligate consequence of fenestrations. Therefore, the endovascular treatment of choice for most chronic dissections is endovascular grafting. Because of the increased risk of spinal malperfusion, lumbar drainage for spinal protection is used liberally in chronic dissections.

Preoperative planning with CTA or MRA is important to define the anatomy and plan the deployment of the endovascular graft. Multiple connections between the true and the false lumen may be identified in chronic dissections. It is important to seal all entry points with the endovascular graft to depressurize the false lumen. Follow-up imaging and close surveillance after the endovascular procedure are necessary.

### SURGICAL THERAPY

The purpose of surgical intervention in chronic aortic dissection is to replace all segments of dissected aorta at risk for rupture and prevent the possibility of subsequent malperfusion syndrome. The conduct of the operation including surgical approach, monitoring lines required, anesthetic technique, and cardiopulmonary bypass is similar to that described for acute dissections. Greater emphasis is placed on methods of spinal cord protection.

The incidence of paraplegia after repair of thoracoabdominal aneurysms resulting from aortic dissection is reportedly as high as 25%.<sup>88</sup> Both mechanical and pharmacologic interventions have been advocated over the last decade to reduce this risk. Partial left heart bypass alone for replacement of the thoracic aorta above the level of T9 can reduce paraplegia rate between 5 and 8%.<sup>89</sup> We routinely use a lumbar drain for aneurysms extending below T9.<sup>54</sup> Reimplanting intercostals and lumbar arteries between T9 and L1 can be an important adjunct.<sup>90</sup> The aortic cross-clamp is sequentially moved distally to perfuse branches as they are reimplanted. The combination of distal perfusion, CSF drainage, and reimplanting large intercostal and lumbar arteries has significantly reduced the incidence of paraplegia at our institutions. Additional techniques used for spinal cord protection include measurement of sensory and motor evoked potentials, regional epidural cooling, and the use of a variety of pharmacologic agents for cellular protection.

The techniques used for replacement of the descending thoracic aorta are identical to those described for treatment of acute type B dissection. The extent of resection, however, for chronic type B dissection is usually greater with the goal to remove all dissected aorta at risk for rupture or symptoms. Usually these operations can be performed through the left chest, but more extensive aneurysms or cases of visceral malperfusion require a thoracoabdominal incision or a staged repair. The proximal anastomosis is ideally made to undissected normal aorta but infrequently the distal arch is involved, which requires alteration in surgical strategy.

As mentioned, we prefer the combination of partial left heart bypass and CSF drainage for spinal cord protection. Sites for cannulation are the left inferior pulmonary vein and the left femoral artery or descending thoracic aorta. Depending on location and extent of aneurysm, the distal arch is mobilized first. The area between the left common carotid and left subclavian artery is circumferentially dissected, and the left subclavian artery is independently controlled. Partial left heart bypass is then initiated. Ideally, clamps are placed

between the left subclavian and left common carotid arteries and on the aorta distal to the involved segment. If the entire descending thoracic aorta is diseased, the clamp is placed on the mid-thoracic aorta to perform the proximal anastomosis first. The aorta is opened and small intercostal arteries are oversewn. The proximal anastomosis is made to normal aorta whenever possible with running 3-0 Prolene; 4-0 Prolene is used if the tissue is fragile. The clamp is moved distally onto the graft to inspect the proximal anastomosis and achieve hemostasis. Several centimeters of the dissection flap is then resected from the lumen of the distal aorta and the distal anastomosis created to the adventitia of the chronic dissection. In more extensive thoracoabdominal disease, the clamp is progressively moved distal as intercostal arteries below T7 to L2 and visceral vessels are reimplemented (Fig. 47-25). Bypass is terminated and the operation completed.

Full cardiopulmonary bypass with deep hypothermic circulatory arrest may be necessary in cases in which the proximal anastomosis cannot be safely or adequately performed with a clamp in the usual position.

## RESULTS

The operative mortality for chronic type A dissections is between 4 and 17%.<sup>90,91</sup> The stroke rate after repair is 4%, with early neurologic complications occurring in 9%.<sup>28</sup> Regular follow-up of the aortic valve is necessary when the native valve is preserved at the initial operation. This is best performed using TTE on a yearly basis. Early reports indicated that nearly 20% of patients require reoperation secondary to progressive aortic regurgitation. The most recent data from David et al, however, reveal a  $90 \pm 4\%$  5-year freedom from severe or moderate aortic insufficiency in patients with aortic root aneurysm and  $98 \pm 2\%$  in patients with ascending aortic aneurysm following valve-sparing operation.<sup>84</sup>

The perioperative mortality after surgical treatment of chronic type B dissections has been reported to be as low as 10% with a rate of permanent paraplegia of 9%.<sup>28</sup> Long-term survival for type A and B chronic dissections is similar with rates at 1, 5, 10, and 15 years after surgery of 78, 60, 45, and 27%, respectively.<sup>92</sup> Approximately one-third of deaths

**FIGURE 47-25** Replacement of the thoracoabdominal aorta. (A) A left femoral cannula perfuses the lower body and viscera while the heart continues to eject. The arch is transected near or at the left subclavian and any dissection involving the proximal cuff is repaired. (B) The clamp is moved down and a second arterial cannula is inserted into the proximal graft to perfuse the upper body and heart. The anterior wall of the dissection is incised longitudinally and bleeding intercostals of the upper six pairs are oversewn. A group of lower intercostal arteries above the celiac axis is sutured to the graft. (C) The clamp is moved down and the distal aortic clamp is moved to the left common iliac artery. A patch of aorta containing the celiac, superior mesenteric, and right renal artery is sewn into the graft. The left renal artery is sutured separately to the graft. (D) The proximal clamp is moved below the visceral anastomoses and the distal aortic anastomosis is made to the aortic bifurcation.

are cardiac-related, and at least 15% of deaths are related to complications or extension of the aortic dissection.

Recently, endovascular therapies have been used for management of chronic type B aortic dissections. The outcomes cited in Table 47-6 are similar to the outcomes after endovascular treatment of acute dissections. Although the results of these studies look promising, this topic needs to be studied further before recommendations or indications of endovascular repair in chronic type B dissections are elucidated.

## CONCLUSION

Considerable improvement in the treatment of patients with acute and chronic aortic dissection has occurred over the last 50 years. The management of aortic dissections will continue to evolve as improved medical, endovascular, and surgical techniques are refined. At the present time, surgical therapy remains the standard of care for acute type A aortic dissections. Uncomplicated type B dissections should continue to be treated with optimal medical management and close surveillance until further studies define whether “prophylactic” endovascular repair will play a role in these patients. The treatment of acute complicated type B dissections has significantly evolved over the last few years, with endovascular therapies now providing an alternative to surgical therapy. The long-term outcomes of endovascular treatment are still unclear but appear to be promising. Patients undergoing operative intervention for aortic dissection will undoubtedly benefit from the novel basic and clinical research taking place in the areas of spinal cord and cerebral protection, strategies for cardiopulmonary bypass, improved vascular graft and endograft technology, and procedures for preservation of the aortic valve. Such progress may even permit advancement in our greatest remaining clinical challenge, those patients who are hemodynamically unstable following aortic dissection.

# Ascending and Arch Aortic Aneurysms

Chase R. Brown • Joseph E. Bavaria • Nimesh D. Desai

The Greek physician Galen first described superficial false aneurysms arising from venesection in the antecubital fossa and in gladiators injured during battle in the second century A.D.<sup>1</sup> Antyllos, during the same time period, distinguished between true and false aneurysms and attempted surgical treatment with proximal and distal ligation, opening of the aneurysmal sac, and removal of its contents.<sup>2</sup>

The French physician Jean Francois Fernel, in 1542, described aneurysms, “in the chest, or about the spleen and mesentery where a violent throbbing is frequently observable.”<sup>3</sup> In 1543, Andreas Versalius described a thoracic aortic aneurysm. In the late 1500s, Ambroise Paré described a death by a ruptured thoracic aortic aneurysm and either Fernel or Paré proposed that syphilis played a causative role in some aortic aneurysms.<sup>1</sup> In 1760, Morgagni reported the first cases of aortic dissection and in 1773, Alexander Monro described three coats of the arterial wall, and the destruction of the wall in the formation of true and false aneurysms.<sup>1</sup>

Peripheral arterial ligation was developed in the 1800s by John Hunter, who demonstrated safe and reproducible means of ligating certain peripheral arteries.<sup>4</sup> Innovative measures used to cause thrombosis of aneurysms included the insertion of long segments of wire<sup>5</sup> with the application of an electric current,<sup>6</sup> and wrapping of aneurysms with cellophane or other irritating materials.<sup>7,8</sup>

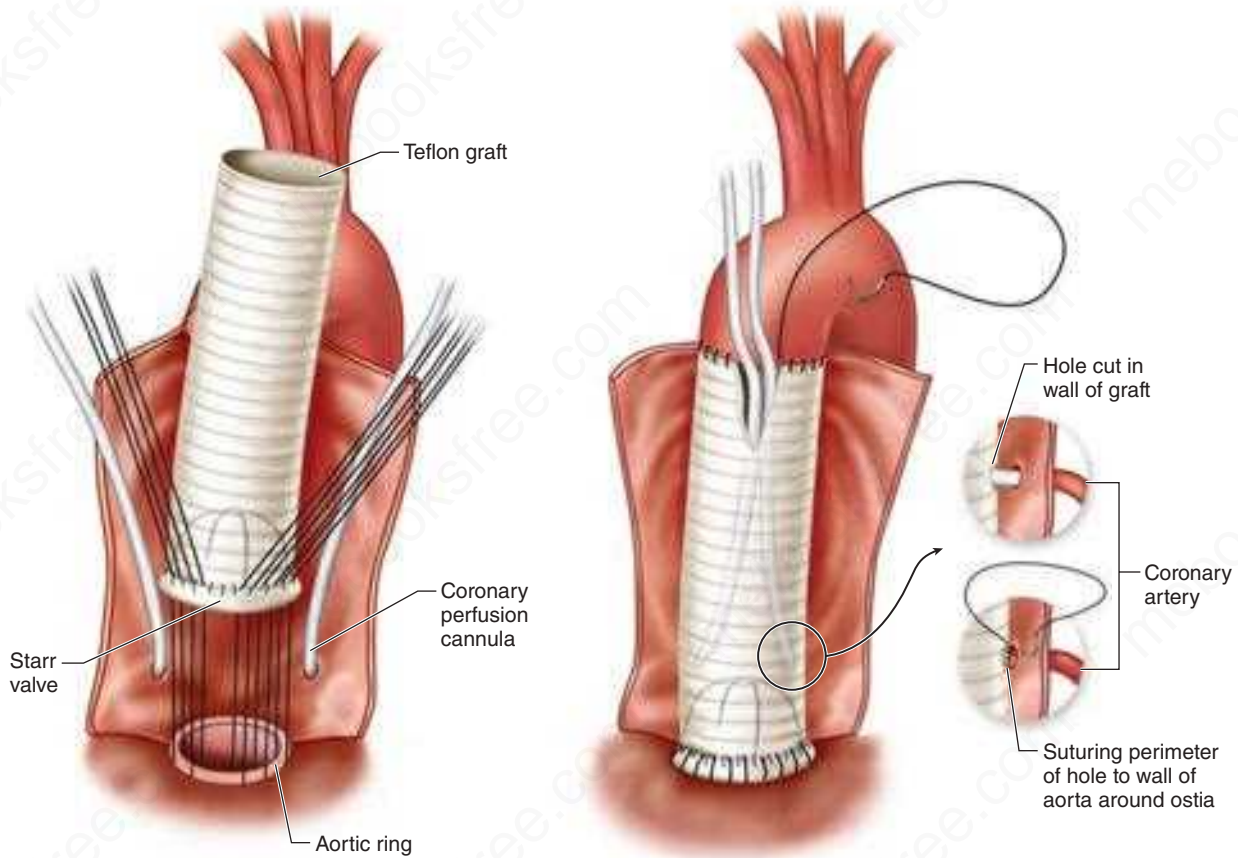

In 1888, Rudolph Matas introduced obliterative endoaneurysmorrhaphy in which stitches placed from within the aneurysm sac obliterated the arterial openings.<sup>9</sup> This allowed closure of large aneurysms that would have been difficult to ligate externally. Recognizing the importance of maintaining arterial continuity for certain aneurysms, he subsequently devised techniques of restorative or reconstructive endoaneurysmorrhaphy, in which diseased segments of the aneurysm wall were resected and the remaining vessel wall was reconstructed to reestablish flow.<sup>10</sup> The number of aneurysms to which these techniques could be applied, however, was very limited. The broad application of surgical treatment for major arterial aneurysms would have to await the development of satisfactory conduits and the techniques to insert them.

The first report of a descending aortic repair was described by Cooley and DeBakey in 1952. The technique involved lateral resection and aortography performed on a saccular aneurysm without cardiopulmonary bypass (CPB).<sup>11</sup> In 1956, Cooley and DeBakey performed replacement of the ascending aorta with a segment of homograft with CPB.<sup>12</sup> Polyester cloth grafts were introduced by DeBakey, who discovered it in a Houston department store, and it soon became the artificial conduit of choice for aortic replacement.<sup>13</sup> Technical improvements in graft replacements included the impregnation of polyester grafts with albumin, collagen, or gelatin, which has greatly reduced the blood loss through the grafts.<sup>14</sup>

Wheat et al in 1964, resected the ascending aorta and entire aortic root except for the aortic tissue surrounding the coronary arteries.<sup>15</sup> They then performed a mechanical valve insertion and fashioned the proximal tube graft to accommodate the coronary arteries, which were left in situ. The first composite aortic root replacement was performed by Bentall and De Bono in 1963 to treat an ascending aortic aneurysm in a patient with Marfan syndrome (MFS) who had severe thinning of the aortic wall in the sinus segment.<sup>16</sup> The original technique involved hand sewing a Starr #13 mechanical prosthesis to a preclotted graft (Fig. 48-1). An inclusion-type technique with aortic wrap in which the coronary buttons were left in situ and anastomosed to holes made in the graft was performed. Due to concerns about coronary malposition, in 1981, Cabrol et al described the use of an 8 to 10 mm Dacron graft to attach to independently mobilized coronary artery buttons.<sup>17</sup> Techniques eventually evolved to the current method of individual coronary button reimplantation as described by Kouchoukos and Karp with end-to-end anastomoses as opposed to the inclusion technique which tended to be prone to pseudoaneurysm formation.<sup>18</sup>

## SURGICAL ANATOMY

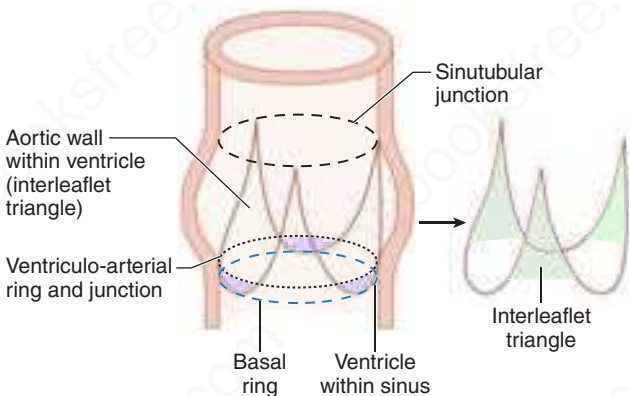

The aortic root is in extension of the left ventricular outflow tract and that provides the scaffolding for the elements of the

**FIGURE 48-1** The original root replacement operation as described by Bentall and De Bono. (Reproduced with permission from Bentall H, De Bono A: A technique for complete replacement of the ascending aorta, *Thorax* 1968 Jul;23(4):338-339.)

aortic valve and connects to the descending aorta. Its components include the aortic valve cusps, the sinuses of Valsalva, the aortic annulus and subcommissural triangles, and the sinotubular junction (Fig. 48-2).<sup>19</sup> The aortic valve cusps attach to the aortic annulus at hinge point following a semilunar

contour being a three-pointed crown type arrangement not a circular or oval ring. The annular tissue itself is typically 50 to 60% fibrous tissue along the hinge point between the aortic and mitral valves as well as the membranous portion of the septum, and the remainder is muscular. Small projections of collagen anchor the aortic root to the ventricular muscle.<sup>20</sup> The apices of the attachments of the cusps to the aortic annulus are known as commissures and the most superior aspect of the commissures interrelates with the sinotubular junction. The sinotubular junction is a ridge which marks the beginning of the ascending aorta. The sinotubular junction diameter is typically 15 to 20% smaller than annular diameter in younger patients.<sup>21</sup> With aging, the sinotubular junction diameter becomes larger. When the sinotubular junction is more than 10% larger than the annular diameter there is frequently resultant aortic insufficiency as the leaflets were no longer coapt due to displacement of the commissures.

**FIGURE 48-2** Aortic Root Geometry. (Reproduced with permission from Sutton JP 3rd, Ho SY, Anderson RH. The forgotten interleaflet triangles: a review of the surgical anatomy of the aortic valve, *Ann Thorac Surg* 1995 Feb;59(2):419-427.)

Between the sinotubular junction and the aortic annulus are expanded segments of the aorta referred to as the sinuses of Valsalva. The sinuses form a cloverleaf rather than circular alignment when viewed in cross-section (Fig. 48-3).<sup>22</sup> Dilatation of the aortic sinuses and annulus is referred to as aortoannular ectasia. Each sinus is named for its corresponding coronary artery (right, left, and noncoronary).

**FIGURE 48-3** Anatomy of the aortic root from a Cardiac Gated CT Angiogram. Note the “cloverleaf” orientation of the sinuses.

The noncoronary sinus is anatomically related to the left and right atria as well as the transverse sinus. The left coronary sinus anatomically relates to the left atrium and the right coronary sinus is related to the right atrium and right ventricle. The subcommissural triangle between the right and noncoronary arteries is anatomically related to the conduction system within the membranous septum as well as the septal leaflet of the tricuspid valve. The left and noncoronary subcommissural triangles are related to the anterior leaflet of the mitral valve. The ascending aorta starts at the level of the sinotubular junction and ascends to the level of the takeoff of the innominate artery.

## PATHOPHYSIOLOGY

The ascending aorta histologically contains a high proportion of compliant elastic tissue allowing it to serve as a reservoir and that stores kinetic energy from the systolic pulse wave as it expands and uses it to maintain flow during diastole via elastic recoil. The ascending aorta is a three layered structure composed of a smooth intimal layer composed of a single layer of endothelial cells adhered to a basal lamina; a medial layer composed of layers of elastin sheets, collagen, smooth muscle cells, and extracellular matrix; and an outer layer of adventitial tissue which includes the vasa vasorum and nerves.<sup>23</sup> The elastin content of the aorta decreases distally and in the abdominal aorta is less than half of that in the ascending aorta.<sup>24</sup> The principle biologic causes of aneurysm formation in the ascending aorta are related to degenerative processes in the elastic media, as compared to primarily atherosclerotic changes in the descending and abdominal aortas.<sup>25</sup>

Ascending aortic aneurysm formation is the result of several biologic and mechanical mechanisms. Disruption of the

balance between homeostatic mechanisms within the aortic wall including elastic and collagen elements, proteoglycans, proteolytic enzymes and their inhibitors, and inflammatory mediators causes a spectrum of aortic pathology which manifests in the final pathway as aortic enlargement eventually leading to rupture or dissection. Fragmentation of the extracellular matrix of the aortic media occurs due to matrix-degrading enzymes such as matrix metalloproteinases and cathepsin groups.<sup>26-30</sup> Matrix metalloproteinases comprise a family of proteases that are capable of degrading virtually all components of the extracellular milieu and perform a variety of tasks necessary for normal homeostasis, including maintenance of the dynamic integrity of the extracellular structure within the arteries.<sup>26-28</sup> Aneurysms form as elastic layers fragment, smooth muscle cells become dysfunctional, and eventually elastic and smooth muscle components are replaced with a cystic appearing mucoid material (Fig. 48-4).<sup>31</sup> This process is referred to as cystic medial degeneration. The term cystic medial necrosis has also been applied to this condition but has been largely

**FIGURE 48-4** Cystic Medial Degeneration with (A) pools of glycosaminoglycans with 25% transmural extent and (B) associated loss of elastic fibers.

abandoned as there is no true necrotic process involved. To a lesser extent, mild degeneration of the aortic wall is common with advanced age and is responsible for the slow dilation of the ascending aorta with age. Smoking tends to exacerbate this degeneration.<sup>32</sup>

Mechanical changes to aortic wall characteristics such as alterations in cross-sectional symmetry, compliance, and stress-strain relationships likely predate dilatation. The Young-Laplace relationship describes the relationship between aortic diameter and wall tension where increases in aortic wall diameter lead to increases in wall stress at similar pressures (tension = pressure  $\times$  radius). Changes in aortic wall compliance, broadly defined as the change in volume of the vessel with a change in pressure, lead to increased stress applied to the aortic wall during the systolic impulse and further exacerbate the biologic derangements leading to aneurysm formation.<sup>33</sup> The coupling between mechanical forces on the arterial wall and the biochemical changes leading to aneurysm formation (mechano-transduction) are not yet clearly elucidated.

Degenerative aortic aneurysms cause asymmetric enlargement of the ascending aorta as the segment of aorta along the inner curvature is adherent to the pulmonary artery.<sup>34</sup> Hence, there is significant rightward and anterior displacement of the aortic wall (Fig. 48-5). This causes a relative elongation of

**FIGURE 48-5** Massively dilated aortic root in a Marfan syndrome patient. Note the severe dilation of the aortic annulus and relative sparing of the proximal arch.

the ascending aorta in an asymmetric fashion which tends to push the heart into a horizontal arrangement. This also causes a significant change in the orientation of the aortic valve annulus to more oblique arrangement.<sup>34</sup> Aneurysmal widening will typically involve the aorta to the level of the sinotubular junction and frequently involves the noncoronary sinus to a lesser extent.<sup>35</sup> This widening at the level of the sinotubular junction is responsible for aortic insufficiency in these cases and frequently placement of tube graft to the sinotubular junction will resolve significant central aortic insufficiency. The left and noncoronary sinuses are fairly normal in these cases. The noncoronary aortic valve cusp may be elongated along its free margin in order to compensate for the asymmetric enlargement of the noncoronary sinus.

## SPECIFIC ETIOLOGIES

### Marfan Syndrome

MFS is an autosomal dominant syndrome with complete penetrance. Up to 25% of Marfan cases are from sporadic dictation in the overall incidence is one per 3000 to 10,000 live births.<sup>36</sup> Traditionally it is thought to have been caused by alterations in the gene (FBM1) coding the aortic wall protein fibrillin-1 leading to elastin derangement, medial degeneration, and aneurysm formation.<sup>37,38</sup> More recently, homology between fibrillin-1 molecules and latent transforming growth factor (TGF) beta binding proteins has led investigators to infer that altered sequestration of the latent form of TGF beta in the extracellular matrix may increase TGF beta activity which negatively impacts smooth muscle development and the extracellular matrix.<sup>39</sup> Approximately 80% of patients with MFS develop aortic root aneurysms and nearly half develop mitral regurgitation.<sup>40</sup> The clinical manifestations of MFS involve multiple organ systems as it is a systemic disease. Diagnosis has traditionally been made using the Ghent criteria, although it is now made definitively using genotyping.<sup>41</sup> Anatomically, MFS results in severe aortoannular ectasia and can have massively dilated sinuses and aortic annulus (Fig. 48-5).

More recently, reports have shown that the use of angiotensin-converting enzyme inhibitors can prolong the life expectancy of smooth muscle cells in the aortic tissue of Marfan patients via an angiotensin-2 type II receptor blockade mechanism which may antagonize TGF beta.<sup>42</sup> This has led to the clinical application of the angiotensin receptor blocker losartan as a prophylactic therapy to diminish aortic degeneration and aneurysm formation, which has been shown in animal models to be effective when given in the early stages of the disease.<sup>43</sup> A small clinical study of 18 pediatric patients also showed decreased aortic growth rate with treatment of losartan.<sup>44</sup>

### Loeys-Deitz Syndrome

Loeys-Deitz syndrome (LDS) is a more recently described autosomal dominant syndrome.<sup>45</sup> Rather than a fibrillin-1

defect, however, there is a mutation in TGF beta receptors 1 and 2. Characteristics of LDS include cleft palate, bifid uvula, scoliosis, orbital hypertelorism, pectus deformities, developmental abnormalities, and congenital heart defects including persistent patent ductus arteriosus and atrial septal defects.<sup>45</sup> Patients may phenotypically have characteristics that overlapped between LDS and MFS.<sup>46</sup> Histologically, it is associated with increased medial collagen and a subtle but diffuse form of elastic fiber fragmentation and extracellular matrix deposition.<sup>47</sup> LDS has a more rapid clinical course than MFS and prophylactic aortic root replacement or reimplantation is often recommended at younger ages and with smaller aortic dimensions.

## Ehlers-Danlos Syndrome

Ehlers-Danlos syndrome is caused by either sporadic mutation or inherited autosomal dominant trait resulting in a connective tissue disorder derived from defective type III collagen synthesis. The type IV variant of the Ehlers-Danlos syndrome is associated with spontaneous arterial rupture. Most commonly this occurs in the mesenteric or carotid arteries. However, spontaneous rupture of the descending aorta and aortic arch has been described.<sup>48</sup> The arterial wall of these patients is extremely thin and friable. Ascending aortic involvement may occur as a consequence of retrograde extension of a primary brachiocephalic branch pathology.

## Familial Thoracic Aortic Aneurysms and Dissections

Approximately 20% of patients with thoracic aortic aneurysms have a first-degree relative with an aortic aneurysm.<sup>49</sup> These families often exhibit strong tendencies for thoracic aortic aneurysm formation without any clearly definable syndromic connective tissue disorder such as MFS or LDS. Grouped together as familial thoracic aortic aneurysms and dissections (FTAAD), mutations in ACTA2, SMAD3, TGFBR1, TGFBR2, TGFB2, and MYH11 have been identified to predispose patients to thoracic aortic aneurysms and dissections in an autosomal dominant manner. These mutations result in incomplete penetrance, variable expression, and variable age of aneurysm onset.<sup>49-55</sup> Genetic testing for patients and family members with multiple first- and second-degree relatives and suspected FTAAD is available. New evidence suggests that these patients are at increased risk for earlier rupture and dissection at diameters less than 5 cm, as seen in patients with LDS and MFS. Genetic testing has the opportunity to stratify these patients and identify those at greatest risk for rupture.

## Infectious and Inflammatory Etiologies

Infections and systemic inflammatory disorders can occasionally cause damage to the wall of the ascending aorta leading to aneurysm formation. Frequently, despite high-quality

preoperative imaging and even with intraoperative tissue pathology, it is not possible to distinguish definitively between the different possible etiologies.

Ascending aortic aneurysms caused by infection are extremely uncommon. Such mycotic ascending aortic aneurysms are frequently related to concomitant left-sided valvular endocarditis. Most common organisms include, in order of decreasing frequency, *Staphylococcus aureus*, *S. epidermidis*, *Salmonella*, and *Streptococcus*.<sup>56</sup> In cases of atherosclerotic aneurysm, if there is intraluminal clot in the ascending aorta, transient bacteremia may lead to infected clot leading to a mycotic aneurysm.<sup>57</sup>

Syphilis, caused by the spirochete *Treponema pallidum*, was the predominant cause of ascending aortic aneurysms in the pre-antibiotic era and accounted for 5 to 10% of all cardiovascular deaths.<sup>58</sup> Typically syphilitic aortitis involves the thoracic aorta with a particular predilection for the ascending aorta, likely due to its rich vascular and lymphatic supply. The pathologic process involves a multifocal lymphoplasmacytic infiltrate of the vasa vasorum leading to degeneration of the medial elastic fibers. The intima develops wrinkles, ridges, and plaques described as a “tree bark” appearance.<sup>59</sup> Inflammation around the coronary artery ostia may lead to high-grade proximal occlusions. The inflammatory process may be either patchy or diffusely involve a large section of aorta. Once established, treatment of syphilis with antibiotics does not reverse the vascular lesions.

Other systemic arteritis conditions may also produce ascending aortic aneurysms. Takayasu's arteritis, associated with inflammation of the vasa vasorum, medial necrosis and may also have intimal changes similar to syphilis. It is typically seen in females between 15 to 30 years of age and frequently involves occlusive lesions to major branch vessels of the arch.<sup>60</sup> While syphilis aortitis often leads to rapid aneurysmal degeneration, this is much less common in Takayasu's aortitis, occurring only in 15% of cases.<sup>61</sup> Giant cell arteritis is a systemic arteritis that occurs in elderly patients, most commonly affecting the temporal artery. It is also more common in females and is also associated with polymyalgia rheumatica. Giant cell arteritis is an inflammatory process with inflammatory infiltration with lymphocytes, plasma cells, and histiocytes. There is variable presence of giant cells.<sup>62</sup> Aortitis leading to aortic aneurysm may also be associated rarely with Behçet's disease, rheumatoid arthritis, sarcoidosis, ankylosing spondylitis, lupus erythematosus, and Wegener's granulomatosis.

## Bicuspid Aortopathy

Bicuspid aortic valve is a complex familial syndrome with a male predominance of 3:1.<sup>63</sup> It is also associated with Turner syndrome. There is a 9% prevalence of bicuspid aortic valve disease in first-degree relatives of patients with bicuspid aortic valve disease.<sup>64</sup> More than half of the patients with aortic coarctation have an associated bicuspid aortic valve.<sup>65</sup> Several genetic defects have been implicated in the formation of bicuspid aortic valve disease however

no single genetic etiology has been derived. Aortic dilatation is frequently associated with bicuspid aortic valve disease; however, the mechanism for this occurring is not well delineated. Originally thought to be a sequela of post-stenotic dilatation, aortic aneurysm formation in patients with bicuspid aortic valve may occur without any significant aortic stenosis although there is clearly flow perturbation in the proximal sinuses of Valsalva and descending aorta in patients with bicuspid aortic valve.<sup>66</sup> Recent investigation has shown that embryologically, the aortic valve and ascending aorta arise from the neural crest cells implicating a potential common mechanism for the development of a bicuspid aortic valve and subsequent aneurysm formation.<sup>67</sup> The aortic wall in the patients with bicuspid aortic valve disease shows increased elastic fragmentation, fibrillin-1 deficiency, matrix disruption, increased levels of matrix metallic proteinases, and smooth muscle cell apoptosis.<sup>67-72</sup>

Fazel and colleagues using a cluster-type analysis identified four distinct patterns of aortic dilatation including aortic root alone (13%), ascending aorta alone (10%), ascending aorta and proximal transverse arch (28%), and aortic root, ascending aorta, and proximal transverse arch (45%) (Fig. 48-6).<sup>73</sup> This study suggests that for younger patients, definitive treatment of bicuspid aortic valve disease with aortic dilatation requires strategies that address the aortic root, ascending aorta, and proximal transverse hemi-arch. It is advisable to perform an aggressive hemi-arch resecting all aortic tissue along the lesser curve to the level of the subclavian artery take-off in younger bicuspid aortic valve patients to eliminate as much of the diseased aorta as possible. However, total arch replacement with brachiocephalic branch reimplantation is rarely necessary as the aneurysmal component rarely involves the distal aspect of the transverse arch.

### Isolated Sinus of Valsalva Aneurysm

Aneurysms of the sinuses of Valsalva (SVA) that occur as isolated lesions are rare abnormalities caused by either a congenital defect in the continuity between the medial layer of the affected sinus and the aortic valve annulus or, less commonly, acquired causes such as endocarditis, syphilis, tuberculosis, focal dissection, iatrogenic causes.<sup>74</sup> They are more common in males and may be associated with subaortic stenosis, ventricular septal defects, and aortic insufficiency. In over 90% of cases, they involve the right coronary sinus (Fig. 48-7).<sup>75,76</sup> The noncoronary sinus of the second most common location and these aneurysms are extremely uncommon in a left coronary sinus. They are generally asymptomatic until they rupture when they usually cause intracardiac shunts. Right sinus of Valsalva aneurysms typically rupture into the right ventricle, effectively causing a hemodynamic defect similar to a ventricular septal defect. Aneurysms of the noncoronary sinus typically rupture into the right atrium and the left coronary sinus rupture into the pulmonary artery or left ventricle. Occasionally an unruptured left

coronary sinus of Valsalva aneurysm may compress the left main coronary artery.<sup>76</sup>

## CLINICAL PRESENTATION

### Symptoms

Most ascending aortic aneurysms are asymptomatic when diagnosed, being incidentally noted on chest x-ray or echocardiogram. Anterior chest pain is the most frequent symptom. The pain may be acute in onset signifying impending rupture or a chronic gnawing pain from compression of the overlying sternum. Occasionally signs of superior vena cava (SVC) or airway compression are present. Hoarseness resulting from stretch injury of the left recurrent laryngeal nerve suggests involvement of the distal aortic arch or proximal descending thoracic aorta. Less commonly, aneurysms of the ascending aorta or aortic root can rupture into the right atrium or the SVC, presenting with high-output cardiac failure or bleed into the lungs with ensuing hemoptysis. Acute dissection of the ascending aorta presents with severe tearing pain in over 75% of patients.<sup>77</sup>

### Physical Examination

Physical examination is often unremarkable. If there is related aortic insufficiency, a widened pulse pressure or diastolic murmur may be present. If dilation is isolated to the ascending aorta, however, the aneurysm can reach large dimensions without producing physical findings. A thorough vascular examination should be carried out to look for any concomitant peripheral vascular disease, carotid disease, or abdominal aortic aneurysm. Abdominal aortic aneurysms may be present in 10 to 20% of patients with atherosclerotic involvement of an ascending aortic aneurysm.<sup>78</sup>

## DIAGNOSTIC STUDIES

### Electrocardiogram

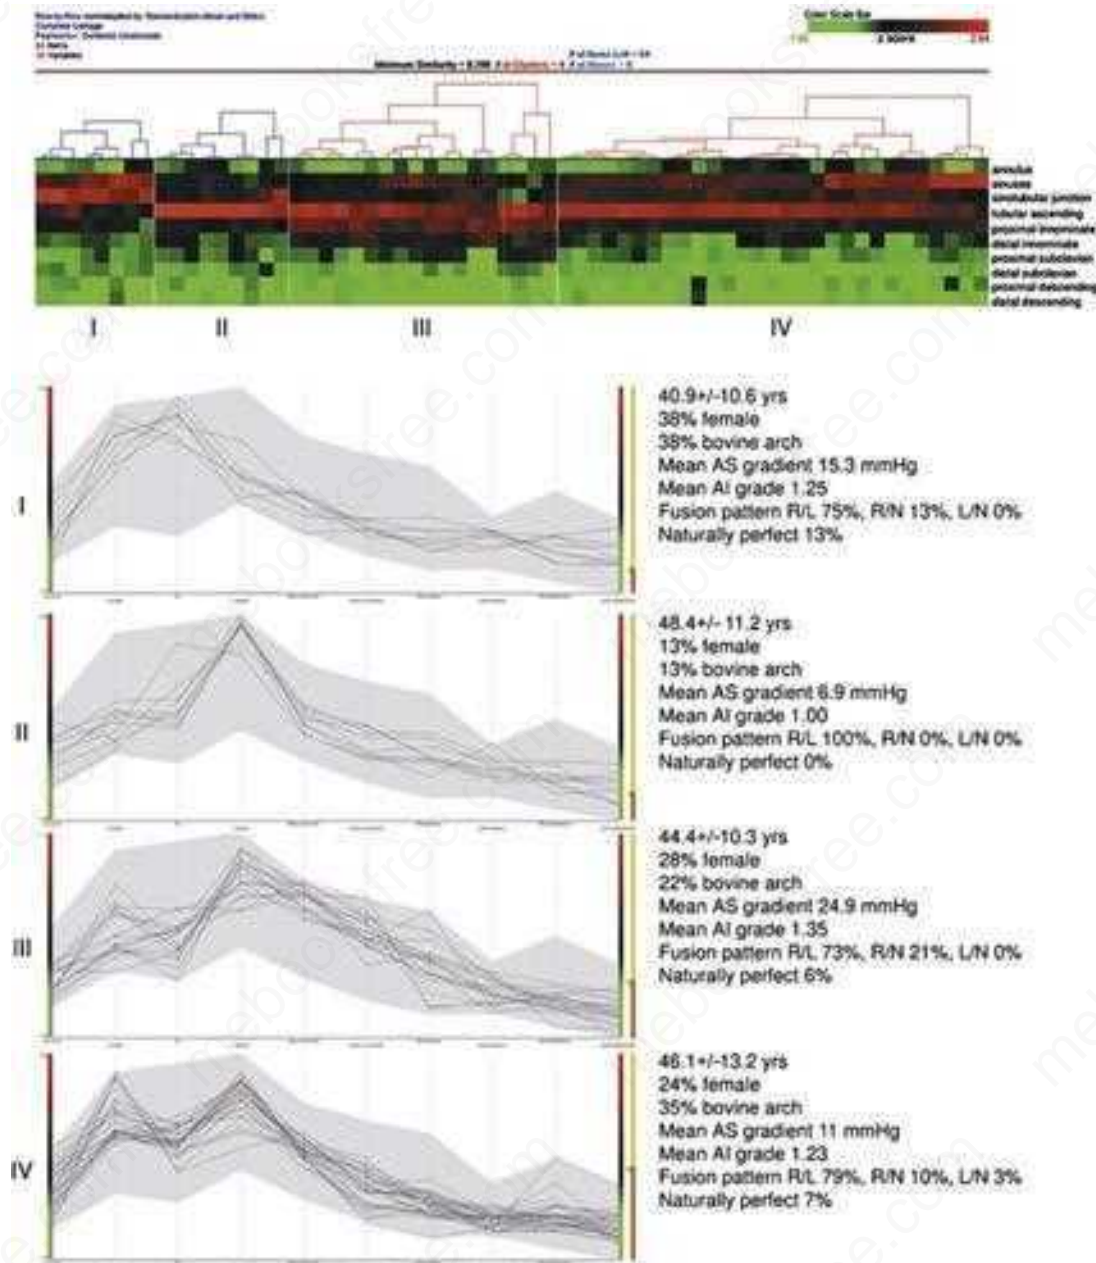

With significant aortic insufficiency, left ventricular hypertrophy or strain is evident. Patients with generalized atherosclerosis may show evidence of concomitant coronary artery disease or previous myocardial injury.

### Chest Radiography

Many asymptomatic ascending aortic aneurysms are first detected on chest x-ray. The enlarged ascending aorta produces a convex contour of the right superior mediastinum (Fig. 48-8A). In the lateral view, there is loss of the retrosternal air space (Fig. 48-8B). Aneurysms confined to the aortic root can be obscured by the cardiac silhouette and may not be evident on chest radiograph.<sup>79</sup>

### Echocardiography

Transesophageal echocardiography (TEE) is a portable diagnostic tool that accurately detects and differentiates between

**FIGURE 48-6** Patterns of aortic pathology in bicuspid aortopathy patients using hierarchical clustering methodology. The top panel shows a “heat map” in which each column represents a patient and each row represents aortic diameters that have been color coded according to the calculated within-patient z scores on a continuous scale shown on the top right corner of the panel. Cluster I patients had predominant involvement of the aortic root (n = 8). Cluster II patients had predominant involvement of the tubular portion of the ascending aorta and the transverse arch (n = 18). Cluster III patients had involvement of the tubular portion of the ascending aorta and the transverse arch (n = 18). Cluster IV patients had diffuse involvement of the thoracic aorta with dilation extending from the aortic root to the midtransverse arch (n = 29). The 4 clusters are shown again in the bottom 4 panels, which depict the metric aortic diameters across the thoracic aorta for each individual patient. The clinical data for each cluster are summarized to the right of each cluster panel. AS, Aortic stenosis; AI, aortic insufficiency. (Reproduced with permission from Fazel SS, Mallidi HR, Lee RS, et al: The aortopathy of bicuspid aortic valve disease has distinctive patterns and usually involves the transverse aortic arch. *J Thorac Cardiovasc Surg*. 2008 Apr;135(4):901-907.)

ascending aortic aneurysms, dissections, and intramural hematoma (Fig. 48-9).<sup>80-82</sup> TEE is an invasive imaging modality and carries a small risk of esophageal perforation, respiratory compromise, and hemodynamic instability. Imaging

of the distal ascending aorta is obscured on TEE by air in the tracheobronchial tree, with up to 40% of its distal extent not well visualized, although this is somewhat mitigated with the use of modern multiplanar probes.<sup>83</sup> Although somewhat

**FIGURE 48-7** Contrast MR showing three-chamber view (A) and the aortic valve plane (B) demonstrate a right SVA protruding into the right ventricular outflow tract (arrows). There is an associated turbulent jet of aortic regurgitation. LA, left atrium; LV, left ventricle; Ao, aorta; RVOT, right ventricular outflow tract. operator dependent, TEE provides a reliable technique to measure the annular, sinus, sinotubular junction, and ascending dimensions. It is uniquely well suited to examine the most proximal aspects of the aortic root, which are often blurred by motion artifact on computed tomography (CT) scans. Transthoracic echocardiography is far less reliable but may be useful for assessing the severity of aortic regurgitation.

### Computed Tomography

Contrast-enhanced CT is the most widely used noninvasive technique for imaging the thoracic aorta. CT scanning provides rapid and precise evaluation of the ascending aorta in regards to size, extent, and location of the disease process (Fig. 48-10). CT scanning detects areas of calcification, and modern scanner accurately identifies dissections and mural thrombus.<sup>81</sup>

**FIGURE 48-8** Posteroanterior and lateral chest radiograph of a patient with an ascending aortic aneurysm. The posteroanterior view (A) shows convexity of the right mediastinum, and the lateral view (B) shows loss of the normal retrosternal air space. **FIGURE 48-9** Transesophageal echocardiogram of a massive aortic root aneurysm with dissection (arrow).

CT scan technology has evolved with multidetector scanners such that the entire thoracic aorta can be evaluated on one breath-hold and the distance between axial slices can be as small as 0.5 mm. Three-dimensional volume rendering is a highly useful tool for determining true in-plane aortic diameters and the proximal and distal extent of aortic disease relative to the arch vessels, which can aid the surgeon in operative planning

**FIGURE 48-10** CT angiogram of an enlarged aortic root in a Marfan patient.

(Fig. 48-11). Ideally, the entire thoracic and abdominal aorta should be examined for evidence of concomitant aneurysm disease in the arterial tree. Gating to the electrocardiogram during image acquisition eliminates the motion artifact that may be seen in the most proximal aspects of the aortic root and can also allow for assessment of the coronary arteries.<sup>85</sup> The main disadvantage of CT scans is the need for contrast solution for optimal resolution, which may be contraindicated in those patients with renal insufficiency or a history of a dye allergy. Noncontrast CT scans allow for assessment of aortic diameters but cannot identify dissection flaps or other acute pathologies.

### Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) can provide axial and three-dimensional reconstruction of the ascending aorta with the avoidance of iodinated contrast agents and radiation exposure. Contrast-enhanced MR angiography with gadolinium allows more precise measurements of the aorta and its major branches with images comparable to conventional angiography (Fig. 48-12).<sup>86</sup> MRI scanners are relatively unsuitable for those patients connected to mechanical ventilators or hemodynamic monitoring equipment. MRI is more expensive, less readily available, and requires significantly more acquisition time than CT scanning and is used less frequently.

### NATURAL HISTORY

Elective aortic replacement is used as a means to prophylactically prevent aortic catastrophe such as dissection and rupture which carry high mortality. Recent data from the International

**FIGURE 48-11** 3D reconstruction of an aortic root aneurysm in a Marfan patient.

**FIGURE 48-12** MR angiogram (without contrast) depicting an acute type A dissection. The partially thrombosed false lumen is denoted by the arrow.

Registry of Acute Aortic Dissections (IRAD) show an operative mortality for emergent type A aortic dissection repair of 26%, although this is generally lower in more experienced centers.<sup>87</sup> Bickerstaff et al examined the natural history of 72 patients that were diagnosed with aortic aneurysms and

did not undergo surgery.<sup>88</sup> Over a 5-year follow-up period, 74% of patients experienced aortic rupture or dissection (Fig. 48-13). Of these 94% died. The overall 5-year survival was only 13% in untreated aneurysm patients compared with 75% in control patients without aortic aneurysms.

Traditionally, the most important criterion for ascending aortic replacement on an elective basis is maximal aortic diameter. In natural history studies by Coady et al, patients with 3.5 to 3.9 cm aortic aneurysms were very unlikely to rupture within 3 to 4 years, and each incremental 1 cm increase from this point increased rupture risk (Fig. 48-14).<sup>89</sup> Patients with aneurysms greater than 5 cm showed substantially higher dissection and rupture risk within the first year. Using a logistic regression model, they found that the aneurysm with maximal diameter of 6.0 to 6.9 cm had a 4.3 times greater increased risk of rupture or dissection than an aneurysm that is 4.0 to 4.9 cm in diameter. Growth rates for aortic aneurysms less than 4 cm are about 0.1 cm per year and this increases gradually as aortic

**FIGURE 48-13** Actuarial survival estimates of 72 patients followed nonoperatively with thoracic aneurysms and dissections.

**FIGURE 48-14** The incidence of acute dissection or rupture of thoracic aneurysms according to size. The height of the column corresponds to the total number of patients and the blue area to the proportion of patients who suffered complications of dissection or rupture. (Reproduced with permission from Coady MA, Rizzo JA, Hammond GL, et al: What is the appropriate size criterion for resection of thoracic aortic aneurysms? *J Thorac Cardiovasc Surg* 1997; 113:476.)

size increases up to 0.4 cm per year.<sup>90,91</sup> Uncontrolled hypertension, smoking, and presence of connective tissue disorders are associated with more rapid aortic growth.<sup>90</sup> Patients with MFS are at particularly high risk for rupture or dissection of smaller sizes and dissection is frequently seen with a maximal ascending aortic dimension of less than 5 to 6 cm (Fig. 48-15).<sup>92</sup> Strikingly the average age of death for untreated patients with MFS is 32 years, with complications of the aortic root being responsible for 60 to 80% of these deaths.<sup>93</sup> Marfan's patients with a family history of early dissection or rupture are at the highest risk for aortic catastrophe occurring at smaller dimensions.<sup>94</sup>

Although size clearly correlates with rupture risk, it is important to note that many aortic dissections occur in ascending aortas that are less than 5.5 cm in diameter. In the IRAD registry, over 59% of 591 enrolled patients with acute type A aortic dissections had maximum aortic dimensions less than 5.5 cm and 40% were less than 5.0 cm (Fig. 48-16).<sup>95</sup>

**FIGURE 48-15** Diameter of the aneurysm in 524 adult patients with Marfan Syndrome, according to the Presence of Aortic Dissection.

**FIGURE 48-16** Distribution of aortic size at time of presentation with acute type A aortic dissection (cm). (Reproduced with permission from Pape LA, Tsai TT, Isselbacher EM, et al: Aortic diameter  $\geq$  5.5 cm is not a good predictor of type A aortic dissection: observations from the International Registry of Acute Aortic Dissection (IRAD), *Circulation*. 2007 Sep 4;116(10):1120-1127.)

As the understanding of the biologic mechanisms behind aortic aneurysm formation improves, in the future, serum biologic markers and sensitive imaging techniques that can detect subtle changes in aortic strain characteristics or compliance may provide more accurate identification of the high-risk aorta.

## MEDICAL TREATMENT OF PROXIMAL AORTIC ANEURYSMS

Therapies designed to limit the growth of aortic aneurysms are targeted at mechanisms either to diminish stress on the aortic wall or to prevent deleterious degenerative biochemical changes. In general, patients with aortic aneurysms should avoid high intensity isometric exercise such as weight lifting as aortic pressures may increase rapidly and exert significant stress on the aortic wall. Weight lifting restriction should be less than 1/3 to 1/2 of the patient's body weight. Additionally exercises with rapid bursts of acceleration and deceleration such as basketball may place excess of stress of aortic wall.

Anti-impulse therapies are the mainstay treatment for thoracic aortic aneurysms. Due to their negative chronotropic and inotropic effects, beta blockers are typically used as a first line treatment.<sup>96</sup> The primary goals of beta blocker therapy are to decrease the overall blood pressure and to decrease the change in aortic pressure over time ( $dP/dT$ ) to diminish the stress applied to the aorta in systole thereby limiting damage to the media layer. The rationale for using beta blockers was initially established with an ex vivo plastic model of

aortic dissection by Wheat et al in which a tear created in an artificial intimal layer of rubber cement in the plastic tubing propagated less when the pulse pressure was artificially flattened, while variation of mean blood pressure and flow rates had no effect.<sup>97</sup> Studies performed on turkeys, which are uniquely prone to aortic dissection, showed that the combination of sodium nitroprusside and propranolol were effective at preventing rupture, while lowering blood pressure with nitroprusside alone was ineffective and may have actually increased  $dP/dT$  due to reflex sympathetic stimulation causing increased chronotropy and inotropy.<sup>98</sup> In a landmark study by Shores et al, young patients with MFS randomized to a regimen of beta blocker therapy had significantly less aortic dilatation over a 10-year follow-up period (Fig. 48-17)

**FIGURE 48-17** Changes in the Aortic ratio in the propranolol-treated group and untreated controls. Aortic ratio is ratio of the diameter of the aorta measured in a patient to the diameter expected in a subject with the same body-surface area and age. Line indicates the length of follow-up. One patient in the control group had an exceptional aortic ratio ( $>3.4$ ) at 100 months. Two patients in the treatment group (arrows) did not comply with propranolol therapy. (Reproduced with permission from Palmer RF and Wheat MW Jr: Treatment of dissecting aneurysms of the aorta, *Ann Thorac Surg* 1967 Jul;4(1):38-52.)

and also had a lower incidence of a composite end point of death, congestive heart failure, aortic dissection, severe regurgitation, or aortic root surgery versus controls.<sup>99</sup> These results have been extrapolated to a wider variety of patients with ascending aortic aneurysms in whom beta blockade is used extensively.

## INDICATIONS FOR SURGERY

### Non-Elective Indications

Any new onset of acute dissection, rupture, or intramural hematoma generally warrants immediate surgery. The presence of symptoms of chest pain in patients with ascending aortic aneurysms greater than 4.5 to 5 cm is a sign of impending rupture and should also be managed operatively with expediency. Acute severe congestive heart failure secondary to root dilatation and loss of sinotubular junction either from rapid aneurysm expansion or from chronic dissection also warrants early operative management, although aggressive diuresis and cardiac optimization for 1 to 2 days prior to surgery are frequently helpful.

### Elective Indications

Despite the limitations of size criteria, decisions to intervene are still largely decided based on maximal aortic diameter and growth rate. For degenerative aneurysms in the absence of connective tissue disorders or other cardiac pathology, elective repair is reasonable at an absolute maximal diameter of 5.5 cm.<sup>100</sup> Growth rate of greater than 1 cm per year is generally accepted as a strong indication to proceed with surgery for degenerative aneurysms regardless of diameter.<sup>101</sup> Some groups have also advocated the use of normalized aortic dimensions to body size to provide a more accurate reflection of the aneurysm dimension for an individual patient.<sup>102</sup>

The aortic ratio is calculated as measured diameter divided by predicted diameter for a given age and body surface area. Using this method, elective replacement is warranted at an aortic ratio of 1.5 in an asymptomatic patient without a connective tissue disorder or other complicating factors.<sup>103</sup> This leads to intervention at a size of only 4.8 to 5.0 cm in an adult less than 40 years of age with a body surface area of 2 m<sup>2</sup>.<sup>104</sup> Because the ascending aorta normally increases in size with age, the diameter for intervention would be higher in a patient more than 40 years old.

### Special Considerations

Patients with MFS are at higher risk for rupture and the ascending aorta should be replaced prophylactically at a diameter of 4.5 cm or an aortic ratio of 1.3 to 1.4.<sup>103,104</sup> Patients with Loeys-Dietz rupture at a smaller dilation than in MFS and should be electively repaired at 4.2 cm.<sup>105</sup> Among patients with bicuspid aortic valves, there remains ongoing debate. The 2013 Society of Thoracic Surgeons Clinical Practice guidelines suggest 5.0 cm (4.5 cm if there is a

family history of aortic dissection) whereas the ACC/AHA Valve guidelines recommend 5.5 cm (5.0 cm for a family history of aortic dissection or rapid aortic growth greater than 5 mm/year).<sup>106,107</sup> In the setting of connective tissue disorders, bicuspid aortic valve or chronic dissection, a growth rate of greater than 0.5 cm per year should warrant repair. A chronically dissected aorta, which the external aortic wall is supported only by the residual outer third of the medial and adventitial layers, should be replaced when aortic diameters reach 4.5 cm or a ratio of 1.3 to 1.4 due to the intrinsic weakness of the aortic wall.<sup>103,108</sup> Pseudoaneurysms, which are frequently from previous aortic suture lines, should be repaired upon diagnosis due to high rupture risk related to their extremely thin walls.

In younger patients, where aortic root reimplantation is preferred to avoid life-long anticoagulation, earlier repair may prevent the development of aortic valve cusp pathology and improve the chances of successful repair. Among patients undergoing aortic valve replacement who have ascending aortic aneurysms, Prenger et al reported a 27% incidence of aortic dissection if the aorta was greater than 5 cm versus 0.6% incidence if aortic size was normal.<sup>109</sup> In general, in the setting of other cardiac surgery, ascending aortas with a maximal dimension of 5.0 cm or a ratio of 1.5 should be replaced.<sup>103,109</sup>

## PREOPERATIVE PREPARATION

Nearly one-third of patients undergoing surgery for thoracic aortic disease have chronic obstructive pulmonary disease.<sup>110</sup> Patients with suspect pulmonary function should have spirometry and room air arterial blood gases. Smoking cessation, antibiotic treatment of chronic bronchitis, and chest physiotherapy may prove beneficial in elective situations. Normal renal function should be ensured with the appropriate blood work, and abnormal results should prompt further investigation. Because unaddressed severe carotid disease is a risk factor for stroke during ascending aortic operations, patients over the age of 65 should have duplex imaging of their carotids.<sup>111</sup> Younger patients with peripheral vascular disease, extensive coronary artery disease, carotid bruits, or history suspicious for cerebral ischemia should be investigated as well. CT or MRI of the thoracic and abdominal aorta is usually indicated. Coronary angiography should be performed in all patients to evaluate for significant coronary atherosclerosis and lesions with greater than 50 to 60% stenosis should be bypassed. Coronary angiography also helps define the coronary anatomy to identify anomalous or intramural coronary arteries which may complicate root replacement.<sup>112</sup>

## OPERATIVE MANAGEMENT

### Monitoring and Anesthesia

All procedures are performed using central venous access and a pulmonary artery catheter. Location of arterial line for blood pressure monitoring should be discussed with the anesthesia team preoperatively although generally right radial is

preferred. Nasopharyngeal and bladder temperature monitors are used. Bilateral near infrared spectroscopy (NIRS) is employed to provide real-time estimation of cerebral saturation though out the bypass run.<sup>113</sup> Precipitous drops in cerebral saturations are managed with increasing perfusion pressure and hematocrit to the cerebral circulation. In circulatory arrest cases, EEG monitoring is also employed to ensure EEG silence during interruption of cerebral circulation.

TEE plays a critical role in diagnosis, particularly of degree of aortic insufficiency and sinus segment and sinotubular junction anatomy that is not well assessed by CT angiography. It is also critical for hemodynamic management separating from CPB.

Anesthesia management includes fentanyl 25 to 50 µg/kg, midazolam 0.1 to 0.2 mg/kg, isoflurane 0.5 to 1.5%, pancuronium 0.1 to 0.2 mg/kg, and end-tidal concentration in CO<sub>2</sub>. Aminocaproic acid is dosed initially as an intravenous bolus of 5 g, followed by a maintenance intravenous infusion of 1 g/h and stopped within 2 hours of patient admission to the intensive care unit. Pharmacologic adjuncts in circulatory arrest cases include 1 g of methylprednisolone, 1 g of magnesium sulfate, 2.5 mg/kg of lidocaine, and 12.5 g of mannitol.<sup>114</sup>

### Myocardial Protection

Typically, 1 L of cold blood hyperkalemic cardioplegia (4°C) is given antegrade into the aortic root. A left ventricular vent is employed to prevent distension. In cases of severe aortic insufficiency, the aorta is opened and the coronary ostia are cannulated directly with handheld cannula. A temperature probe is placed through the anterior myocardium into the septum and a myocardial temperature of 6 to 8°C is achieved. Retrograde cardioplegia is administered at least every 20 minutes and continuously when possible. It is important to give cardioplegia immediately prior to commencing circulatory arrest and at its conclusion.

### Circulation Management

Cannulation strategies vary significantly with individual pathology and the modern cardiovascular surgeon must be proficient in several different techniques. With experience, ascending aortas as large as 7 cm may be directly cannulated. This can be done with the traditional stab-technique or using a Seldinger technique over a wire in thin-walled aortas. In aneurysms which terminate prior to the innominate artery, the transverse arch is easily directly cannulated. In cases where antegrade cerebral perfusion is required, either the ascending aorta may be cannulated directly if using selective direct perfusion cannulas or the right axillary artery may be employed. Right axillary artery cannulation, which has grown in popularity in recent years, should be performed through an 8 or 10 mm Dacron graft anastomosed end-to-side to the axillary artery as there is risk of dissection from direct cannulation of this friable artery. In some instances, femoral artery cannulation can be employed, but should

be avoided in patients with atheroma in the thoracic aorta by CT scan or TEE. A standard two-stage venous cannula is used unless performing concomitant mitral or tricuspid surgery.

## DEEP HYPOTHERMIC CIRCULATORY ARREST AND CEREBRAL PROTECTION

The use of deep hypothermic circulatory arrest (DHCA) was first described in conjunction with cardiac operations in the 1960s.<sup>115</sup> In the 1970s, there was renewed interest in DHCA after its successful use during repair of complex congenital defects.<sup>116</sup> Later, Greipp and Stinson reported the first case series using DHCA during arch aneurysm repairs and supported its efficacy in cerebral protection.<sup>117</sup> As interest in DHCA continued to grow; investigators, using dog models, illustrated how profound cerebral hypothermia dramatically decreased cerebral metabolism.<sup>118-120</sup> As knowledge of DHCA physiology increased, it promoted the development of new techniques such as antegrade and retrograde cerebral perfusion (RCP) and allowed for more complex aortic aneurysm repairs.

There are two basic mechanisms that lead to ischemic cerebral injury during repair of proximal aortic aneurysms. While the stroke is one of the most common postoperative complications of aortic aneurysm repairs, its risk is not associated with duration of DHCA.<sup>121</sup> Rather, stroke risk is associated with plaque, clot, and the arteromatous burden in the aortic arch and brachiocephalic vessels.<sup>122,123</sup> The second type of brain injury is temporary neurological dysfunction (TND) and is characterized by confusion, agitation, obtundation, and even transient parkinsonism. Studies suggest that TND results from inadequate cerebral protection during DHCA. In 200 adults who underwent DHCA, 19% of patients had clinical symptoms of TND, which correlated significantly with age and the duration of DHCA (33 min in patients without TND and 47 min in those with TND).<sup>122</sup> Furthermore, in patients with advanced age, DHCA duration longer than 25 minutes was an independent risk factor for long-term neurocognitive impairment, specifically for worse performance on fine motor and memory testing.<sup>124</sup> It is posited that due to its high metabolic demand, the hippocampus is acutely sensitive to hypoperfusion, which may be the reason for memory impairment and cognitive dysfunction after DHCA.<sup>125</sup> Nonetheless, while TND does occur in some patients, clinical studies in adults after DHCA have demonstrated that a safe period of arrest is about 30 minutes at 15°C and 40 minutes at 10°C, after which cerebral anoxia occurs.<sup>126</sup>

### Cooling and Rewarming During Deep Hypothermic Circulatory Arrest

Data from Cheung et al have shown that only 60% of subjects undergoing DHCA achieve EEG silence at a core temperature of 18°C or a cooling time of 30 minutes.<sup>127</sup> In cases where EEG monitoring is not available, a safer technique is to cool for a minimum of 50 minutes, at which point 100%

of patients will have EEG silence.<sup>128</sup> Cooling is performed maintaining less than a 2 to 3°C gradient between arterial inflow temperature and venous return temperature to ensure even cooling. Nasopharyngeal temperature and bladder temperature which correlate with intracranial temperature and core body temperature, respectively, are also monitored during cooling to guide initiation of arrest.

During rewarming, the bladder, nasopharyngeal, and the systemic perfusion temperatures are monitored. The perfusion is kept at a gradient of not more than 10°C above the nasopharyngeal temperature. This ensures that oxygen demand will not exceed oxygen supply during the interval of cerebral vasoconstriction after DHCA.<sup>129-131</sup> Avoiding high perfusate temperatures is important and should not exceed 37°C. The bladder temperature which is raised from 32 to 34°C represents the core body temperature and will lag considerably behind the nasopharyngeal temperature. Monitoring bladder temperature helps to ensure uniform rewarming and minimize rebound hypothermia after CPB.

### Cerebral Protection Techniques: Historical Perspective

In the 1980s, mounting evidence suggested that DHCA alone was neither efficacious nor safe for the long durations of cross-clamp time and arrest required for repairing extensive, complex proximal aortic aneurysms. This necessitated the need to develop novel techniques. While first reported in 1957 by Debakey during his early aortic arch aneurysm repairs, selective antegrade cerebral perfusion (ACP) was used. The setup involved multiple pumps and bilateral cannulation of the subclavian and carotid arteries. However, this ACP technique had difficulty in uniformly perfusing separate vascular beds simultaneously,<sup>65</sup> and resulted in high mortality rates and was quickly abandoned. It was later recognized that using ACP in combination with DHCA improved outcomes compared to DHCA alone.<sup>132,133</sup> In 1986, Kazui et al described his first approach with selective ACP.<sup>134</sup> His results from 1990 to 1999 showed that 220 patients underwent total arch replacement with ACP and DHCA with 12.7% in-hospital mortality and 3.3% permanent stroke rate, a significant improvement from only DHCA alone. Later in 2003, Di Eusanio demonstrated efficacy with ACP and DHCA in further reducing both risk of stroke and TND. In a multicenter trial, 580 patients underwent partial and total aortic arch replacement, the risk of permanent stroke and TND was 3.8 and 5.6%, respectively, with an overall mortality of 8.7%.<sup>135</sup> These results were only possible because of the introduction and refinement of the antegrade and retrograde cerebral protection techniques.

### Antegrade Cerebral Perfusion Techniques

Used routinely by many centers, antegrade cerebral perfusion is primarily beneficial over RCP in situations where the expected circulatory arrest time is greater than 35 to 45 minutes.

Common strategies include direct cannulation of the cerebral vessels with balloon-tip catheters as described by Kazui or by right axillary cannulation.<sup>136</sup> When performing direct arch vessel cannulation it is advisable to use balloon tip catheters which have individual pressure-monitoring lines so the true perfusion pressures can be monitored to avoid cerebral hypertension. Right radial artery monitoring may also be helpful. Perfusion is typically performed at 10 cc/kg/min and mean pressures are maintained at 40 to 70 mm Hg. Perfusate temperature should approximate the core temperature. Optimal protection is gained by direct perfusion of all three arch branches, not just the left common carotid and innominate arteries.

Axillary cannulation is performed via cut down to the right axillary artery with a 8 to 10 mm Dacron graft sewn on in an end-side fashion (Fig. 48-18A,B). The graft is ligated

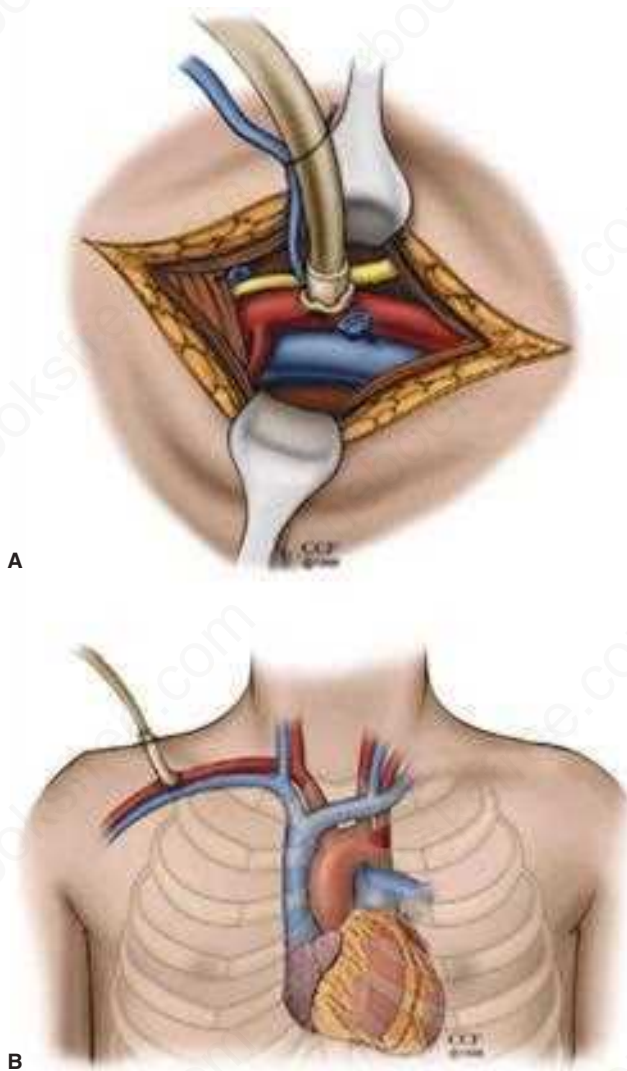

at the end of the procedure. Given the fragility of the axillary artery, few surgeons cannulate it directly. As with direct cerebral vessel perfusion, perfusion pressure is maintained at 10 cc/kg/min and mean pressures are 40 to 70 mm Hg. The innominate artery is either snared or clamped at its origin. While antegrade cerebral perfusion via this method is rapid and effective, it only provides unilateral perfusion and contralateral ischemia may still occur. To maintain adequate cerebral perfusion pressure and eliminate the effect of arterial-arterial collaterals stealing flow, ideally the left common carotid and subclavian artery origins are controlled as well with additional selective cerebral catheters.<sup>137</sup>

### Retrograde Cerebral Perfusion Techniques

RCP is an alternate technique that provides retrograde perfusion to the brain via the venous circulation. While the nutritive flow of RCP is questionable, it provides cooling and excellent de-airing of the cerebral circulation. For RCP, a 24 Fr wire reinforced cannula is placed cephalad to the azygous vein in the SVC and secured with a caval tape. RCP with oxygenated blood is adjusted to maintain a right internal jugular venous pressure of 25 mm Hg, a flow rate of 200 to 300 cc/min, with the patient in an approximately 10-degree Trendelenburg position.<sup>127</sup> Minimal exsanguination into the pump is performed upon cessation of bypass to facilitate later deairing. RCP may be initiated via a Y-connection to the arterial line or from the cardioplegia system through a high pressure stopcock that can connect to the Y-connection between the SVC and right atrial cannulas. RCP may be interrupted for variable periods of time during deep hypothermia as required by various surgical maneuvers. The temperature of the retrograde perfusate is maintained at 12 to 18°C. After completion of aortic arch anastomoses, air is removed from the aorta and graft by allowing it to fill by RCP. After arch deairing, a cross-clamp is placed across the ascending aortic graft, and standard CPB with antegrade cerebral perfusion, that is, antegrade graft perfusion, is reinstated for the final repair and rewarming. Our practice is to always reestablish antegrade flow via direct cannulation of the ascending graft using either a prefabricated 8 or 10 mm sidearm or by placing a purse-string suture in the graft and directly cannulating it.

### An Algorithmic Approach to Decision-Making for Proximal Aortic Aneurysms

Choice of procedure when managing ascending or arch aortic aneurysms is predicated on a detailed understanding of individual patient anatomy and pathophysiology. The potential operative decisions include whether to replace the aortic valve, aortic sinuses, ascending aorta, or aortic arch. Any combination of these procedures is theoretically possible. A systematic approach to evaluate the aorta and aortic root begins with determining if there is a suspicion for connective tissue disorder. Patients with MFS, Ehlers-Danlos syndrome, LDS, bicuspid valve-related aortopathy, or strong family history of

**FIGURE 48-18** (A) Direct cannulation of axillary artery with right-angle arterial cannula (note division of crossing vein). (B) Cannulation of axillary artery with a side graft. A straight arterial cannula is inserted into graft. (Reprinted with permission, Cleveland Clinic Center for Medical Art & Photography ©2016. All rights reserved.)

aortic dissection or rupture should generally be treated more aggressively by replacing the sinus segment, ascending aorta, and proximal arch as late reintervention is more likely in this group.<sup>138</sup> Proximal reconstruction in these patients may be accomplished by either root replacement or a valve-sparing root reimplantation procedure.<sup>139</sup>

The next step is to determine the pathology of the aortic valve. Moderate or worse aortic stenosis with or without insufficiency generally requires replacement while the management of pure aortic insufficiency is more complex. Aortic insufficiency caused solely by dilatation of the sinotubular junction, typically from an atherosclerotic aneurysm in an elderly patient, may be full addressed with tube graft replacement of the ascending aorta alone with anastomosis to the sinotubular junction (Fig. 48-19). Care must be taken in this instance to appropriately size the graft to within 10% of the annular dimension to allow full coaptation of the aortic valve leaflets.<sup>140</sup> The sinus segment must also be closely interrogated. If it is particularly thin or aneurysmal this should be replaced. Normal dimensions of the sinus of Valsalva are typically 30 to 32 mm when the aortic annulus measures 23 to 24 mm and the sinotubular junction measures 24 to 25 mm.<sup>141</sup> If there are aneurysmal sinuses and annular dilatation, that is, aortoannular ectasia, but the leaflets appear fairly normal, then a valve-sparing aortic valve reimplantation is often feasible (Fig. 48-20). Technical details of this procedure are discussed in a previous chapter. If the annulus

**FIGURE 48-19** Replacement of the ascending aorta and transverse arch with an aggressive hemiarch anastomosis.

**FIGURE 48-20** Valve-sparing aortic root reimplantation using a Dacron graft with a premade Sinus of Valsalva segment.

or sinus are dilated and the leaflets are abnormal and not repairable, root replacement is performed. Prosthesis options include prefashioned composite mechanical root prostheses, sewing a stented tissue valve to a conduit, or using a porcine biroot. Prosthesis selection is based on several competing factors including the elevated hazard for structural deterioration of biologic prostheses in younger patients, anticoagulant-related complications with mechanical prostheses, complexity and difficulty of performing future redo root replacements for bioprosthetic failure, and the growing trend toward the avoidance of warfarin in younger patients. The innovation of transcatheter valves, which have the potential to extend the life of a biologic root prosthesis without repeat sternotomy, has generated interest in using these prostheses in younger patients.<sup>142</sup> Pulmonary autografts may also be used as root replacements, but their practicality in aneurysm patients is somewhat limited as degenerative aneurysms tend to occur in older patients who would not benefit from the durability of the pulmonary autograft. Younger aneurysm patients, who could potentially benefit, frequently have bicuspid pathology or connective tissue disorders that may lead to early valve failure. Bicuspid patients have been shown to have significant histologic arterial wall derangements including the cystic medial necrosis, elastic fragmentation, and changes in the smooth muscle cell orientation in the autograft root.<sup>143</sup>

In patients where there is an isolated dilatation of the noncoronary sinus in degenerative aneurysms with preserved sinus dimensions in the coronary sinuses, the noncoronary

sinus may be individually excised and a “tongue” of the ascending aortic graft is used to reconstruct this sinus with the rest of the graft anastomosed above the native annulus, that is, a Yacoub-type remodeling procedure isolated to the noncoronary sinus.<sup>144</sup> Such a procedure carries the risk of late dilatation or suture-line disruption as the remaining aortic tissue is often thin and weak. It is also possible to perform an isolated noncoronary sinus reimplantation as described by David and Feindel.<sup>145</sup> Unless operative risk is prohibitive, it is preferential to perform a full root replacement or reimplantation in such patients rather than treat only one sinus.

In cases where the aortic valve needs to be replaced due to leaflet pathology, the sinus segment is not aneurysmal and there is an ascending aneurysm, a modified Wheat procedure with replacement of the aortic valve and placement of a tube graft to the sinotubular junction is used (Fig. 48-21).<sup>15</sup> This approach is especially useful in elderly patients who have mild-to-moderate sinus segment dilatation but a root replacement carries significant extra perioperative risk and the likelihood of future proximal reoperation is negligible.

Distal repair may be done as either a total arch, hemi-arch, open distal, or clamped distal anastomosis. Aneurysmal extension into the proximal aortic arch is a common variant and is well treated with an aggressive hemi-arch. Resection of the ascending aorta to the innominate artery on the greater curve and to the level of the subclavian take-off on the lesser curve provides excellent protection from future aneurysmal

degeneration of the arch (Fig. 48-21). While clamped techniques for the distal arch are suitable for isolated root pathologies such as complex endocarditis repair, in aneurysm cases it is preferable to excise the cross-clamped portion of aorta and perform an open distal anastomosis.

Total arch replacement with or without elephant trunk (ET) extension is typically reserved for patients with full arch aneurysms extending into the descending thoracic aorta or mega-aorta syndrome. The key decision point when determining the aggressiveness of the arch operation is to determine whether the open proximal operation will completely treat the pathology or if further intervention of the distal arch/descending aorta is required. If open intervention of the distal aorta is anticipated, creation of an ET anastomosis will prevent the need for circulatory arrest in the second stage. If thoracic endovascular aortic repair (TEVAR) is anticipated, creation of a 3 to 4 cm Dacron landing zone for TEVAR placement by forward mobilization of the cerebral vessels is a simpler approach than ET and avoids the difficulty of cannulating the free-floating ET for TEVAR. These approaches as well as debranching and hybrid approaches are described later in this chapter.

### ASCENDING AORTIC REPLACEMENT: SPECIFIC OPERATIVE TECHNIQUES

After the aortic cross-clamp is applied and cardioplegic arrest is achieved as described above, the ascending aorta is transected about 1 cm below the clamp and resected to the level of the sinotubular junction. The aorta is carefully freed from the pulmonary artery using low-energy electrocautery. Using a metric sizer, the diameter of the sinotubular junction that provides adequate leaflet coaptation is determined and this should be within 10% of the annular diameter. The aortic valve is inspected to ensure that it is trileaflet and free from significant calcification or leaflet pathology. If the aortic valve is to be replaced, this is performed at this point using standard techniques. An appropriate size graft is then anastomosed to the sinotubular junction using a running 4-0 polypropylene. The external aspect may be reinforced with Teflon felt if the aorta appears especially thin and a root replacement is not feasible. In cases of acute dissection individual pledgeted sutures are placed at upper aspects of the commissures to resuspend the aortic valve and Teflon felt is placed inside between the dissected layers to form a robust neomedia that can hold sutures.

### Composite Root Replacement

Aortic root replacement involves excision of the entire ascending aorta to the native valve annulus with mobilization of coronary buttons and placement of a composite valve and polyester graft conduit into the annulus. After cross-clamping and administration of cardioplegia, the ascending aorta is resected to the level of the sinotubular junction. The sinuses are mobilized off of the pulmonary arteries and

**FIGURE 48-21** Separate ascending aortic replacement and aortic valve replacement with retention of the native sinus segment.

right ventricle and the coronary buttons are mobilized as described below. Unless a root reimplantation procedure is being performed, excessive proximal mobilization of the root is unnecessary.

The aortic valve leaflets are excised. The annular dimension is sized and an appropriately sized prosthesis is selected. Mechanical composite prostheses come prefabricated with either a polyester straight tube graft or artificial neo-sinuses created by changing the orientation of the polyester in the sinus segment. If a tissue valve is desired, a polyester graft that is either straight or has neo-sinuses is anastomosed with a running 3-0 or 4-0 polypropylene suture to an appropriately sized stented tissue valve. If using a Dacron graft with neo-sinuses, this should be sewn 3 to 4 mm below the start of the neo-sinus segment. The valve sutures must pass through both the valve sewing ring and the Dacron graft to ensure hemostasis.

The composite prosthesis may be placed with either pledgetted everting (ie, "intraannular") mattress sutures with pledgets on the outside of the annulus or in a "supraannular" configuration with pledgets on the ventricular side of the annulus. Typically, the everting technique is used as it is hemostatic and strong. Implanting the root with pledgets on the ventricular side requires less mobilization of the sinuses which may be advantageous in certain situations and may allow for a slightly larger prosthesis. When implanting a mechanical prosthesis, the everting technique is preferred as it is less prone to pannus formation which may interfere with valve function. Care must be taken with either technique to not shorten the mitral valve anterior leaflet with excessively large bites with the annular sutures along the left and noncoronary sinuses. Polyester, braided 2-0 sutures with a larger needle than used for aortic valve replacement are employed.

Once the valve-conduit is tied down, the coronary buttons are anastomosed using 5-0 prolene sutures as described below (Fig. 48-22). Pressurization of the new root by inserting a catheter into the proximal graft, running cardioplegia, and clamping the graft distally after de-airing the neoroot allows assessment of all suture lines.

Implantation of stentless biroot, homograft roots, pulmonary autografts, and valve-sparing procedures is discussed in previous chapters.

## Management of Coronary Arteries

Mobilization of the coronary artery buttons in root operations remains the most technically demanding and least forgiving aspect of root operations. The left main button is mobilized after the aorta has been fully dissected from the pulmonary artery. It is frequently useful to work from the inside of the aorta outward, gently scoring the dissection plane with low intensity electrocautery. Generally, 1 to 2 cm of freedom of motion in all directions is required for adequate mobilization. Care must be taken mobilizing the right coronary artery to ensure the right ventricle is not inadvertently entered. Application of retrograde and direct

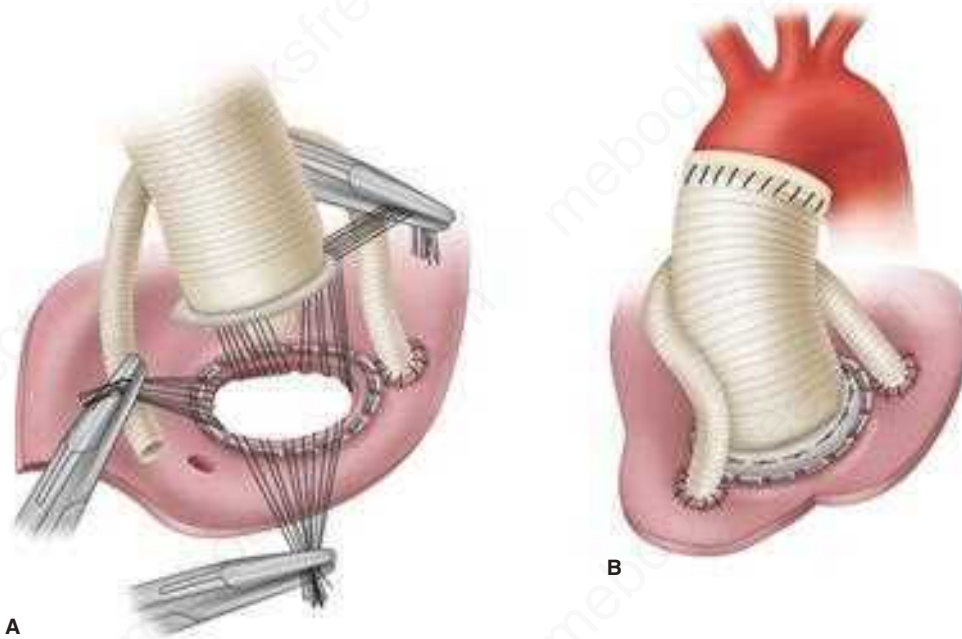

**FIGURE 48-22** Composite root replacement with a mechanical prosthesis.

antegrade cardioplegia into the coronaries after mobilization will identify any small branch disruptions or major injuries while they are still repairable.

When anastomosing the left coronary button to the aortic graft, if a graft with pre-made sinuses of Valsalva is used, the button is typically sewn at or below the level of the equator of the sinus segment. The right coronary, which is more likely to kink as the right ventricle pushes it cephalad once the heart fills, is sewn at or above the level of the equator. When using a straight graft, some surgeons will determine the final position of the right coronary button after completing the graft-to-graft anastomosis, filling the heart, and briefly removing the cross-clamp. When separating from bypass, if there are new gross wall motion abnormalities, coronary artery injury or kinking should be immediately suspected. Our preference in these situations is to immediately bypass the affected territory rather than attempt to salvage a friable coronary button. For a right-sided problem, a bypass graft to the right coronary artery will typically resolve the problem expediently.

In complex endocarditis, dissection, severe calcification, or reoperative cases, coronary artery buttons may be too damaged or immobile to directly attach to the graft. In such situations, a Cabrol-type coronary anastomosis, where the coronary ostia are anastomosed to an 8 to 10 mm Dacron grafts in a "moustache" configuration may be employed (Fig. 48-23). Alternatively, segments of reversed saphenous vein can be used as interposition grafts. Typically these grafts are 3 to 5 cm in length, are anastomosed fairly high on the

**FIGURE 48-23** Classic Cabrol technique for coronary reimplantation. (A) An 8- to 10-mm Dacron tube graft is anastomosed end-to-end to the aortic tissue surrounding the left and right coronary ostia. (B) An opening is made in the mid-portion of the coronary graft and an anastomosis is formed. The modified Cabrol technique involves the formation of individual coronary buttons allowing the small-caliber Dacron graft to be sewn to the full thickness of the aortic tissue surrounding the coronary ostia. (Reproduced with permission from Edmunds LH: *Cardiac Surgery in the Adult*. New York: McGraw-Hill; 1997.)

aortic graft, and follow a gentle s-shaped curve to prevent kinking. In cases of right coronary button problems, proximal ligation and bypass to the main right coronary artery is another alternative.

### Distal Anastomosis

Distal reconstruction is performed as a clamped or open anastomosis. In aneurysm cases, open distal techniques which eliminate all diseased aorta and the weakened cross-clamp site are routinely employed. Circulatory arrest techniques as previously described are employed. Distal anastomoses are performed with a beveled polyester graft using a running 4-0 polypropylene suture. The distal anastomosis is performed as an “on-lay” type anastomosis with the graft invaginated into the distal aorta. This pushes the graft material into the native aorta when the aorta is pressurized and prevents leaks. In cases of extremely friable aorta, Teflon felt placed along the outer aspect may also be beneficial but does not substitute for a proper “on-lay” technique.

### ENDOVASCULAR APPROACHES FOR THE ASCENDING AORTA

Advances in the design of highly flexible and low profile thoracic aortic stent grafts have generated an interest in using these devices for the ascending aorta in patients who are otherwise not reasonable risk surgical candidates. Key design requirements for ascending aortic stent grafts include a high

degree of flexibility and conformability, short graft lengths, no exposed bare metal, and long delivery systems as most TEVAR delivery systems will not reach the proximal ascending aorta from the femoral artery. Alternative approaches for access sites for the stent graft include axillary artery, carotid artery, and perhaps most promising, transapical. Graft lengths are more critical in the ascending aorta than in the thoracic aorta as the distance between sinotubular junction and/or coronary ostia and the take-off of the innominate artery is typically shorter than 10 cm, and is therefore shorter than most thoracic devices. The antegrade transapical technique may also offer potential advantage by limiting the distance between the sheath and the device thereby minimizing potential for device migration during deployment, as is seen in transapical deployment of transcatheter aortic valves. Stent graft placement has been described to treat focal ascending aneurysms in nonoperative candidates (Fig. 48-24).<sup>146,147</sup>

### AORTIC ARCH REPLACEMENT: SPECIFIC OPERATIVE TECHNIQUES

There has been a diversity of surgical approaches across institutions on how best to repair aortic arch aneurysms. Originally reported in 1960s, the first arch aneurysm repair was completed by using an “island technique” and anastomosing the supra-aortic vessels to the aortic graft. It was not until the twenty-first century that novel approaches were developed that limited cerebral ischemia and the duration of CPB

**FIGURE 48-24** Placement of a covered stent graft in the ascending aorta to treat a pseudoaneurysm after previous cardiac surgery. Preoperative CT angiogram (A) demonstrates a saccular pseudoaneurysm in the ascending aorta after previous coronary artery bypass graft. Postoperative CT angiogram (B) demonstrates exclusion of pseudoaneurysm with no evidence of endoleak. (Reproduced with permission from Szeto WY, Moser WG, Desai ND, et al: Transapical deployment of endovascular thoracic aortic stent graft for an ascending aortic pseudoaneurysm, *Ann Thorac Surg* 2010; 89(2):616-618.)

time. In 2000, Kazui et al developed an integrated branched arch graft that contained three fixed limbs for anastomosing the great vessels and a side arterial cannulation limb for CPB.<sup>134</sup> In 2002, Speilvogel et al described the technique of debranching the great vessels from the arch and anastomosing them to a trifurcated graft that could then be sewed to the main aortic graft.<sup>148</sup> These techniques improved patient outcomes by decreasing the duration of DHCA, improving cerebral protection, and excluding the diseased aorta from the anastomosis, as was necessary with the island technique. More recently, with the advancements in endovascular device technology, hybrid approaches are available that combine debranching procedures and stent grafts in a single-staged repair. These hybrid approaches have even further reduced CPB and DHCA time.

## OPEN TECHNIQUES

### Branched Arch Grafts (Kazui Technique)

The branched aortic arch graft is prefabricated graft with 3 branches for the great vessels and an additional side branch for systemic perfusion.<sup>134</sup> This technique (Fig. 48-25A-H) begins with systemic cooling and initiation of DHCA. The aortic arch is opened and the brachiocephalic vessels are transected distal to their origins and selective ACP catheters are inserted into the innominate and left common carotid arteries, while the left subclavian artery is clamped (Fig. 48-25B). Then the distal anastomosis of the graft is first performed on the descending aorta (Fig. 48-25C). After this is completed, antegrade systemic circulation is started from the side branch of the graft (Fig. 48-25D). Next, the left subclavian artery is reimplemented to the graft and perfused (Fig. 48-25E). The proximal anastomosis is then finished (Fig. 48-25F), and attention is turned toward the anastomosis of the left carotid and left innominate arteries to the branched graft (Fig. 48-25G,H).

The aorta is de-aired, cross-clamp is released, and the side branch for CPB is ligated.

Since clot and atheroma in the aorta develop more often at the origin of the brachiocephalic vessels, manipulation of these arteries increases the risk of stroke after aortic arch repair. One benefit of this technique is that brachiocephalic vessels are transected distal to their origins before the resection of the aortic arch, preventing embolization and decreasing stroke risk. Depending on the extent of aneurysmal disease, this operation can be completed in one or two stages. For concomitant descending thoracic aneurysmal disease, an ET graft can be completed during the arch replacement as an easy setup for the second stage, which could include an endovascular option or smaller left thoracotomy approach. However, one limitation of this technique is that the cerebral branches of the graft are short and fixed to the graft. This decreases options to tailor the graft based on the patient's exact anatomy.

### Debranching Graft Techniques

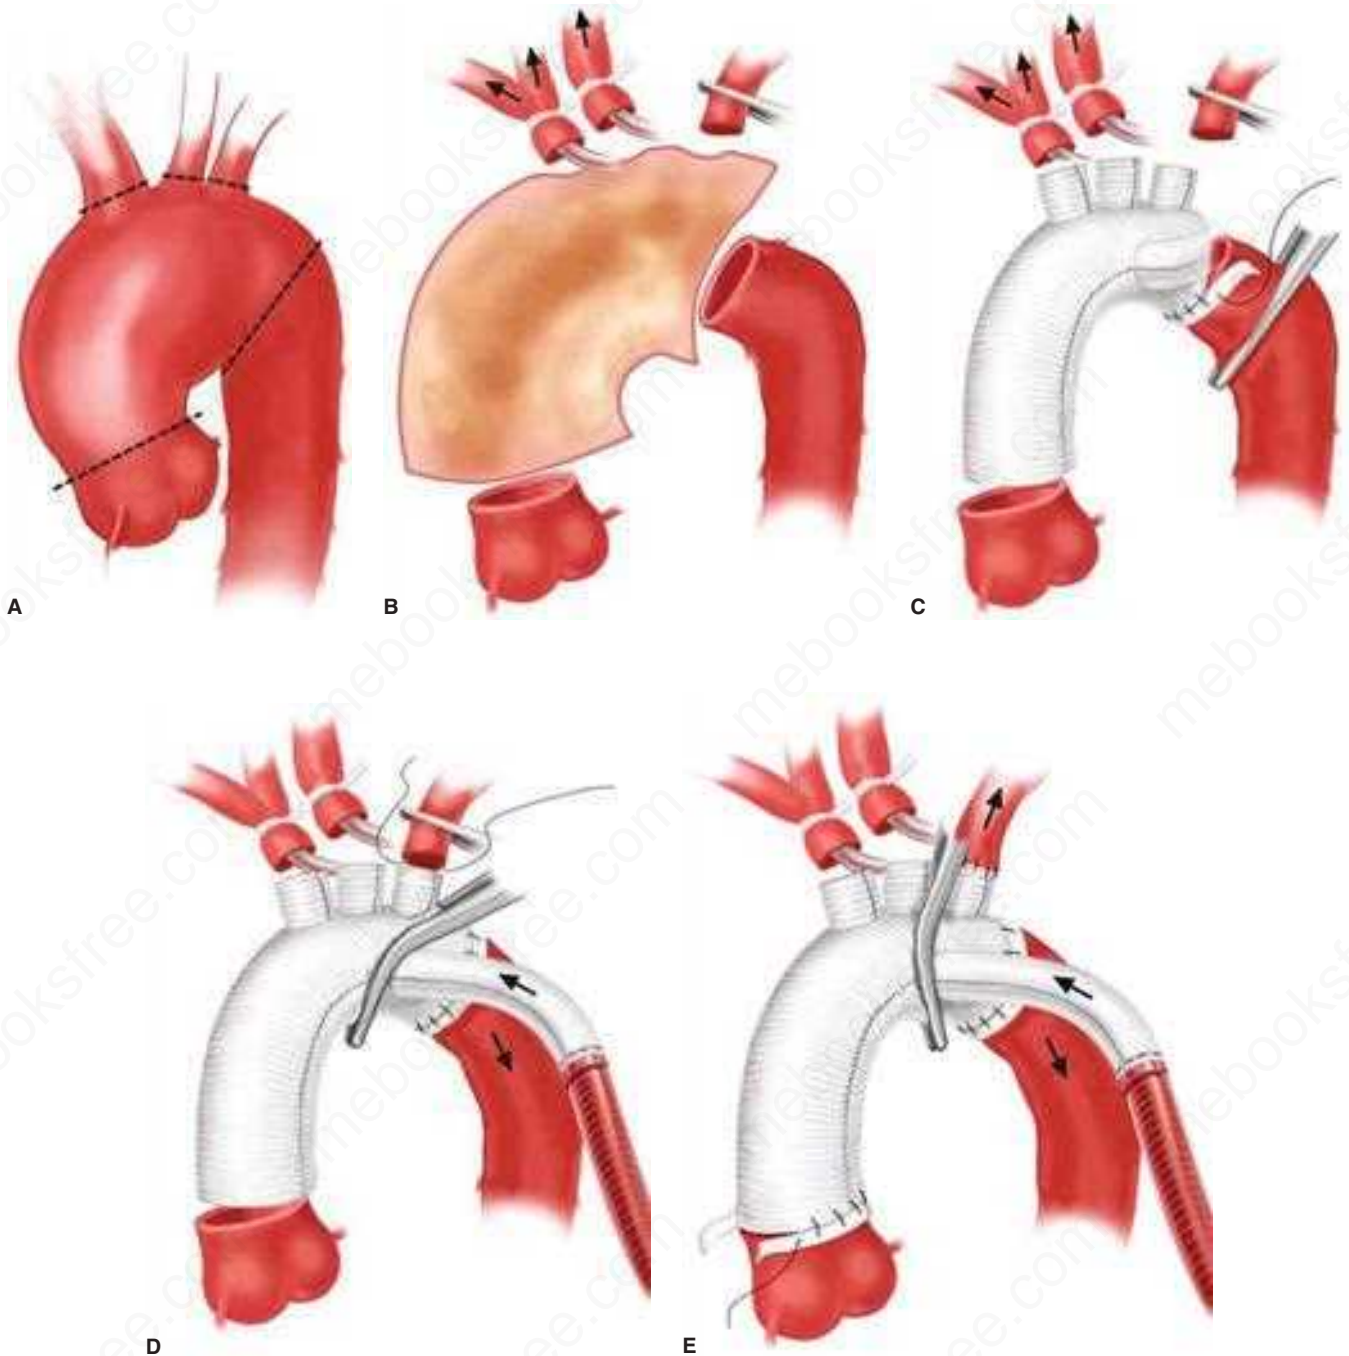

Several types of debranching grafts are available on the market to repair aortic arch aneurysms. One of the first grafts used was a double-Y or trifurcated graft that could be anastomosed to the main aortic body graft during the operation (Fig. 48-26). However, other grafts currently available have the branched limbs pre-anastomosed to the aortic graft. While stylistically different, the generalized debranching concepts presented are similar.

In the debranching approach, the aorta is cross-clamped proximal to the innominate artery and CPB is initiated via the axillary artery. While the patient is being cooled to core hypothermia, the proximal aorta is opened and a multibranch limb graft or tube graft is anastomosed to the sinotubular junction. If aortic valve and/or root pathology is present, surgical repair can be completed while the patient is cooled.

Once hypothermia is reached, ACP is initiated via axillary artery cannulation. Attention is then turned toward the distal aortic arch and the main body of the graft is anastomosed to healthy, nonaneurysmal aorta. At this point, the distal clamp is removed and CPB is reinitiated either down the side limb of the graft or via direct cannulation of the aortic body graft. ACP is continued via axillary cannulation and selective perfusion catheters may be used for bilateral ACP until the left subclavian, left carotid, and innominate arteries are each

anastomosed to the three graft limbs, respectively. After debranching is completed, the proximal aortic reconstruction is de-aired and the patient is decannulated from CPB.

In case of a laterally displaced left subclavian artery from the aortic aneurysm, a left subclavian to carotid artery (LSCA) bypass can be completed 2 to 4 days before the debranching procedure. After a LSCA bypass, the debranching procedure only needs to be executed for the innominate artery and left carotid artery (Fig. 48-27).

**FIGURE 48-25** (A-H). Branched Arch Graft (Kazui) Technique. (Continued)

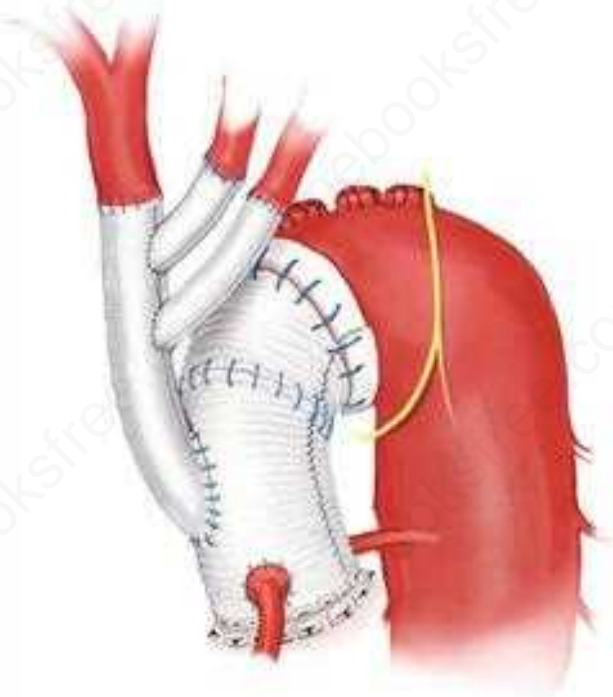

**FIGURE 48-25 (F-H).** Kazui Technique using a four branch graft for total arch replacement.

### Elephant trunk

The elephant trunk (ET) is part of a two staged approach to treat arch aneurysms with extensive pathology distal to the left subclavian artery. First used in the 1980s by Borst et al, the benefit of the ET is it provides a platform for an easier second stage operation to treat distal aortic aneurysms and

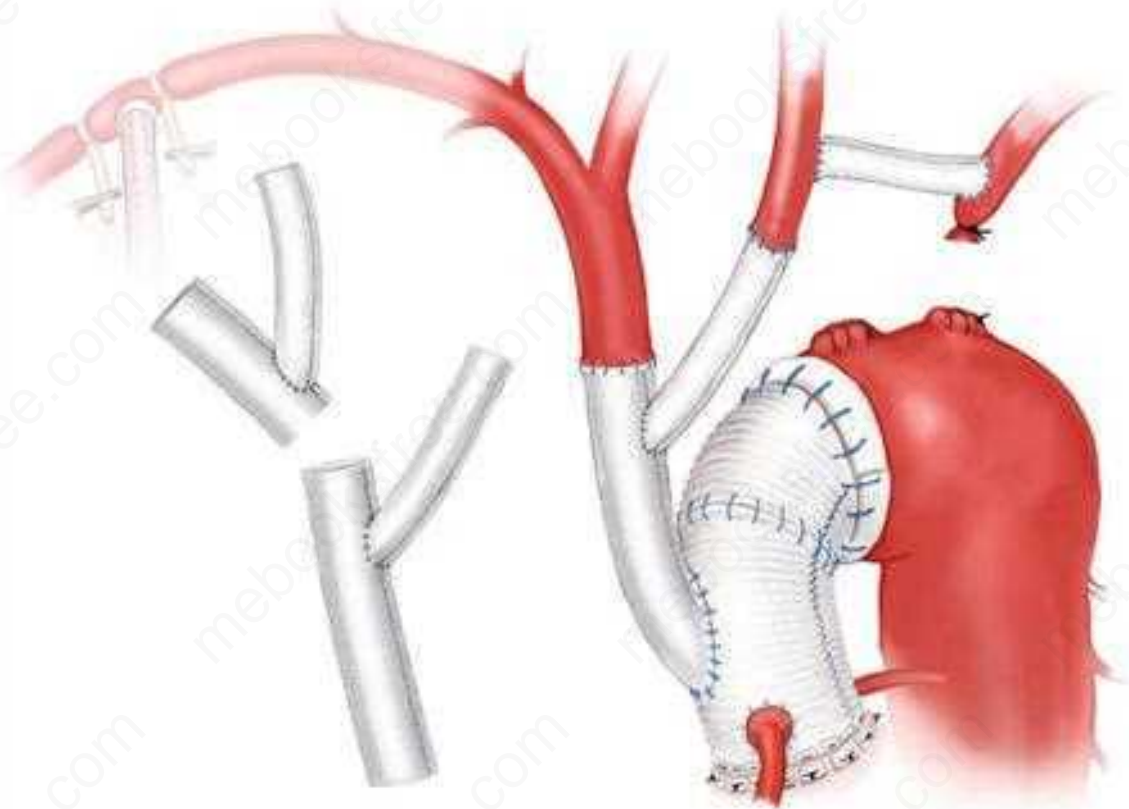

dissections with either an open or an endovascular repair.<sup>149</sup> Open repairs with an ET graft make for technically easier operations with smaller incisions and less cross-clamp time. Furthermore, it creates a proximal landing zone within the diseased distal aorta to place a stent graft.

Figure 48-28A-J illustrates the total arch replacement with a trifurcated graft and ET technique. Similar to as described

**FIGURE 48-26** Trifurcated graft used to debranch the innominate, left carotid, and left subclavian arteries.

above, right axillary cannulation is created to initiate CPB (Fig. 48-28B) and the aorta is cross-clamped proximal to the innominate artery (Fig. 48-28C). Once DHCA is reached the innominate, left carotid, and left subclavian arteries are anastomosed to the trifurcated graft and ACP is initiated from the right axillary artery, restoring perfusion to the brain and upper extremities (Fig. 48-28D,E). Attention is then turned toward the distal aorta. It is important to protect the left recurrent laryngeal nerve, so a suitable cuff of aortic tissue adjacent to the nerve is preserved. Studies demonstrate that the ET technique decreases the risk for laryngeal nerve injury during extensive aortic arch and descending aortic aneurysm repairs.<sup>149,150</sup> Next the proximal end of the ET graft is invaginated in itself and the midportion of the graft is anastomosed to the distal aorta with Teflon felt reinforcement (Fig. 48-28F). The origins of the left carotid and subclavian arteries are then oversewn. The proximal end of the anastomosis is then pulled out of the ET and can be anastomosed to the sinutubular junction, or as in Fig. 48-28G,H, the distal end of the graft from the aortic root repair. If a graft-to-graft anastomosis is required, it is necessary to bevel each graft end to maintain proper curvature (Fig. 48-28G). Next, the trifurcated graft limb remains clamped and is anastomosed to the proximal aspect of the aortic graft (Fig. 48-28E). Once the clamp is removed from the trifurcated limb, full myocardial

**FIGURE 48-27** In case of a laterally displaced left subclavian artery from the aortic aneurysm, a left subclavian artery to carotid artery (LSCA) bypass can be completed.

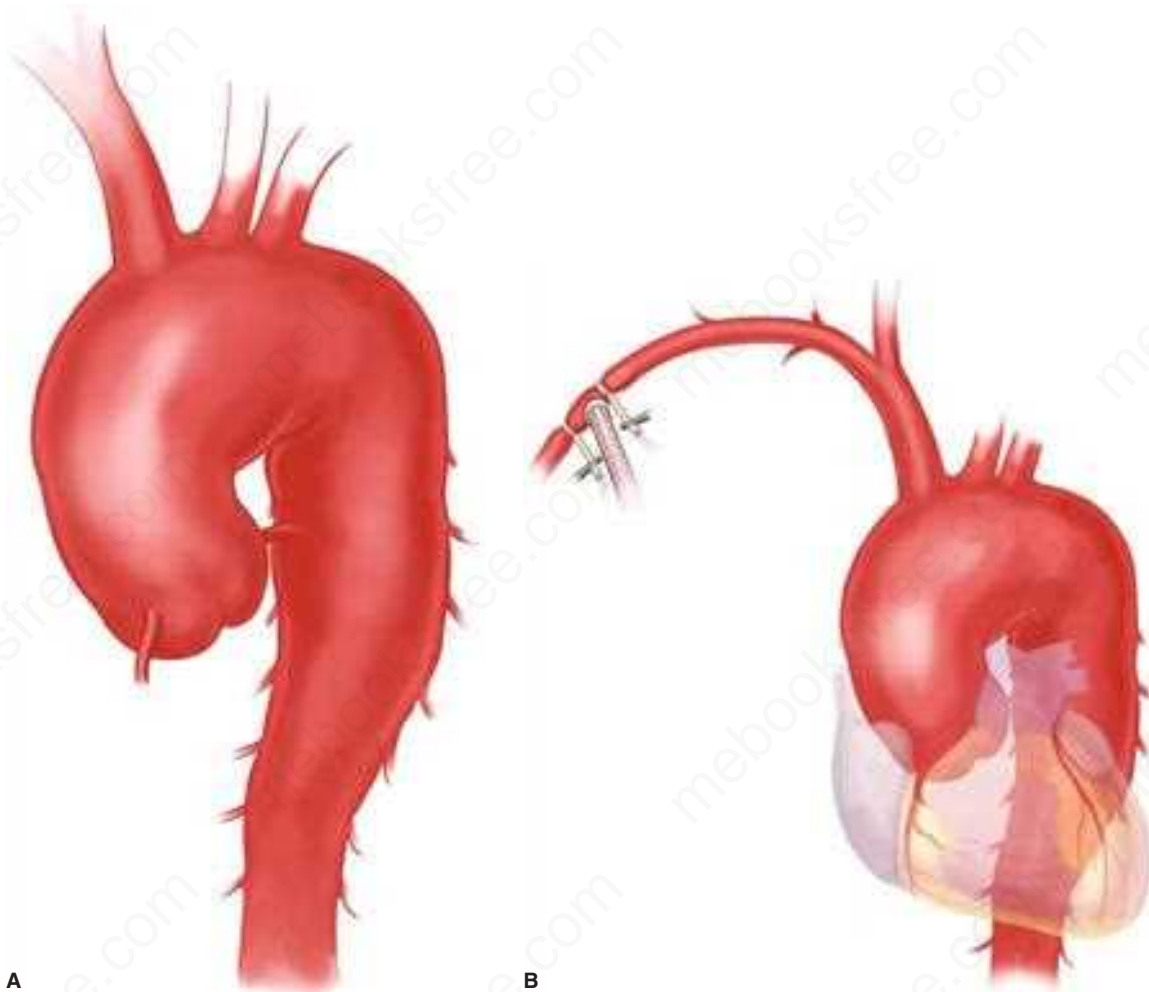

and systemic perfusion is restored (Fig. 48-28J). With the stage 1 repair complete, the patient can then undergo the stage 2 procedure at another time with either an endovascular graft or open repair through a left thoracotomy. Nonetheless, while ET sets up for a convenient, easier stage 2 procedure, it is not without complications and pitfalls. Complications include kinking of the graft, spinal cord ischemia, peripheral thromboembolism, and visceral malperfusion.<sup>151-153</sup>

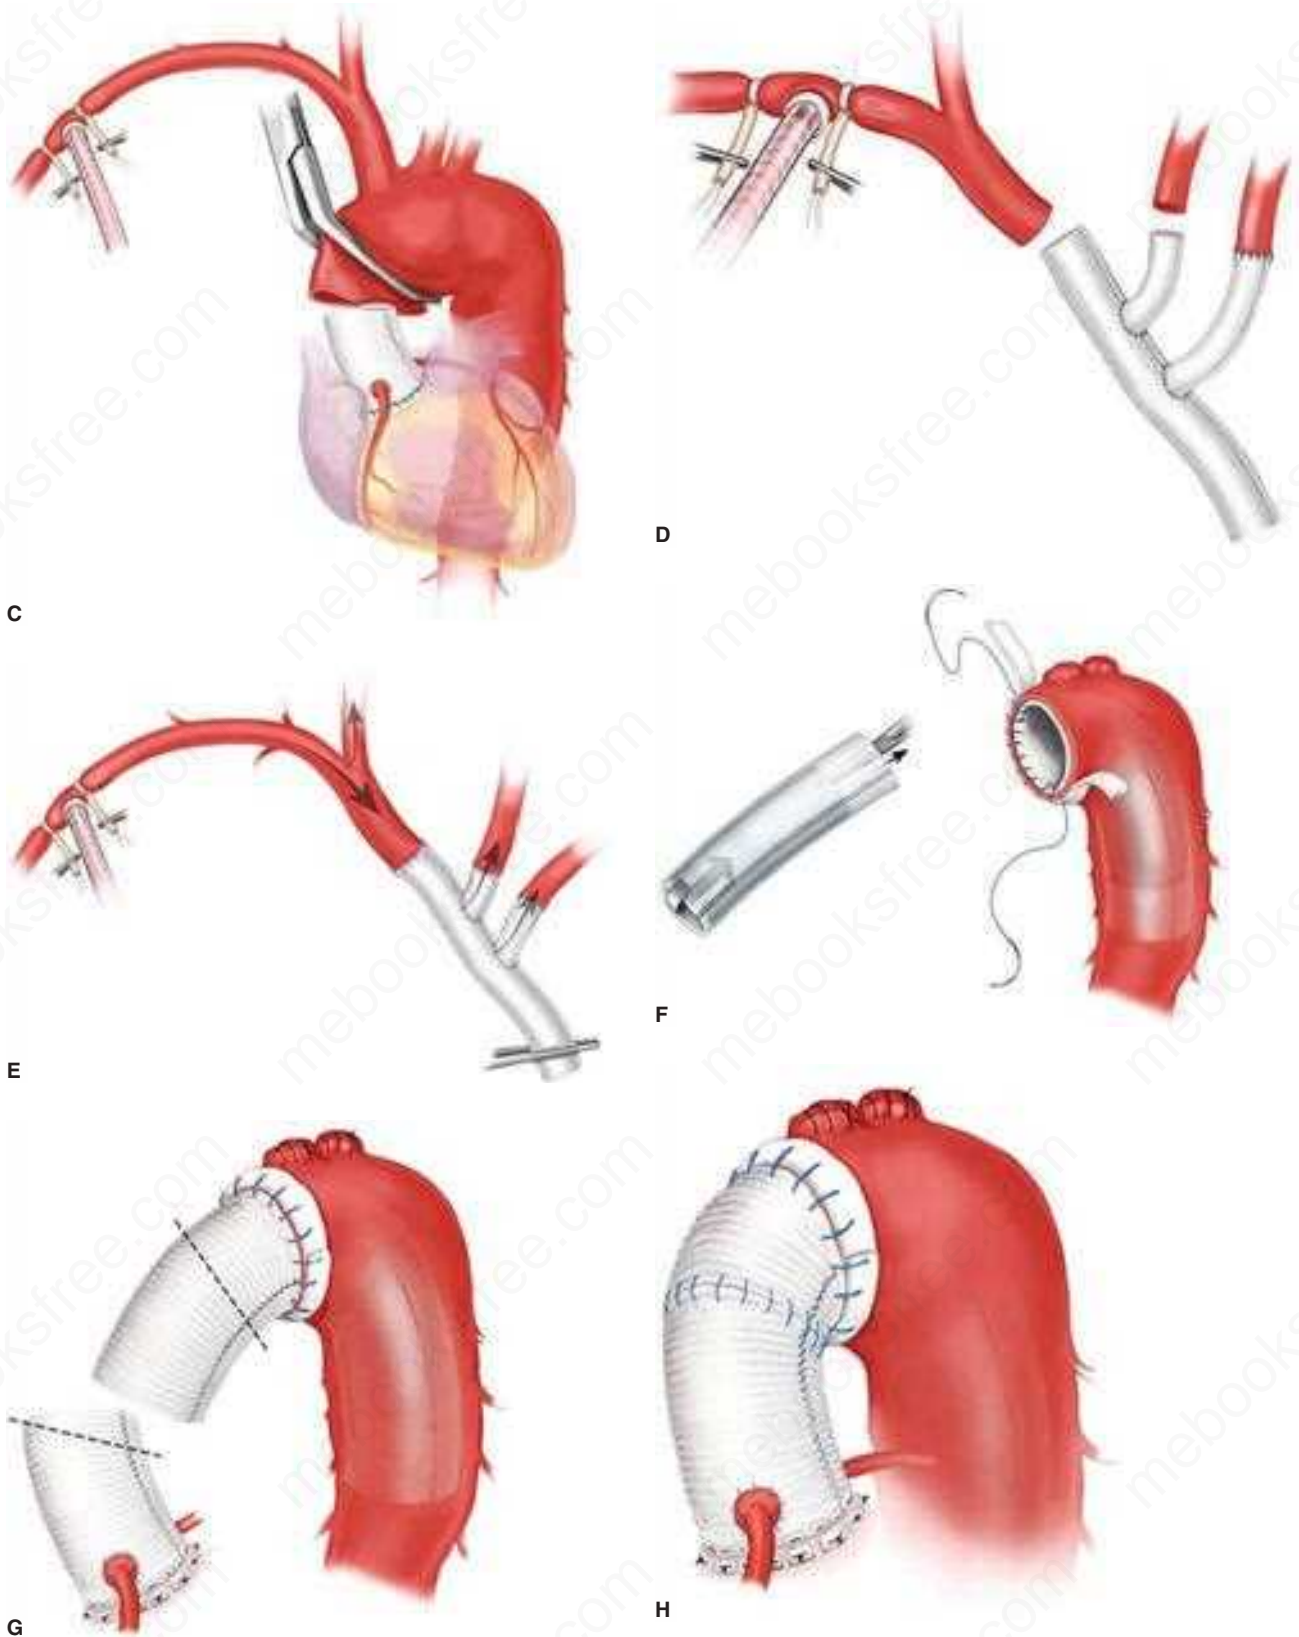

### Arch First Technique

The “arch first” technique was described by Kouchoukos and Rokkas as an additional approach to treat aortic arch and proximal descending aortic aneurysm disease.<sup>154</sup> This single stage repair is performed via bilateral anterior thoracotomies providing excellent exposure of the aortic arch and descending aorta. One significant pitfall to this approach is it requires sacrificing both internal mammary arteries. Figure 48-29A-G illustrates the “arch first” technique. First, the heart and arch are exposed by bilateral thoracotomies in the fourth interspace with a transverse sternotomy. CPB is initiated via right

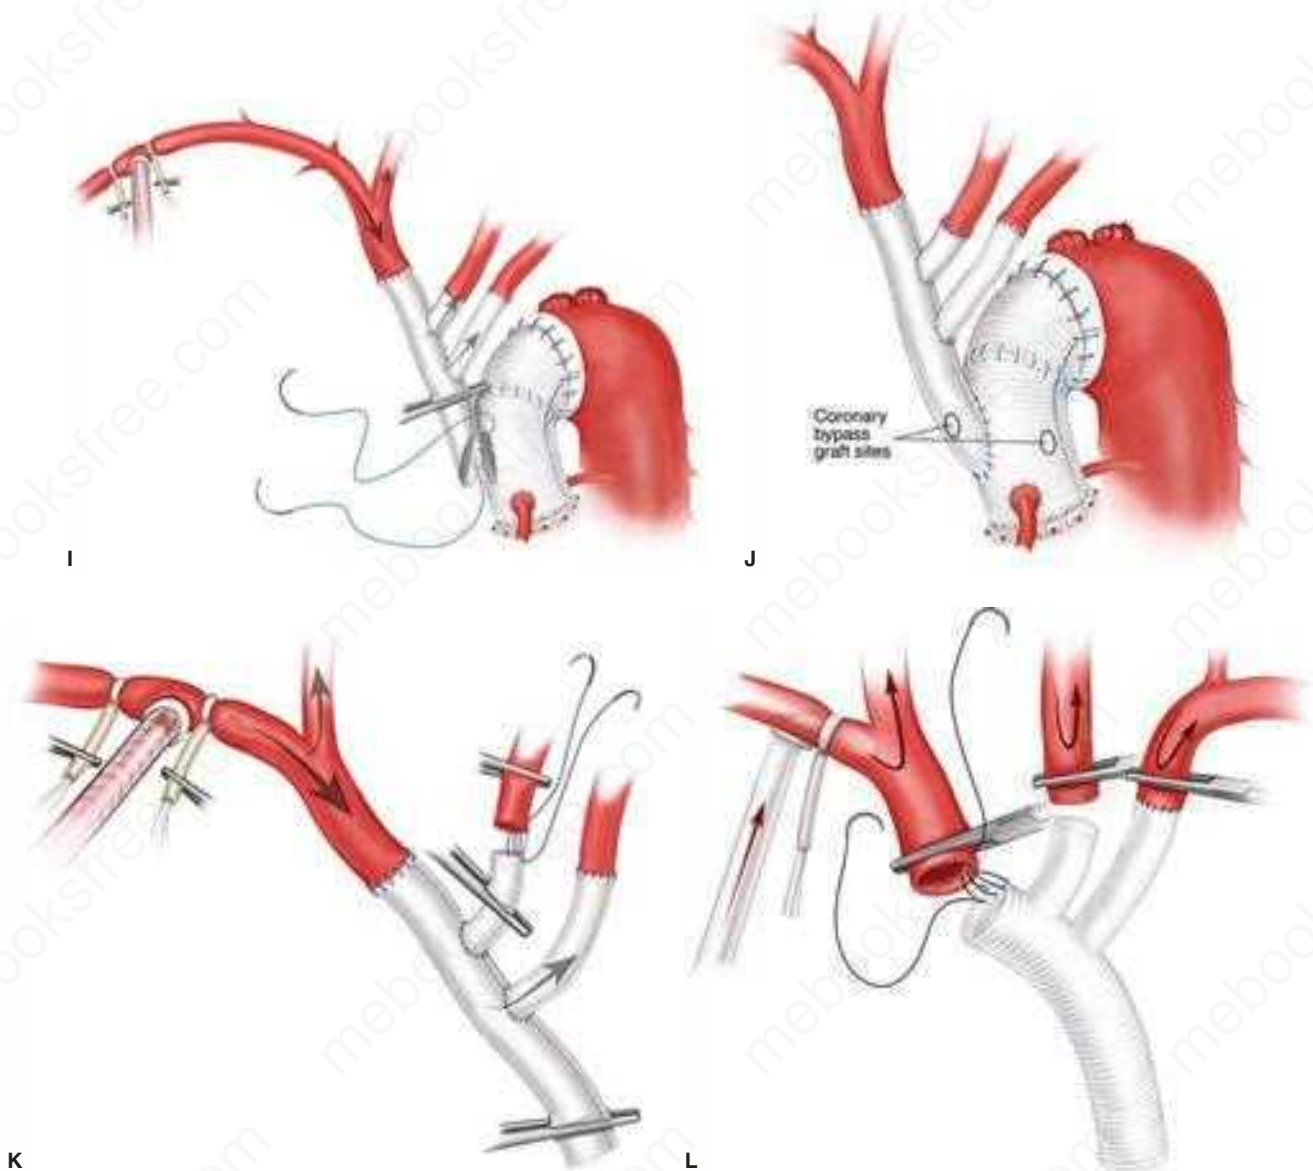

axillary artery cannulation. While the patient is cooled, the great vessels are exposed with great attention to preserve the recurrent and phrenic nerves. The most distal aspect of the descending aortic aneurysm is mobilized. Once the DHCA is initiated, the innominate, left carotid, and left subclavian arteries are transected and clamped. Then both the proximal and the distal aorta are transected (Fig. 48-29B). The distal aorta can be clamped and lower body perfusion can be established via a femoral artery. As described in the Kazui technique, a four-branched graft is used and the great vessels are anastomosed starting with the left subclavian artery and moving proximally (Fig. 48-29C,D). After these anastomoses are completed, the brachiocephalic arteries can be flushed off to remove emboli (Fig. 48-29E). The graft body is then clamped both proximally and distally to reestablish cerebral and upper body perfusion (Fig. 48-29F). Next, the systemic perfusion from the femoral artery is discontinued and the distal anastomosis is completed. Systemic circulation is then started via the sidearm graft. Finally, the proximal aortic anastomosis is finished to complete the repair and clamps are removed (Fig. 48-29G). Kouchoukos et al reported on 46 “arch first”

procedures with a hospital mortality of 6.5%. There were no reports of permanent neurological events but 13% of patients developed clinical signs of TND.<sup>154</sup>

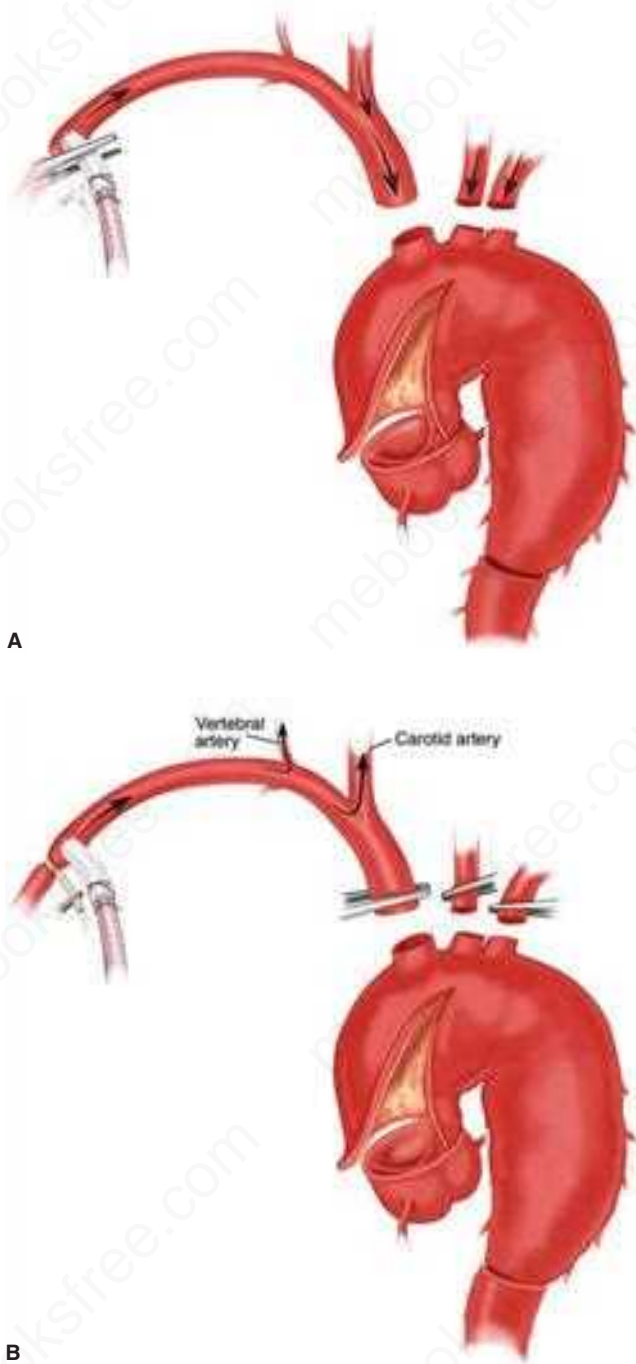

## HYBRID TECHNIQUES

Hybrid arch procedures that combine open cerebral debranching with concomitant antegrade endovascular stent placement have emerged over the previous decade as a novel treatment option for aortic arch aneurysms. The benefit of this technique significantly limits the duration of cross-clamp time and cerebral ischemia and is beneficial in older patients with a high comorbidity indices.<sup>155</sup> The three key concepts to this approach are to (1) debranch the cerebral vessels (2)

reconstruct the ascending aorta to create a landing zone (Zone 0) for an endovascular stent graft, and (3) deploy an antegrade stent graft from Zone 0 to healthy distal aorta to exclude the arch aneurysm.

To grasp these concepts, an appreciation of landing zone classification is crucial. Thoracic aortic landing zones can be divided into five anatomic regions (Fig. 48-30).

- Zone 0: ascending aorta to the innominate artery
- Zone 1: between the innominate and the left carotid artery
- Zone 2: between the left carotid and left subclavian
- Zone 3: beyond the left subclavian and along the curved portion of the distal arch
- Zone 4: straight portion of the distal arch starting at the level of T4

**FIGURE 48-29** (A and B) Arch first technique to repair an aortic arch and proximal descending aortic aneurysm via bilateral thoracotomies.

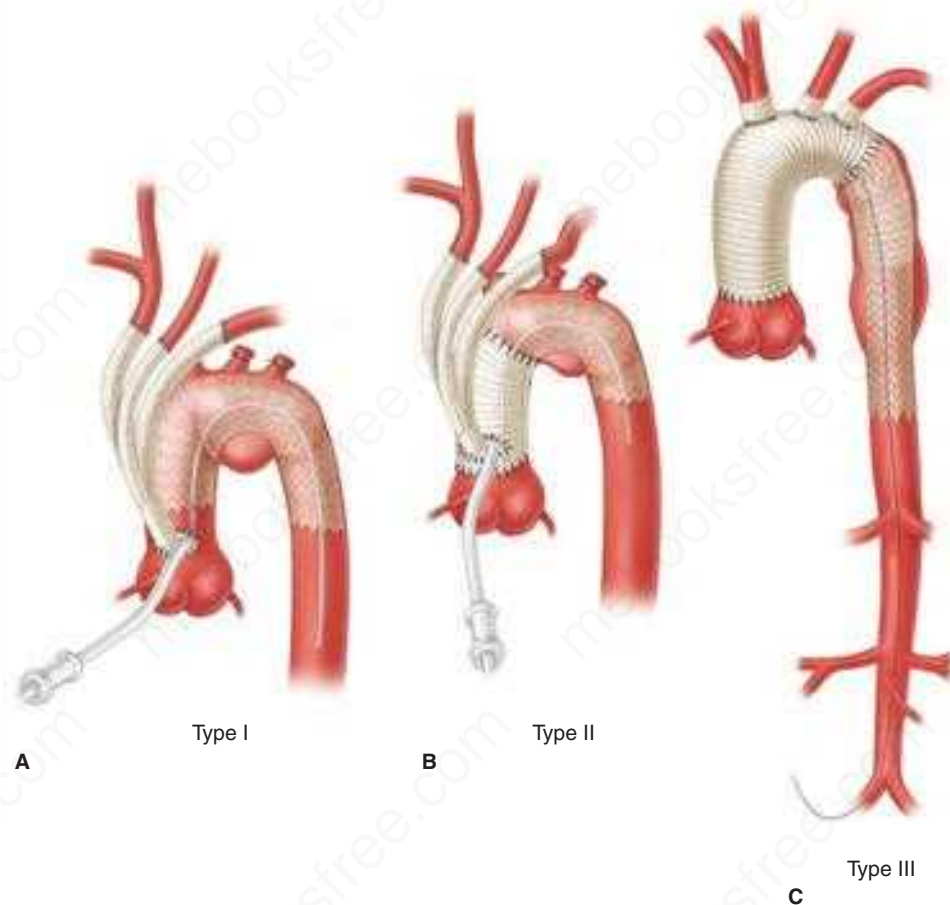

Based on these zones, we have previously proposed a classification system for aortic arch pathology for hybrid repairs.<sup>156</sup> As seen in Fig. 48-31, a Type 1 hybrid arch has a suitable (nonaneurysmal) proximal aortic Zone 0 and distal Zone 2/3 landing zones for a stent graft. A Type 2 hybrid arch needs reconstruction of the Zone 0 landing zone but has a suitable landing zone in Zones 2 and 3. A Type 3 hybrid arch represents a mega-aorta

and needs reconstruction of the distal landing zone (Zone 0) with a proximal landing zone below the diaphragm.

In a Type 1 hybrid arch, a debranching procedure is performed to bypass the cerebral vessels and involves an end-to-side anastomosis of a four-branched graft to the ascending aorta. This can often be completed with a side-biting clamp and done off CPB. After the debranching is performed, an endovascular stent graft is deployed antegrade via a separate side branch of the multibranched graft with distal landing zone in the native ascending aorta at Zone 0 under fluoroscopic guidance.

**FIGURE 48-30** Classification of thoracic endovascular landing zones.

**FIGURE 48-31** Classification of hybrid arch repairs based on location of aortic aneurysms. (A) Type 1 hybrid arch has a suitable aortic Zone 0 and distal Zone 2/3 landing zones for a stent graft. (B) A Type 2 hybrid arch needs reconstruction of the zone 0 landing zone but has a suitable landing zone in zones 2/3. (C) A Type 3 hybrid arch represents a mega-aorta and needs reconstruction of the landing zone (zone 0) with the other landing zone in the below the diaphragm.

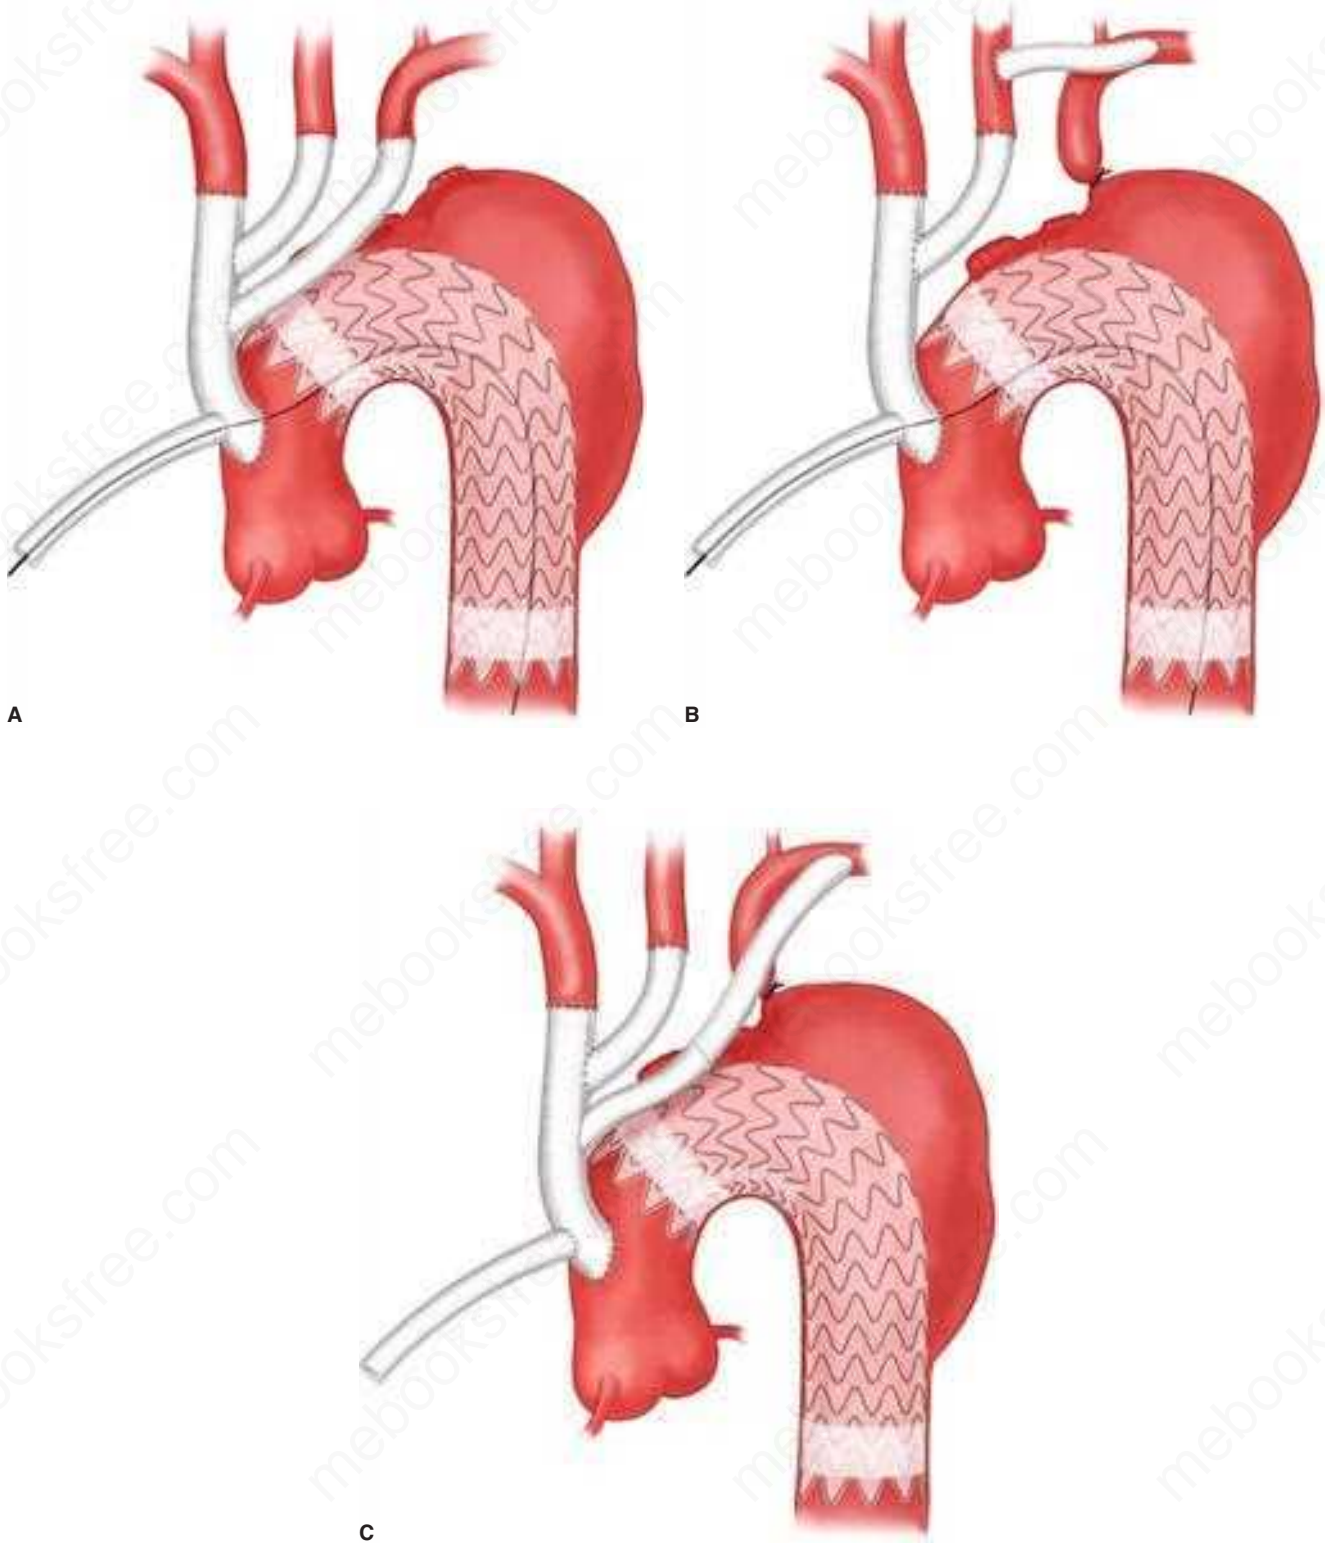

A Type 2 hybrid arch does not have a proximal landing zone in Zone 0 due to ascending aortic pathology. Therefore, this repair involves replacement of the ascending aorta and debranching of the cerebral vessels so a stent graft can be deployed to exclude the arch aneurysm. A multibranch tube graft is used to replace the ascending aorta and the cerebral vessels are bypassed. DHCA may be necessary if a hemi-arch anastomosis is required. After the graft is anastomosed, the stent graft is deployed antegrade via a separate side branch of the multibranch graft and landed distally in Zone 0 within the graft.

A Type 3 hybrid arch is a mega-aorta with diffuse proximal and distal aortic aneurysmal disease. This requires replacement of the ascending aorta and debranching as previously described for a Type 2 hybrid arch. The distal anastomosis of the graft is completed in the aneurysmal aorta but will be later excluded after the stent graft is deployed. Again, the stent graft is deployed antegrade via a side branch in the multibranch graft with the distal landing zone at Zone 0 in the graft and the proximal landing zone in the distal aorta.

Figure 48-32 shows a Type 1 hybrid arch repair for a Zone 2/3 descending aortic aneurysm. For this repair, there is a

suitable proximal and distal landing zone to exclude the aneurysm after the great vessels are debranched. To complete this repair, CPB is initiated and a side-biting clamp is placed on the aorta. It is best to utilize CPB so the side-biting clamp is not directly placed on the pulsatile ascending aorta. The main trunk of the trifurcated graft is anastomosed to the aorta. Next, the left subclavian artery is clamped and transected. The proximal stump is oversewn and the artery is then anastomosed to a limb of the trifurcated graft at which point perfusion is restored. In a similar fashion, the left carotid and innominate arteries are anastomosed to the remaining limbs of the trifurcated graft (Fig. 48-32A). An endovascular stent graft can then be deployed antegrade through a side branch to exclude the aneurysm. If the left subclavian anatomy is difficult on preoperative imaging, one approach would be to first perform a left subclavian to left carotid artery bypass (Fig. 48-32B). It is also possible to perform an intraoperative extra-anatomic bypass to the left axillary artery by tunneling the graft through the first or second intercostal space (Fig. 48-32C).

While hybrid repairs are technically easier, require less cross-clamp and require less DHCA time, there are several

**FIGURE 48-32** (A) Type 1 hybrid arch repair using side-biting clamp on the proximal aorta to anastomose the main body of the trifurcated graft. The great vessels are then debranched with the limbs of the trifurcated graft. An endovascular stent graft is then deployed antegrade through a side limb. (B) Left subclavian to left carotid artery bypass for difficult left subclavian anatomy. (C) Intraoperative extra-anatomic bypass to the left axillary artery by tunneling the graft through the first or second intercostal space for difficult subclavian anatomy.

pitfalls. Complications consist of embolic stroke, type 1 endoleaks, and stent migration. In a systemic review of hybrid arch repairs of 1886 patients, there was a pooled perioperative mortality rate of 10.8%, stroke rate of 7%, and spinal cord ischemia of 7%.<sup>157</sup> Endoleaks are unique to hybrid operations in comparison to open techniques and have an incidence up to 15% in some reports.

## COMPLETE ENDOVASCULAR AORTIC ARCH REPAIRS

Complete endovascular repair of aortic arch aneurysms remains in its infancy. Several techniques have been employed comprising custom fenestrated grafts, chimney/snorkle techniques, and in situ double branched graft fenestrations.<sup>158,159</sup> While the literature abounds with case reports and small series, no large studies exist to demonstrate long-term efficacy.

Figure 48-33A-C demonstrates an endovascular approach to an arch aneurysm and reveals the single chimney technique. This repair involves a staged operation by first completing a left subclavian to carotid artery transposition and a left carotid to innominate artery transposition (Fig. 48-33B). While transpositions are not always feasible due to anatomical variability, a left subclavian to carotid artery bypass and a left carotid to innominate artery bypass could equally have been completed. After several days, a stent graft is deployed retrograde from a femoral artery and landed proximally in Zone 0/1 with the fenestration at the innominate artery. The right axillary or right carotid artery can then be accessed to deploy a retrograde stent into the innominate fenestration. The advantage of this approach is CPB and DHCA are unnecessary. However, while studies have demonstrated feasibility with total endovascular aortic arch repair, the rates of stroke, type 1 endoleaks, need for secondary interventions, and early conversions to open repairs are high.<sup>158-160</sup> Patient

selection is critical and these approaches are for patients at too high of a risk for the open, gold standard repair.

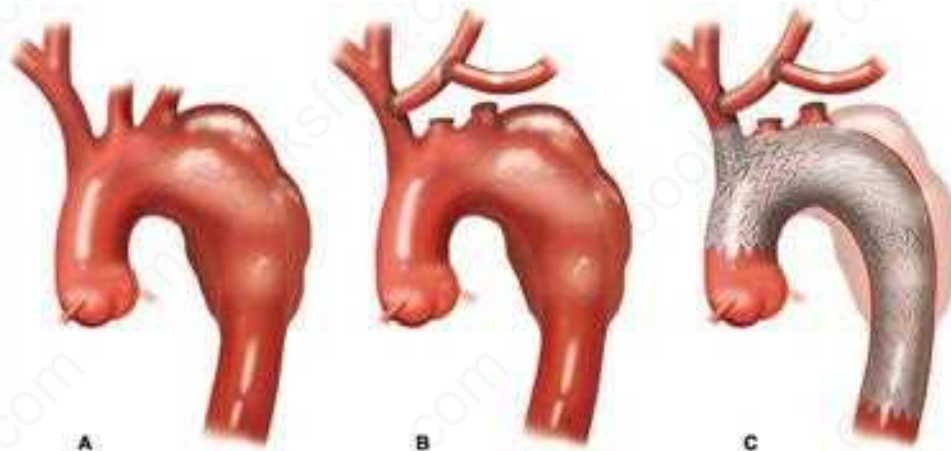

## ADDITIONAL CONSIDERATIONS

### Concomitant Mitral Surgery

Mitral valve disease is frequently encountered in patients with aortic aneurysms. This is particularly true for patients with MFS, in whom the incidence approaches 30%.<sup>161</sup> Patients who have evidence of moderate-to-severe mitral regurgitation should undergo mitral valve repair at the time of aortic replacement. Gillinov et al reported results of mitral valve repair in patients with MFS, many of whom also had simultaneous replacement of the aortic root.<sup>162</sup> They observed an 88% actuarial rate of freedom from significant mitral regurgitation at 5 years. A fairly liberal approach to mitral valve intervention is warranted in aortic root replacement patients as reoperation for late mitral regurgitation may be particularly technically difficult. Additionally, care must be taken when taking the annular stitches along the aortomitral continuity to avoid shortening the anterior leaflet of the mitral valve.

### Aortic Wrapping and Reduction Aortoplasty

Reduction ascending aortoplasty and aortic wrapping are less common techniques to address ascending aortic aneurysms typically reserved for patients undergoing concomitant aortic valve replacement but who are deemed too high risk for either composite root or ascending aortic replacement or who have ascending aortic dimensions less than the recommendations for replacement as a prophylactic measure to prevent aneurysm formation. Reduction aortoplasty involves excision of a segment of the ascending aorta to achieve a normal radial maximal dimension. It may be performed either with

**FIGURE 48-33** An endovascular approach to exclude an arch aneurysm using the single chimney technique and fenestrated graft. (A) A type 1 hybrid arch. (B) A left subclavian to carotid artery transposition and a left carotid to innominate artery transposition. (C) Retrograde endovascular stent graft from the femoral artery and an antegrade stent placed into the innominate artery from the right axillary or right carotid artery.

a side-biting aortic clamp, cross-clamped or with open technique depending on the length of aortoplasty and technique used.<sup>163-165</sup> The excised segment may be taken in the long axis of the aorta down to the sinotubular junction (true reduction annuloplasty) or lesser plication techniques. External reinforcement can also be performed in conjunction with reduction aortoplasty. Concerns regarding this technique include dehiscence or aortic rupture at the suture line, which is constantly under tension from the radial force on the aortic wall during systole.

Aortic wrapping or girdling is performed either by itself or in conjunction with reduction aortoplasty. Wrapping has been performed with cellophane, polyester grafts and meshes, polytetrafluoroethylene (PTFE), and other materials. Neri et al described two patients required reoperation because of development of false aneurysms following aortic valve replacement with aortoplasty and wrapping.<sup>166</sup> The unwrapped parts of the ascending aorta in both patients appeared normal; conversely, the aortic wall underlying the wrap was severely atrophic, a phenomenon previously reported with abdominal aneurysms that were wrapped without aortoplasty. In a larger series by Cohen et al, among 102 patients who underwent aortic wrapping with a polyester mesh followed for a median of 4.7 years, there were no instances of major aortic complications and an average aneurysm growth of 2.6 mm over the follow-up period.<sup>167</sup>

## REOPERATIVE CONSIDERATIONS

Reoperative surgery on the ascending aorta and aortic root can be particularly challenging but is becoming more frequent in experienced centers. Increased use of tissue aortic valves in younger patients, biologic porcine or composite pericardial roots, and homografts in past few decades suggest that many patients may require reoperative root intervention. Additionally, root replacement may be required after the development of ascending aortic aneurysms in bicuspid patients who have previously undergone aortic valve replacement only. Indications for reoperation include aortic insufficiency, development of aneurysms or dissections in remaining segments of the thoracic aorta, false aneurysms, prosthetic valve dysfunction, infection or thrombosis, or degeneration of biologic prostheses.

Reentry is usually accomplished with a repeat sternotomy incision, although for complex arch operations involving the proximal descending aorta, a thoracosternotomy approach may be required.<sup>168</sup> In cases of massive ascending aortic aneurysm, adhesion of the aorta to the posterior table of the sternum or contained ruptures and exposure of alternative cannulation site such as the right axillary artery or femoral artery are necessary. Massive aortic hemorrhage upon sternal entry should be locally controlled by forcibly reapproximating the sternum, heparinizing the patient, instituting peripheral CPB, and cooling to deep hypothermia such that the sternal reentry can be completed under lower flow conditions with active pump-suction in the operative field. If entering the aorta on reentry is felt to be inevitable, starting CPB and

cooling prior to sternotomy may be a superior strategy. In cases of moderate-to-severe aortic insufficiency, venting of the left ventricle prior to cardiac fibrillation is mandatory and can be accomplished by a small left anterior thoracotomy incision and direct venting of the apex.

Cross-clamping in the reoperative scenario may also be hazardous as previous graft material may cause severe adhesions to the pulmonary artery making the dissection of a clamping site difficult. Previous use of a porcine root prosthesis or left-sided bypass grafts makes this dissection particularly difficult. If the pulmonary artery is inadvertently entered, patching with a pericardial substitute is usually necessary.

Mobilization of the coronary arteries is frequently difficult and creation of a Cabrol-type anastomosis, interposition grafts, or bypass grafts are frequently necessary. Previous coronary bypass grafts should be reimplemented, and frequently, interposition vein grafts are required to accomplish this. Direct cardioplegia administration down bypass grafts is preferred but avoided when there is diffuse vein graft disease.<sup>169</sup> Retrograde cardioplegia is extremely helpful in this circumstance.

In cases of reoperation for failed porcine bioproths, root replacement is preferable to simple aortic valve implantation within the porcine root as there is a higher likelihood for valve dehiscence due to the degenerative nature of the root tissue.<sup>170</sup> If aortic valve implantation into a porcine root is being performed, all of the aortic valve implantation sutures must traverse the native aortic root tissue, not just the porcine tissue.

## OPERATIVE COMPLICATIONS

### Bleeding

Woven Dacron grafts impregnated with collagen or gelatin are relatively impervious to blood and have reduced blood loss following replacement of the ascending aorta compared with knitted grafts. Precise suturing with careful attention to avoid torque on the suture needles while constructing anastomoses is critical to avoid the inevitable needle-hole bleeding at the end of the surgery. Tension must be avoided at the sites of coronary reimplantation, as this is a frequent site of bleeding. The modified Cabrol method or an interposition graft should be used when any tension is present. The inclusion technique of graft insertion is associated with an increased incidence of bleeding and pseudoaneurysm formation and has largely been abandoned. In very friable aortas, Teflon felt may be used to reinforce the suture line on the outside of the anastomosis in which a thin strip of felt is slipped into the suture line as it is tightened. Alternatively, it may be sewn to the inside, outside, or both sides of the native aorta with a running polypropylene stitch prior to sewing the graft.

In cases of refractory coagulopathy, the anastomosis can be wrapped tightly with a small segment of polyester graft or Teflon felt to reduce tension on the suture line and reduce needle-hole bleeding (Fig. 48-34). Blood transfusion can be avoided in a significant number of patients with the use of blood conservation

**FIGURE 48-34** Suture line bleeding may be effectively controlled with a circumferential wrap of the anastomosis with a strip of Teflon felt or Dacron. (Reproduced with permission from Edmunds LH: *Cardiac Surgery in the Adult*. New York: McGraw-Hill; 1997.)

techniques such as Cell Savers, autologous blood donation, plateletpheresis, the reinfusion of chest tube drainage, and the use of antifibrinolytics such as aminocaproic acid and tranexamic acid. Since the removal of the antifibrinolytic agent aprotinin from the market due to concerns regarding renal dysfunction and mortality, bleeding has anecdotally become more common. Activated human recombinant factor VII may be helpful as a last resort when treating refractory bleeding that does not respond to any other therapies, although this may induce unanticipated thrombosis in arterial structures.<sup>171</sup>

In cases of ongoing postoperative hemorrhage, expedient return to the operating room for reexploration is preferable to massive transfusion or tamponade. Postoperative bleeding requiring reexploration ranges from 2.4 to 11.1%.<sup>172,173</sup>

## Stroke

Neurologic injury following proximal aortic surgery remains a significant cause of morbidity and mortality. Embolization of atherosclerotic debris or thrombus from the ascending aorta and arch produces focal neurologic deficits. Diffuse injury can be attributed to microemboli of air or cellular debris, insufficient or uneven cooling, and a prolonged circulatory arrest period. After circulatory arrest periods exceeding 40 minutes the incidence of stroke greatly increases.<sup>174</sup> Profound hypothermia may itself be injurious to the central nervous system without associated circulatory arrest.<sup>175</sup>

Stroke due to embolization is diminished when the aorta is evaluated via epiaortic ultrasound or other imaging modality to detect atherosclerotic plaques and thrombus.<sup>176</sup> This allows appropriate adjustments to be made in clamping and cannulation strategies. Resumption of antegrade circulation through the graft once the distal aortic anastomosis is complete, rather

than retrograde via the femoral vessels, after a period of circulatory arrest avoids embolization of distal aortic debris. Patients with severe carotid artery occlusive disease are at increased risk of stroke during ascending aortic procedures, and patients older than 65, those with peripheral vascular disease, or those with pertinent histories should be evaluated.<sup>177</sup>

Patients with new postoperative strokes should be rapidly evaluated by the consultant neurology service and undergo early brain imaging. New embolic events should be managed aggressively with induced hypertension once intracranial hemorrhage has been ruled out.

## Pulmonary Dysfunction

CPB is known to cause alterations in pulmonary function as evidenced by changes in alveolar-arterial oxygen gradients, pulmonary vascular resistance, pulmonary compliance, and intrapulmonary shunting. Usually these changes are subclinical, but a full-blown adult respiratory distress-like syndrome is reported in 0.5 to 1.7% of patients following CPB.<sup>178-180</sup> The specific cause is the subject of much investigation and debate, but it is generally accepted that exposure of blood elements to the foreign surface of the cardiopulmonary circuit results in the activation of inflammatory cells and the complement cascade resulting in pulmonary injury.<sup>181</sup> The duration of CPB, urgency of the procedure, and general condition of the patient may roughly correlate with the occurrence and severity of pulmonary dysfunction, but it can be unpredictable.

Treatment is supportive, with early diagnosis and treatment of any subsequent pulmonary infections. Ten to eighteen percent of patients require prolonged mechanical ventilation. Preventive measures may include preoperative optimization of pulmonary function, minimization of pump time, judicious use of blood products, heparin-coated bypass circuits, and leukocyte depletion.<sup>182</sup>

## Myocardial Dysfunction

Transient myocardial dysfunction following complex aortic surgery requiring inotropic support is common with 18 to 25% of patients requiring more than 6 hours of inotropic support.<sup>183,184</sup> Meticulous attention should be paid to integrated myocardial protection with cold blood cardioplegia administered frequently in antegrade and retrograde fashions. This is particularly important in patients with significant left ventricular dilatation seen with aortic insufficiency or hypertrophy seen with aortic stenosis. Maintenance of high perfusion pressures after removal of cross-clamp optimizes myocardial perfusion during the critical reperfusion period. Optimization of right ventricular function with afterload reducing agents such as milrinone or inhaled prostaglandins while weaning from CPB is vital for maintaining adequate left ventricular filling in cases of severe diastolic dysfunction or ventricular hypertrophy. Postoperative myocardial infarction, reported in up to 2.5% of cases, may be related to technical problems with coronary reimplantation.<sup>185</sup>

## Perioperative Mortality

Contemporary surgical series on ascending aortic disease using modern grafting techniques and methods of cerebral and myocardial protection report hospital mortality rates of 1.7 to 17.1%.<sup>185-189</sup> Comparison of outcomes is difficult, however, because of heterogeneity of patients. Some series do not include dissection, and the proportion of emergent operations, reoperations, and arch replacements is highly variable. The common causes of early death are cardiac failure, stroke, bleeding, and pulmonary insufficiency.<sup>185,186</sup>

Emergent operation after the onset of acute dissection or rupture is the highest risk factor for early death. Risk of death following elective intervention is increased by increasing New York Heart Association classification, increasing age, prolonged CPB time, dissection, previous cardiac surgery, and need for concomitant coronary revascularization.<sup>188,189</sup>

## LATE COMPLICATIONS

### Late Mortality

Reported actuarial survival, like early mortality, is variable and dependent on the patient cohort. Survival rates are 81 to 95% at 1 year, 73 to 92% at 5 years, 60 to 73% at 8 to 10 years, and 48 to 67% at 12 to 14 years.<sup>190-193</sup> Predictors of late mortality include elevated New York Heart Association class, requirement for arch reconstruction, MFS, and extent of distal disease.<sup>194-197</sup> The most common cause of late death is cardiac, but distal aortic disease accounted for 32% of late deaths in one series.<sup>198</sup>

### Reoperation

Reoperations occur due to pseudoaneurysm formation, valve thrombosis, endocarditis or graft infection, progression of disease in the native valve or remaining aortic segments, or degeneration of a bioprosthesis. Reported mortality for reoperative ascending aortic surgery varies between 4 and 22%.<sup>199,200</sup>

Freedom from reoperation is 86 to 90% at 9 to 10 years (Fig. 48-35).<sup>201,202</sup> Predictors of late reoperation have included MFS, the inclusion cylinder technique, and chronic dissection.<sup>203</sup> Surveillance of patients who have undergone previous aortic surgery to minimize the need for urgent reoperations and appropriate resection of all diseased aortic tissue at the time of original operation improves outcomes. Up to 60% of reoperations occur due to inadequate repair during the initial operation.<sup>204</sup> This is due to failure to resect the most distal aspects of aneurysmal disease by performing a clamped distal anastomosis or failure to adequately address root pathology with full root replacement. Previous inclusion-type anastomotic techniques were associated with higher rates of early reoperation due to pseudoaneurysm formation (Fig. 48-36).<sup>205</sup>

MFS patients are particularly prone to requiring reoperation (Fig. 48-37).<sup>206</sup> Gott et al reviewed the experience with root replacement at 10 surgical centers in 675 Marfan patients between 1968 and 1996.<sup>207</sup> The 30-day mortality was 3.3%,

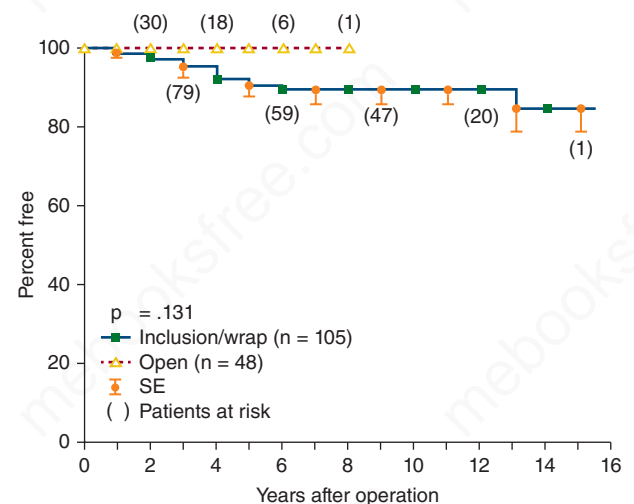

**FIGURE 48-35** Long term freedom from reoperation following full aortic root replacement and separate ascending aortic and valve replacement. (Reproduced with permission from Sioris T, David TE, Ivanov J, et al: Clinical outcomes after separate and composite replacement of the aortic valve and ascending aorta, *J Thorac Cardiovasc Surg* 2004 Aug;128(2):260-5.)

but was only 1.5% for elective repair. Emergency surgery resulted in a 30-day mortality of nearly 12%. The survival rate was 93% at 1 year, 84% at 5 years, 75% at 10 years, and 59% at 20 years. Complications related to the residual thoracic aorta and arrhythmias were the leading causes of death. The most frequent late complication was thromboembolism. Advanced New York Heart Association class at the time of original operation was the only predictor of late death.

### Graft infection

Graft infections are reported in up to 0.9 to 6% of patients following surgery of the thoracic aorta and are associated

**FIGURE 48-36** Long term freedom from reoperation for pseudoaneurysm of the aortic or coronary ostial suture lines by operative technique (inclusion or open). (Reproduced with permission from Kouchoukos NT, Wareing TH, Murphy SE, et al: Sixteen-year experience with aortic root replacement: Results of 172 operations, *Ann Surg* 1991 Sep;214(3):308-18.)

**FIGURE 48-37** Freedom from reoperation (Kaplan-Meier) of patients with Marfan syndrome [Group A] versus those without fibrillinopathic etiologies [Group B]. (Reproduced with permission from Detter C, Mair H, Klein HG, et al: Long-term prognosis of surgically-treated aortic aneurysms and dissections in patients with and without Marfan syndrome, *Eur J Cardiothorac Surg* 1998; Apr; 13(4):416-423.)

with a very high (25-75%) mortality rate.<sup>208-210</sup> Most graft infections occur in the first month after operation and are frequently associated with wound infections. They may occur years later in cases of associated valve endocarditis or bacteremia from indwelling catheters or other systemic infections. The major infectious agents are *Staphylococcus aureus*, *S. epidermidis*, and *Pseudomonas*.<sup>211</sup> The ascending aortic graft may be particularly vulnerable because of proximity to the wound and poor natural tissue coverage. For this reason, full coverage of the ascending graft material with the pericardial fat pad is advisable in all cases. This serves to isolate the graft from the sternum should it become infected.

Patients frequently present with persistent fevers and elevated white cell count. CT or MRI may demonstrate air or fluid collections around the graft. There may be associated pseudoaneurysms, fistula, anastomotic leak, hemolysis, and embolism. Nuclear imaging techniques may be helpful but can be nonspecific for infection versus normal postoperative inflammation.<sup>212</sup> TEE may show valvular vegetations or abscesses.

Ideally, treatment of the stable patient begins with intravenous antibiotics to control septicemia and often clear blood cultures prior to reoperation. In extremely high-risk patients, where reoperative mortality is prohibitive, life-long suppressive antibiotics may be acceptable. Surgical treatment of infected ascending aortic grafts, as described by Hargrove and Edmunds, includes removal of all infected prosthetic material, aggressive tissue debridement, local irrigation, systemic antibiotic therapy, replacement of the infected conduit, and utilization of autologous tissue to surround the graft and obliterate dead space.<sup>213</sup> Aortic homograft may potentially be more resistant to repeat infection. Greater omentum may be also brought up through the diaphragm as a vascularized pedicle to wrap around the aortic graft and isolate it from

the sternum. Concomitant sternal infections should be managed with aggressive debridement, sterilization with vacuum-assisted wound drainage, and delayed flap reconstruction. In severe cases, open continuous antibiotic wound irrigation for several days can assist clearing the infection.<sup>214</sup> Long-term antibiotics should be continued intravenously for at least 6 weeks and suppressive oral antibiotics may be indicated over the long-term thereafter.

# Descending and Thoracoabdominal Aortic Aneurysms

Joseph S. Coselli • Kim de la Cruz • Ourania Preventza  
• Scott A. LeMaire

Treating aneurysms that arise from the aortic segments distal to the left subclavian artery poses challenges that are distinct from those presented by aneurysms of the more proximal ascending and arch segments. The distal aortic segments comprise the descending thoracic aorta, which extends from the left subclavian artery to the diaphragm within the chest, and the abdominal segment that extends from the diaphragm to the iliac bifurcation. The diaphragm divides the thoracic aorta from the abdominal aorta.

An aortic aneurysm that is limited to the chest (distal to the left subclavian artery) is classified as a descending thoracic aortic aneurysm (DTAA). An aortic aneurysm that traverses the diaphragm and extends into both the chest and the abdomen to any degree is considered a thoracoabdominal aortic aneurysm (TAAA) (Fig. 49-1). Aneurysms in these locations can be extensive and can involve many or all of the aortic branch vessels. In the last decade there have been substantial changes regarding the treatment of distal aortic aneurysms because of the emergence of thoracic endovascular aortic repair (TEVAR) and its near dominance in DTAA repair. Although open repair remains the standard of care for TAAAs, it is now selectively used for DTAAAs. Modern critical care and continually refined surgical adjuncts for organ protection have made the outcomes of surgical repair better than they were in previous decades, but operative treatment of DTAA and TAAA continues to represent a significant clinical challenge to the cardiovascular surgeon.

## PATHOGENESIS

The etiology of DTAA and TAAA has changed over time. Whereas tertiary syphilis was the most common cause of thoracic aneurysms in the early 1900s, other causes are more prevalent today. Well-established causes of DTAA and TAAA include medial degeneration, atherosclerosis, aortic dissection, connective tissue disorders, aortitis (eg, Takayasu

arteritis), aortic coarctation, infection, and trauma. As our understanding of genetics increases, and as more advanced genetic testing becomes available, classification systems are likely to evolve to include more molecular factors. Perhaps partly because of improved screening for aneurysmal disease and the increasing age of the population, it is certain that the incidence and prevalence of thoracic aortic aneurysms are increasing over time.<sup>1</sup>

The most common types of aneurysms of the descending and thoracoabdominal aorta today are grouped into the category of atherosclerotic aneurysms. Unfortunately, although this term may be descriptive, it may not accurately describe the mechanism of aneurysmal changes. Although atherosclerosis and aortic aneurysms share common risk factors and frequently coexist, thoracic aortic aneurysms are primarily the result of age-related medial degeneration, which is characterized by changes in elastin and collagen that reduce aortic integrity and tensile strength. Subsequent aortic enlargement and aneurysm formation provide fertile ground for superimposed intimal atherosclerosis and further degeneration of the aortic wall. The usual histologic changes in the aging aorta include elastin fragmentation, fibrosis with increased collagen deposition, and medial degeneration.<sup>2</sup> As with most aneurysmogenic processes, medial degeneration usually causes diffuse, fusiform aortic dilatation. In some cases, medial degeneration produces discrete saccular aneurysms along the descending thoracic aorta; however, saccular aneurysms are more commonly associated with aortic infection (see below). Additionally, saccular aneurysms may be superimposed on or coexist with more generalized, fusiform aneurysmal disease of the thoracoabdominal aorta.

Risk factors for aortic dissection and aortic aneurysm overlap to a great extent, but once an aorta becomes dissected, the dissection itself becomes an independent risk factor for subsequent dilation and aneurysmal changes. Two of the DeBakey types of aortic dissection involve the distal aorta: type I, in

**FIGURE 49-1** Drawing depicting a thoracoabdominal aortic aneurysm. (Printed with permission from Baylor College of Medicine.)

which nearly the entire length of the aorta is dissected, and type III, in which the dissection is limited to varying portions of the distal aorta, and the proximal aorta is unaffected. Aortic dissections occur in the medial layer separating the intima from the adventitia; blood flows through the true aortic lumen and through one or more false lumen channels that can form at various points along the aorta. This process weakens the outer aortic wall, making it prone to progressive aneurysmal dilatation (Fig. 49-2).

In survivors of DeBakey type I dissection, the persistence of a pressurized false lumen has been associated with subsequent distal aneurysm formation, need for intervention, and increased mortality.<sup>3</sup> In an attempt to thrombose the false channel and thereby decrease the risk of late aneurysm formation, endovascular strategies have been developed to exclude segments of the false lumen in both acute ( $\leq 2$  weeks since onset)<sup>4</sup> and chronic<sup>5</sup> aortic dissection. Such approaches are dependent on a variety of factors, including the extent of aortic dissection; downstream portions of the false lumen—those without endovascular obliteration—continue to be pressurized and may perfuse upstream portions in a retrograde fashion.

Penetrating aortic ulcers and intramural hematomas are two variants of aortic dissection that can occur in the descending and abdominal aortic segments. Penetrating aortic ulcers are disrupted atherosclerotic plaques that can penetrate the aortic wall, leading to classic dissection or rupture. Intramural hematomas are collections of blood within the aortic wall that occur without an intimal tear; growth of the hematoma can result in classic dissection.

Genetic mutations or defects can give rise to defective components of the aortic extracellular matrix, leading to aortic aneurysm and dissection. Aortic aneurysms that occur in patients with these genetic disorders can be a part of a named syndrome, accompanied by a constellation of extra-aortic symptoms, or they may be part of a heterogeneous group of familial thoracic aortic aneurysms and dissections that occur in isolation. In a national registry of genetically triggered thoracic aortic aneurysms, Marfan syndrome is the most common genetic cause of aortic aneurysms (36%).<sup>6</sup> Marfan syndrome is a connective tissue disorder that results

**FIGURE 49-2** Drawing and computed tomography image of a thoracoabdominal aortic aneurysm caused by dilatation of the false lumen in a patient with chronic aortic dissection.

from a fibrillin-1 (FBN1) gene mutation; the altered fibrillin leads to aberrant signaling of transforming growth factor beta (TGF- $\beta$ ) and other events that lead to the deposition of extensive amounts of mucopolysaccharides in the aortic extracellular matrix and fragmentation of elastic fibers. The aorta in Marfan syndrome patients is prone to dissection, which is the most common cause of DTAA and TAAAs in these patients.<sup>7,8</sup> Other syndromes that are infrequently encountered during DTAA and TAAA repairs include vascular Ehlers-Danlos, aneurysms-osteoarthritis, and Loeys-Dietz. Like Marfan syndrome, Loeys-Dietz syndrome is an autosomal dominant disorder that is linked to an alteration in TGF- $\beta$  signaling. First described in 2005, Loeys-Dietz is a particularly aggressive aortic disorder, characterized by vascular tortuosity, and a greater propensity for rupture at smaller aortic diameters than in patients with Marfan syndrome. Recently, four types of Loeys-Dietz have been identified, each associated with a mutation in a particular gene: transforming growth factor (TGF)-beta receptor I (*TGFBR1*), TGF-beta receptor II (*TGFBR2*), decapentaplegic homolog 3 (*SMAD3*), and transforming growth factor beta 2 ligand (*TGFB2*).<sup>9</sup>

Both chronic, nonspecific aortitis and systemic autoimmune disorders—such as Takayasu arteritis, giant cell arteritis (temporal arteritis), and rheumatoid aortitis—can cause destruction of the aortic media and progressive aneurysm formation. Although Takayasu arteritis usually causes obstructive lesions related to severe intimal thickening, the associated medial destruction can result in aneurysmal dilatation.

Aneurysms involving the upper descending thoracic aorta can develop in patients with congenital aortic coarctation. These aneurysms may occur concomitantly with unrepaired native coarctation or years after any manner of coarctation repair, including endovascular repair.<sup>10,11</sup> The postrepair aneurysms appear to be more common in patients who have had balloon angioplasty than in those who underwent surgery; this is speculated to be due to the rupture of elastic fibers during dilatation.<sup>11</sup>

Infection can produce a sacular “mycotic” aneurysm in a localized area of the aortic wall that has been damaged by the infectious process. For unknown reasons, such mycotic aneurysms tend to occur along the lesser curvature of the transverse aortic arch or in the upper abdominal aorta adjacent to the origins of the visceral branches. In such cases, only a portion of the aortic circumference is affected; consequently, localized weakening causes a diverticular or sacular outpouching. Common causative organisms include *Staphylococcus aureus*, *Staphylococcus epidermidis*, *Salmonella*, and *Streptococcus*,<sup>12</sup> and more than one pathogen may be present. Although uncommon, when a distal mycotic aneurysm is suspected, urgent evaluation is warranted; mycotic sacular aneurysms tend to be unpredictable, often have periods of rapid growth, and rupture more readily than fusiform aneurysms caused by medial degeneration.<sup>13</sup>

Each of the disease processes described above causes aneurysms through progressive degeneration and dilatation of the aortic wall. In contrast, pseudoaneurysms of the thoracic aorta form as the result of chronic leaks through discrete

defects in the aortic wall. These leaks are initially contained by surrounding tissue; the accumulation of organized thrombus and the associated fibrosis forms the wall of the pseudoaneurysm. Pseudoaneurysms can develop after aortic surgery, endovascular aortic repair, invasive imaging, or from primary defects in the aortic wall. Unrepaired blunt and penetrating injuries are the other common cause of aortic pseudoaneurysms. Chronic traumatic pseudoaneurysms typically develop in the proximal descending thoracic aorta after blunt aortic injuries; the management of these lesions is covered in detail in a subsequent chapter.

## NATURAL HISTORY

An untreated aneurysm in the thoracic and thoracoabdominal aorta can progress to dissection, rupture, or both if given enough time. A dissected aorta that was originally of normal caliber will tend to dilate and become aneurysmal. The causes and genetics of these aneurysms vary, but there are commonalities in the mechanical and pathophysiologic aspects of their formation and development. Understanding these processes will help surgeons determine the timing and the nature of the operative intervention needed.

An aneurysm is defined as a permanent dilation of an artery to at least 1.5 times its normal diameter at a given location.<sup>14</sup> However, the normal aortic diameter is perhaps more difficult to define because it varies by the patient's age, gender, and body size. Even when adjusted for age and body surface area, mean aortic size is significantly smaller in women than in men; on average, aortic diameter is 2 to 3 mm greater in men than in women. In the community-based Framingham Heart Study, computed tomography studies from 3431 adults, at least 35 years old, were analyzed by age, gender, and body surface area. At the descending thoracic aorta, the average aortic diameter was 25.8 mm for men and 23.1 mm for women; at the infrarenal abdominal aorta, it was 19.3 mm for men and 16.7 mm for women; and at the lower abdominal aorta, it was 18.7 mm for men and 16.0 mm for women.<sup>15</sup> In this study, aortic enlargement was strongly correlated with male gender, advancing age, and increased body surface area—for men  $\geq 65$  years old and with a large body surface area ( $\geq 2.1$ ), the mean descending thoracic aortic diameter increased by 4.5 to 30.3 mm; and for women  $\geq 65$  years and with a large body surface area ( $\geq 1.9$ ), this increased by 4.0 to 27.1 mm. Notably, body surface area is a better predictor of aortic size than height or weight, particularly in patients less than 50 years of age.<sup>16</sup>

The descending thoracic aorta has a slightly higher rate of expansion over time than the ascending aorta and is noted to average 1 to 4 mm/year.<sup>17</sup> The rate is not constant, and it increases as the diameter increases. A dissection in an otherwise small aneurysm can lead to a sudden increase in the rate of growth; likewise, a chronically dissected aorta tends to dilate at a faster rate than a nondissected one. The relationship among pressure, vessel diameter, and vessel wall tension is described by Laplace's law. As the luminal diameter increases, there is increasing wall tension, which in turn

contributes to the cycle of progressive dilatation. Unfortunately, as the dilation progresses, the wall tension eventually becomes too great for the maximally stretched aortic wall. A tear can occur within the intimal and medial layers, resulting in a dissection that propagates down the length of the aorta, or a tear can penetrate the full thickness of the aortic wall, resulting in contained or free rupture. The aortic size at which this event occurs is determined by several factors, including the presence or absence of a connective tissue disorder, the presence and severity of hypertension, and the patient's body size. In a large series of patients, Elefteriades and colleagues<sup>18</sup> have shown that in the thoracic aorta, there is a sharp increase in the incidence of aortic complications at aneurysmal diameters greater than 6 cm, with a 14% combined risk of rupture, dissection, and death. In a population-based study, the 5-year risk of rupture doubled from 16% for aneurysms 4 to 5.9 cm in diameter to 31% in aneurysms 6 cm or more in diameter.<sup>19</sup>

### CLINICAL PRESENTATION AND DIAGNOSIS

At the time of diagnosis, patients with DTAAAs and TAAAs are commonly asymptomatic. For example, Panneton and Hollier<sup>20</sup> reported that degenerative TAAAs are asymptomatic in roughly 43% of patients. In asymptomatic patients, DTAAAs and TAAAs are often discovered when imaging studies are performed to evaluate unrelated problems. For example, computed tomography scans may indicate aortic dilatation, and chest radiographs may show widening of the descending thoracic aortic shadow, which may be outlined by a rim of calcification outlining the dilated aneurysmal aortic wall (Fig. 49-3). Aneurysmal calcium may also be seen in the upper abdomen on standard radiograms.

Although DTAAAs and TAAAs remain asymptomatic for long periods of time, most ultimately produce a variety of symptoms before they rupture. Degenerative TAAAs produce symptoms in approximately 57% of patients; 9% of patients present with rupture.<sup>20</sup> The most frequent symptom is back pain between the scapulae. When the aneurysm is large in the region of the aortic hiatus, pressure on adjacent structures may cause mid-back and epigastric pain. Other potential signs and symptoms related to compression or erosion of adjacent organs include stridor, wheezing, cough, hemoptysis, dysphagia, and gastrointestinal obstruction or bleeding. Hoarseness results from traction on the vagus nerve as the distal aortic arch expands and causes recurrent laryngeal nerve paralysis. Thoracic or lumbar vertebral body erosion (Fig. 49-4) causes back pain, spinal instability, and neurologic deficits from spinal cord compression; mycotic aneurysms have a peculiar propensity to destroy vertebral bodies. Additionally, neurologic symptoms, including paraplegia, paraparesis, or both, may result from thrombosis of intercostal and lumbar arteries. This is most frequently seen with acute aortic dissection, which may occur primarily or be superimposed on medial degenerative fusiform aneurysmal

**FIGURE 49-3** Chest radiographs in (A) posteroanterior and (B) lateral projections showing the calcified wall (arrows) of a thoracoabdominal aortic aneurysm.

**FIGURE 49-4** Computed tomography image of a large thoracoabdominal aortic aneurysm that has caused erosion of the adjacent vertebral body.

disease. Thoracic aortic aneurysms, like aneurysms in other locations, may produce distal emboli of clot or atheromatous debris that gradually obliterate and thrombose visceral, renal, or lower-extremity branches.

Imaging technology is critical in diagnosis and determining anatomic details for operative planning. Computed

tomography (CT) scanning and magnetic resonance angiography (MRA) enable clinicians to obtain excellent images without the potential morbidity or cost associated with angiography. CT scanning is widely available and can image the entire thoracic and abdominal aorta, major branch vessels, and virtually all adjacent organs. Computer programs can construct sagittal, coronal, and oblique images, as well as three-dimensional reconstructions, from CT data. Contrast-enhanced CT scanning (Figs. 49-2, 49-4, and 49-5) also provides information about the aortic lumen, intraluminal thrombus, presence of aortic dissection, intramural hematoma, mediastinal or retroperitoneal hematoma, aortic rupture, and periaortic fibrosis associated with inflammatory aneurysms.<sup>21</sup> CT angiography with multiplanar reconstruction is especially useful for planning endovascular procedures. Advantages of CT include being less expensive and somewhat quicker to perform than MRA and, at present, the wider availability of CT expertise. Also, CT can be used with patients who have implanted ferromagnetic prostheses or other devices, which can cause injury in patients undergoing MRA. The chief advantages of MRA are that it does not expose the patient to ionizing radiation and that it reveals disease within the aortic wall, including intramural hemorrhage. The gadolinium-based contrast agents used in MRA were once considered to be safer for patients with renal insufficiency than CT contrast media. Ironically, reports have associated the use of certain gadolinium-based contrast agents with nephrogenic

**FIGURE 49-5** Drawing and contrast-enhanced computed tomography images of a degenerative extent II thoracoabdominal aortic aneurysm with extensive intraluminal thrombus.

systemic fibrosis (NSF)—a scleroderma-like fibrotic process that can affect not only the skin but also internal organs—in patients with renal insufficiency.<sup>22</sup> The current recommendation is to avoid using such agents in patients with advanced renal failure (ie, with a glomerular filtration rate < 30 mL/min) or in patients who are dialysis-dependent.<sup>23</sup>

Ongoing improvements in noninvasive imaging modalities have substantially reduced the role of catheter aortography in assessing thoracic aortic aneurysms. However, catheter aortography remains useful in situations where noninvasive methods are not feasible—for example, when artifact or heavy calcification obscures the area of interest. Anterior, posterior, oblique, and lateral views provide detailed information about branch vessels. The risks posed by aortography include renal toxicity from the large volumes of contrast material required to adequately fill large aneurysms. There is also a risk of embolization from laminated thrombus secondary to manipulation of intraluminal catheters. Furthermore, angiography underestimates the size of an aneurysm in areas of laminated thrombus. Nonetheless, angiography can be helpful in patients with suspected renal or visceral ischemia, aortoiliac occlusive disease, horseshoe kidney, or peripheral aneurysms.

## DETERMINING APPROPRIATE TREATMENT

Whenever possible, patients with known aortic disease (ie, patients with previous aortic dissection, prior aortic repair, or abnormal aortic diameter) are regularly followed by an imaging surveillance protocol to monitor the possible development of distal aortic aneurysm. For this and other incidental findings, once an aneurysm involving the descending thoracic or thoracoabdominal aorta has been discovered, precise determination of the extent and severity of disease is the critical next step toward clarifying the specific diagnosis, determining the appropriate treatment, and, when repair is indicated, planning the appropriate intervention.

## Indications for Operation

In asymptomatic patients, the decision to consider surgical repair is based primarily on the diameter of the aneurysm. To prevent fatal rupture, current guidelines recommend elective operation when the aortic diameter exceeds 5.5 cm in cases of chronic dissection and 6 cm in cases of degenerative aneurysm. In patients with connective tissue disorders, such as Marfan syndrome and related disorders, the diameter-based threshold for operation is lowered. Although guidelines specify a rapid dilatation rate for only the proximal aorta, indicating repair when expansion exceeds 0.5 cm/year, it is not unreasonable to apply this threshold to the distal aorta as well.<sup>24</sup> Nonoperative management—which consists of strict blood pressure control, cessation of smoking, and at least yearly surveillance with imaging studies—is appropriate for asymptomatic patients who have small aneurysms. Symptomatic patients, however, are at increased risk of rupture and

warrant expeditious evaluation and urgent aneurysm repair, even when the abovementioned threshold diameters have not been reached. The onset of new pain in a patient with a known aneurysm is particularly concerning and often heralds significant expansion, leakage, or impending rupture. Malperfusion caused by chronic dissection is also an indication for TAAA repair. Degenerative DTAAAs and TAAAs with superimposed acute dissection are especially prone to rupture and are therefore treated with emergent repair.

## Endovascular Considerations

Since 2005, when a TEVAR device was approved by the US Food and Drug Administration (FDA) to treat DTAA, indications for TEVAR have expanded, and TEVAR devices are now approved for treating all lesions of the descending thoracic aorta—acute or chronic aortic dissection, penetrating aortic ulcer, and blunt trauma—with suitable anatomy. In contrast, custom-manufactured fenestrated or branched endovascular repair of TAAA remains experimental in the United States with ongoing clinical trials.<sup>25</sup> Although endovascular repairs are covered in detail in a subsequent chapter, all patients in our practice are evaluated for possible endovascular intervention, and an individualized surgical option best suited for the patient is selected. Appropriate anatomy is also critical for successful endovascular repair. Landing zones that have inadequate length, excessive angulation, extensive intraluminal thrombus, dissection in the proximal landing zone, or severe vessel calcification will not allow secure endograft fixation, precluding endovascular repair. Two important factors to consider when deciding between open and endovascular aneurysm repair are the patient's physiologic reserve and vascular anatomy.<sup>26</sup> Open repairs have well-documented outcomes and excellent long-term durability, and they allow repair of aneurysms with complex anatomy. However, the patients must have considerable physiologic reserve to undergo and recover from these procedures.

Hybrid, off-label approaches that combine open and endovascular repair have been selectively used to repair DTAAAs and TAAAs. A common type of hybrid DTAA repair involves extending the proximal landing zone by rerouting the left subclavian artery such that the endograft may cover the ostia of the left subclavian artery; this has been done in fairly large numbers of patients and is thought to add little risk and protect against the risk of stroke.<sup>27</sup> Additionally, a traditional open “elephant trunk” repair—which leaves a small section of replacement graft floating in the descending thoracic aorta after replacing the aortic arch—can be subsequently combined with TEVAR, either as part of the initial repair or in a subsequent procedure (see following section). Hybrid “elephant trunk” procedures involve landing the proximal portion of the endograft in the trunk, but this approach is not widely used. In contrast, “frozen elephant trunk” procedures (performed in a single stage) are now commonly performed in Europe, especially for the treatment of acute DeBakey type I dissections, with the use of several readily available hybrid devices. The ultimate goal of this approach is to thrombose the false lumen to prevent additional

late aortic complications.<sup>28</sup> In the United States, there are several versions of this approach, including the antegrade placement of the endograft in the proximal descending thoracic aorta after proximal hemiarach repair.<sup>29</sup>

Hybrid TAAA approaches typically involve open visceral bypass grafting, which is performed to secure organ perfusion, and followed by stent-graft coverage of the entire aneurysm, including visceral and other branch-vessel ostia. However, a recent approach to hybrid TAAA repair involves replacing the visceral portion of aorta with a multibranched graft in an open fashion (such as in an extent III or IV repair) and repairing the more proximal section of the descending thoracic aorta with a stent graft that is then secured to the proximal section of the multibranched graft.<sup>30</sup> Although hybrid TAAA procedures are somewhat less invasive than open TAAA repair, they have not yet yielded a substantial decrease in morbidity and mortality rates, and patient fitness must again be considered in order to obtain an optimal outcome.<sup>31</sup>

Other off-label approaches to TAAA repair include the use of parallel grafts (also called “chimney,” “sandwich,” or “snorkel” approaches); a large diameter endograft is used to cover the aneurysm, and a small diameter stent is run parallel to the main endograft and into branching arteries so that they are perfused. In select patients with substantial comorbidities, parallel endovascular repair remains an option; however, because published reports describe only small patient series,<sup>25</sup> it is difficult to judge the utility of this approach. The same is true for the multilayer modulator stent, which is now being used for TAAA repair outside the United States, because only short-term data are available.<sup>32</sup>

Endovascular descending thoracic aortic repair is widespread, and its use to treat degenerative aneurysm should be strongly considered when feasible per current US guidelines.<sup>24</sup> Furthermore, recent 5-year evidence from the INSTEAD-XL randomized trial of 140 patients with uncomplicated chronic aortic dissection who underwent either optimal medical therapy or TEVAR with optimal medical therapy suggests that TEVAR substantially improves late aortic-specific survival and delays disease progression.<sup>5</sup> Data suggest that, in general, endovascular repair of the descending thoracic aorta is associated with less early mortality and morbidity than open repair,<sup>33,34</sup> and TEVAR is less likely to be affected by whether the repair is performed at a high-volume or low-volume center,<sup>35</sup> even in cases of rupture.<sup>36</sup> However, the early survival benefit may be lost within a few years after repair, because 5-year survival is similar between those with open and endovascular Medicare cohorts<sup>37</sup> or is worse after endovascular repair.<sup>38,39</sup> There also appears to be a greater need for reintervention after TEVAR than after open DTAA repair.<sup>39-41</sup> Of interest, emerging evidence suggests that different aortic pathologies (degenerative aneurysm vs chronic dissection vs acute dissection) are associated with different modes of repair failure after TEVAR.<sup>42,43</sup>

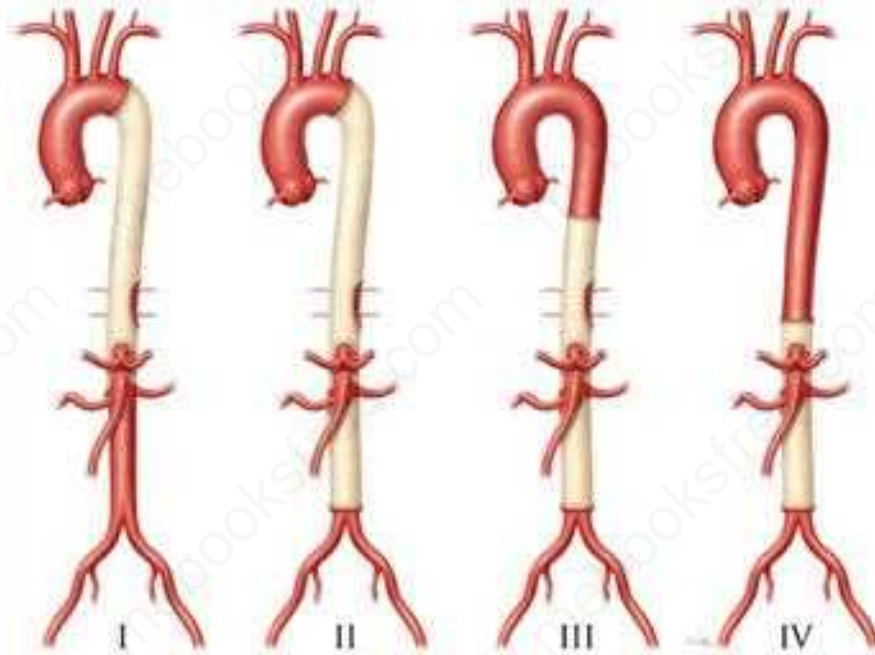

Because endovascular aortic repair has become substantially more common in recent years and the indications for its use have evolved, these devices are increasingly encountered in subsequent open operations. Complications after

endovascular repair may result from progression of the aneurysmal process to an adjacent portion of the aorta that is not amenable to further endovascular treatment, progressive dilation of the treated segment owing to persistent endoleak, infection of the endovascular device, or device migration. In certain cases, endovascular devices do not incorporate into the aneurysm thrombus and aortic intima in the way that conventional Dacron grafts incorporate into the periadventitial tissue. Explantation of the endovascular device and open graft replacement of the thoracic aorta can be accomplished with relatively good success.<sup>44-46</sup> In the absence of infection, salvaging the device or portions of the device is also possible. Although we have applied the aortic cross-clamp to a proximal aortic segment with an endovascular stent graft in place and repaired a distal segment in an open fashion, in cases in which the stent graft encroaches on the aortic arch, it may not be possible to place a cross-clamp, and hypothermic circulatory arrest may be needed. Suturing an existing stent graft to a standard Dacron graft in a hemostatic fashion is also feasible, particularly if the surrounding aortic tissue can be incorporated into the suture line. Notably, endovascular aortic repair in patients with connective tissue disorders is not supported by current US guidelines;<sup>24</sup> however, selective use as bridge to open repair or to treat late complications of open repair may be an appropriate strategy.<sup>47,48</sup>

## PREOPERATIVE EVALUATION

In each patient, the indications for operation discussed above are weighed against the risks posed by surgical intervention.<sup>49,50</sup> The Crawford classification of TAAA (Fig. 49-6) permits standardized reporting of the extent of aortic involvement, thereby allowing appropriate risk stratification, choice of specific treatment modalities according to the extent of the aneurysm, and a type-specific determination of the risks for neurologic deficits and other morbidities and mortality associated with TAAA repair. Extent I TAAA repairs involve replacing most or all of the descending thoracic aorta and the upper abdominal aorta. Extent II repairs involve most or all of the descending thoracic aorta and extend into the infrarenal abdominal aorta. Extent III repairs involve the distal half or less of the descending thoracic aorta and varying portions of the abdominal aorta. Extent IV repairs involve most or all of the abdominal aorta. In general, less extensive distal aortic repair (DTAA, extents III and IV TAAA) tend to pose less operative risk than more extensive distal aortic repair (extents I and II TAAA), although patient-specific disease, such as having a heavy atherosclerotic burden, can increase risk in lesser repairs.

Most commonly, patients with DTAA and TAAA meeting criteria for repair are in their mid-to-late 60s. Younger patients tend to include those patients with connective tissue disorders or chronic aortic dissection. Additionally, there appears to be substantial differences in patient characteristics by extent of repair. Regarding our comprehensive TAAA experience,<sup>51</sup> about 10% of TAAA patients have a connective tissue disorder; however, this increases to 17% in extent II repairs and decreases to 5% in extent IV TAAA repair. Chronic aortic

**FIGURE 49-6** The Crawford classification of thoracoabdominal aortic aneurysm repairs. (Printed with permission from Baylor College of Medicine.)

dissection is present in nearly a third of patients; this proportion is increased in extent I and II repairs (39 and 44%, respectively) and decreased in extent III and IV repairs (19 and 11%, respectively). Furthermore, while roughly a quarter of TAAA patients have had a prior distal aortic repair, this rate is increased in extent III and IV repairs (42 and 36%)—this speaks to the progressive nature of repair in extents III and IV, as many of these prior repairs were abdominal aortic repairs.

An adequate preoperative assessment of physiologic reserve is critical in evaluating operative risk. Many patients have significant comorbidities; chronic pulmonary obstructive disease, coronary artery disease, hypertension, cerebrovascular disease, and peripheral vascular disease are all relatively common in TAAA repair. Chronic elevated serum creatinine levels ( $>3.0$  mg/dL) are relatively uncommon in patients undergoing TAAA repair, and affect 3% of patients in our experience.<sup>51</sup> Unless they require emergency operation, patients undergo a thorough preoperative evaluation with emphasis on cardiac, pulmonary, and renal function.

### Cardiac Status

Impaired myocardial contractility and reduced coronary reserve are common among elderly patients who undergo aortic reconstruction. Patients need substantial cardiac reserve in order to tolerate clamping of the thoracic aorta. Given the prevalence of preoperative cardiac disease and the physiologic strain of aortic clamping, it is not surprising that cardiac complications are a major cause of postoperative mortality. Reports indicate that cardiac disease has been responsible for 49% of early deaths and 34% of late deaths after TAAA repair, attesting to the importance of careful preoperative cardiac evaluation.<sup>20,52</sup>

Several imaging techniques are useful in preoperative screening for cardiac disease. Transthoracic echocardiography is noninvasive and can satisfactorily evaluate both valvular and biventricular function. Dipyridamole-thallium myocardial scanning identifies regions of myocardium that are reversibly ischemic, and it is more practical than exercise testing in this generally elderly population, whose exercise capacity is often limited by concurrent lower-extremity peripheral vascular disease. In patients with evidence of reversible ischemia on noninvasive studies, and in those with a significant history of angina or an ejection fraction of 30% or less, cardiac catheterization and coronary arteriography are performed. Patients who have asymptomatic aneurysms and severe coronary artery occlusive disease (ie, significant left main, proximal left anterior descending, or triple-vessel coronary artery stenosis) undergo myocardial revascularization before aneurysm repair. In appropriate patients, percutaneous transluminal angioplasty is carried out before surgery. If clamping proximal to the left subclavian artery is anticipated in patients in whom the left internal thoracic artery has been used as a coronary artery bypass graft, a left-carotid-to-subclavian bypass is typically necessary to prevent cardiac ischemia when the aortic clamp is applied.<sup>53</sup>

### Renal Status

Preoperative renal insufficiency has been a major risk factor for early mortality throughout the history of TAAA repair.<sup>49,54</sup> It was among the predictive variables selected in Svensson et al's<sup>54</sup> multivariable analysis of Crawford's complete experience with TAAA surgery in 1509 patients treated between 1960 and 1991. Patients with severely impaired renal function who are not receiving long-term hemodialysis

frequently require temporary hemodialysis early after operation and are clearly at increased risk for postoperative complications.

Although patients are not rejected as surgical candidates on the basis of renal function, careful assessment of renal function aids in estimating perioperative risk and adjusting treatment strategies accordingly. Renal function is assessed preoperatively by measuring serum electrolytes, blood urea nitrogen, and creatinine. Kidney size and perfusion can be evaluated by using the imaging studies obtained to assess the aorta. Patients who have poor renal function secondary to severe proximal renal artery occlusive disease are revascularized at operation by renal arterial endarterectomy, stenting under direct vision, or bypass grafting, with the expectation that renal function will stabilize or improve.<sup>52</sup>

Because of the nephrotoxic effects of vascular contrast agents, surgery is delayed (if possible) for 24 hours or longer after CT scanning or aortography has been performed. This is especially important in patients with preexisting renal impairment. Strategies to reduce the risk of contrast-induced nephropathy include periprocedural administration of acetylcysteine and intravenous hydration. If renal insufficiency occurs or worsens after contrast administration, the surgical procedure is postponed until renal function returns to baseline or is satisfactorily stabilized.

## Pulmonary Status

Pulmonary complications are the most common form of postoperative morbidity in patients who undergo DTAA and TAAA repairs. Most patients undergo pulmonary function screening with arterial blood gases and spirometry. Patients with an FEV<sub>1</sub> greater than 1.0 and a PCO<sub>2</sub> less than 45 mmHg are satisfactory surgical candidates. In suitable patients, borderline pulmonary function frequently is improved by smoking cessation, progressive treatment of bronchitis, weight loss, and a general exercise program that the patient follows for a period of 1 to 3 months before operation. However, surgery is not withheld from patients with symptomatic aortic aneurysms and poor pulmonary function. In such patients, preservation of the left recurrent laryngeal nerve, phrenic nerve, and diaphragmatic function is particularly important.

## OPEN SURGICAL REPAIR

### Anesthetic Strategies

Coordination among the surgeon, anesthesiologist, and perfusionist is critical during a DTAA or TAAA repair procedure. Management of hemodynamics during aortic clamping and unclamping, blood volume management, anticoagulation and hemostasis, and proper lung management occur in real time, with anticipation and preparation by the anesthesia team. Swan-Ganz catheters are routinely used for hemodynamic monitoring. The arterial catheter is placed in the right radial artery whenever the left subclavian artery flow may be interrupted during aortic clamping. A large-bore central

venous line is necessary for volume return. We reinfuse filtered, unwashed whole blood from the cell saver through a rapid infusion system during periods of substantial blood loss, such as when the aorta is opened. With careful scavenging of shed blood and meticulous surgical hemostasis, operations without the use of blood and blood products are frequently possible. However, when coagulopathy does occur after the cross-clamp is released, rapid replacement of blood components with fresh frozen plasma, platelets, and cryoprecipitate is necessary. Single lung ventilation, usually by a double-lumen endobronchial tube, is necessary for exposure, although this may not be critical in extent IV TAAA repairs. The lung is handled minimally during anticoagulation to prevent lung hematoma and contusion. Deflating the left lung reduces retraction trauma to the lung, improves exposure, and alleviates the risk of cardiac compression. When motor evoked potentials are used for spinal cord monitoring, muscle paralytics must be avoided. Sodium bicarbonate solution is routinely infused to prevent acidosis during aortic cross-clamping, and mannitol can be given before cross-clamping to enhance renal perfusion. Proximal blood pressure, afterload, and cardiac performance are closely monitored by Swan-Ganz catheter and transesophageal echocardiography probe when necessary and are aggressively maintained.

## Surgical Adjuncts for Organ Protection

Organ ischemia is a major source of the morbidity related to DTAA and TAAA repair. We currently employ a multimodal approach (Table 49-1) that is primarily based on the extent of repair in an attempt to maximize organ protection during these operations (Fig. 49-7).<sup>55</sup> The rationale for and details of several important strategies are discussed below.

### HEPARIN

Potential benefits of heparinization include preserving the microcirculation and preventing embolization. Additionally,

**TABLE 49-1: Current Strategy for Spinal Cord and Visceral Protection During Descending and Thoracoabdominal Aortic Aneurysm Repair**

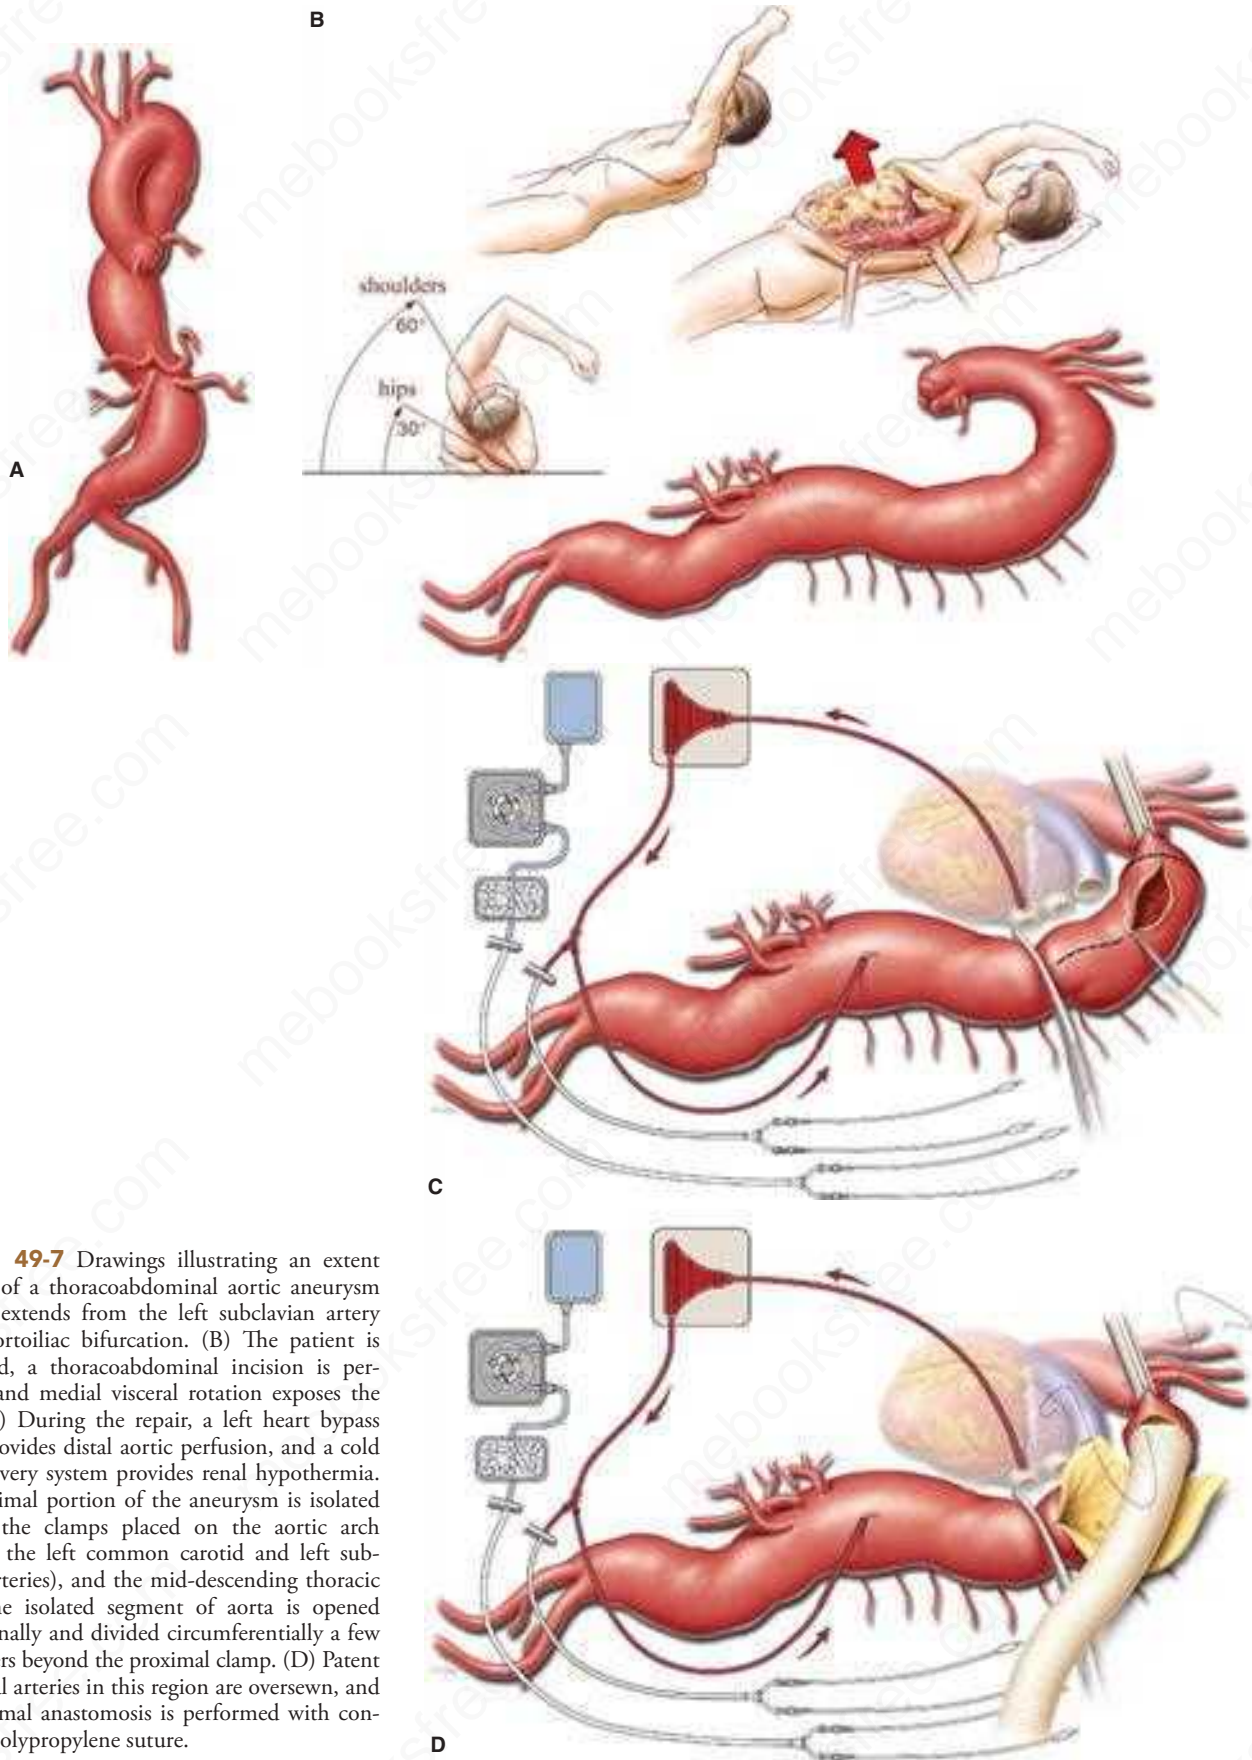

#### *All extents*

- Moderate heparinization (1 mg/kg)
- Permissive mild hypothermia (32-34°C, nasopharyngeal)
- Aggressive reattachment of segmental arteries, especially between T8 and L1
- Perfusion of renal arteries with 4°C solution when possible
- Sequential aortic clamping when possible

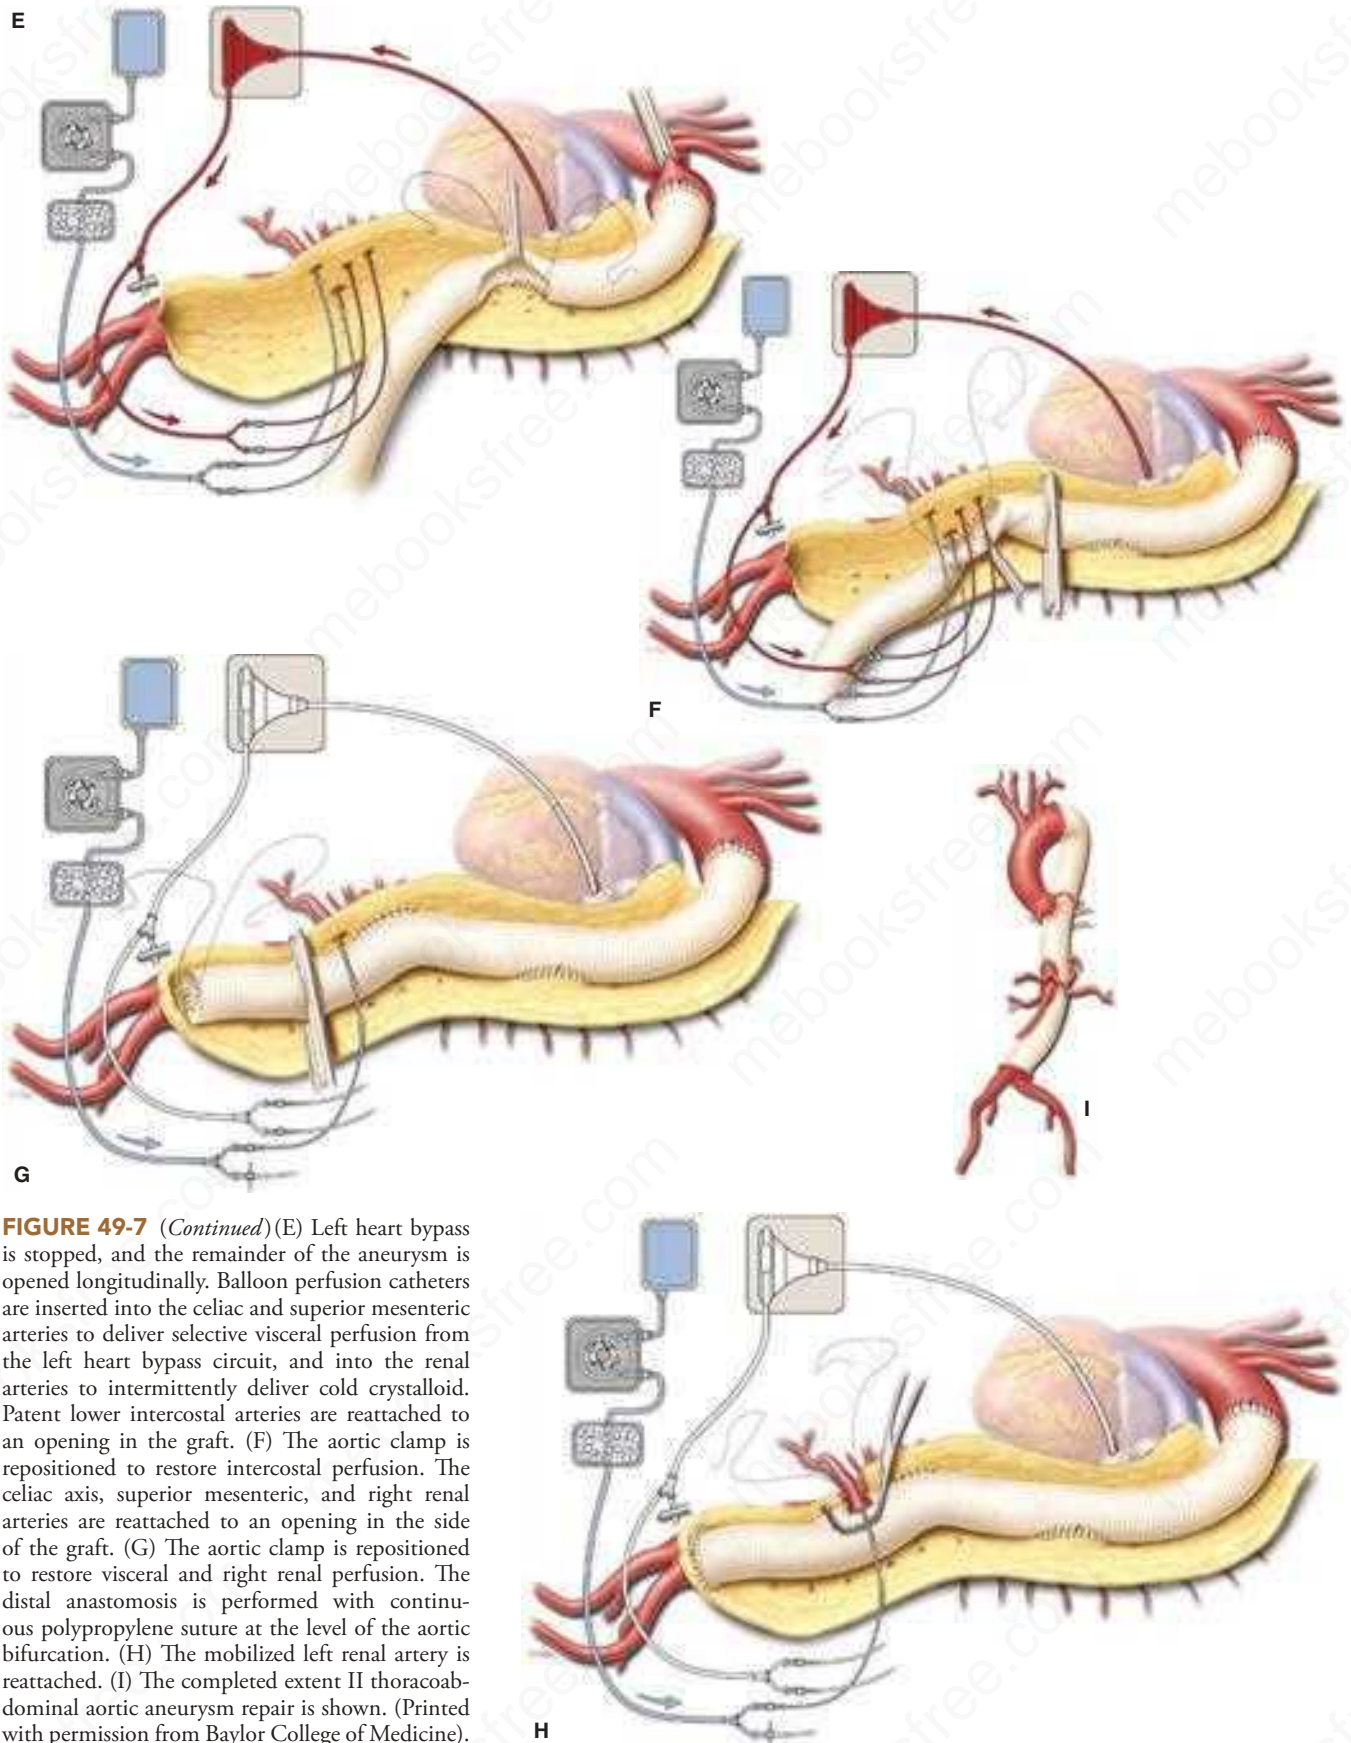

#### *Extent I and II thoracoabdominal repairs*

- Cerebrospinal fluid drainage
- Left heart bypass during proximal anastomosis
- Selective perfusion of celiac axis and superior mesenteric artery during intercostal and visceral anastomoses

**FIGURE 49-7** Drawings illustrating an extent II repair of a thoracoabdominal aneurysm (A) that extends from the left subclavian artery to the aortoiliac bifurcation. (B) The patient is positioned, a thoracoabdominal incision is performed, and medial visceral rotation exposes the aorta. (C) During the repair, a left heart bypass circuit provides distal aortic perfusion, and a cold renal delivery system provides renal hypothermia. The proximal portion of the aneurysm is isolated between the clamps placed on the aortic arch (between the left common carotid and left subclavian arteries), and the mid-descending thoracic aorta. The isolated segment of aorta is opened longitudinally and divided circumferentially a few centimeters beyond the proximal clamp. (D) Patent intercostal arteries in this region are oversewn, and the proximal anastomosis is performed with continuous polypropylene suture.

**FIGURE 49-7** (Continued) (E) Left heart bypass is stopped, and the remainder of the aneurysm is opened longitudinally. Balloon perfusion catheters are inserted into the celiac and superior mesenteric arteries to deliver selective visceral perfusion from the left heart bypass circuit, and into the renal arteries to intermittently deliver cold crystalloid. Patent lower intercostal arteries are reattached to an opening in the graft. (F) The aortic clamp is repositioned to restore intercostal perfusion. The celiac axis, superior mesenteric, and right renal arteries are reattached to an opening in the side of the graft. (G) The aortic clamp is repositioned to restore visceral and right renal perfusion. The distal anastomosis is performed with continuous polypropylene suture at the level of the aortic bifurcation. (H) The mobilized left renal artery is reattached. (I) The completed extent II thoracoabdominal aortic aneurysm repair is shown. (Printed with permission from Baylor College of Medicine).

by inhibiting the clotting cascade, the use of heparin may help to reduce the incidence of disseminated intravascular coagulation.

Heparin (1 mg/kg) is administered intravenously before aortic clamping or the start of left heart bypass (LHB). After this small heparin dose is administered, the activated clotting time generally ranges from 220 to 270 seconds.

### HYPOTHERMIA

Hypothermia decreases the metabolic demand of tissues and is protective during ischemic states. The protective effects of hypothermia on the spinal cord are well accepted. We routinely use mild passive systemic hypothermia during DTAA and TAAA repairs. The patient's temperature is allowed to drift down to a nasopharyngeal temperature of 32 to 33°C. After the aortic repair, rewarming can be accomplished by irrigating the thoracic and abdominal cavities with warm saline.

Profound systemic hypothermia on full cardiopulmonary bypass is an operative strategy for organ protection. Kouchoukos and colleagues<sup>56-58</sup> have reported that hypothermic cardiopulmonary bypass with circulatory arrest can safely and substantially protect against paralysis and renal, cardiac, and visceral organ system failure during operations on the thoracic and thoracoabdominal aorta. Despite these protective effects, many clinicians avoid using this approach, principally because of the associated risks of coagulopathy, pulmonary dysfunction, and massive fluid shift. We use hypothermic circulatory arrest selectively when the aneurysm anatomy precludes safe proximal clamping.

### LEFT HEART BYPASS

Disruption of blood flow to the spinal cord and abdominal viscera contributes significantly to the development of ischemic complications. Conversely, maintaining flow through spinal and visceral arteries during all or part of the anatomic repair should reduce the duration of organ ischemia and prevent associated morbidity. Borst et al<sup>59</sup> found that using LHB for distal perfusion during DTAA and TAAA repair effectively unloads the proximal circulation during aortic occlusion and maintains adequate perfusion of distal vital organs, thereby reducing early mortality and renal failure. Further, combined distal perfusion and aggressive reattachment of distal intercostal arteries decreased the risk of spinal cord damage.

Typically used during the proximal aortic anastomosis, LHB is achieved by establishing a temporary bypass from the left atrium to either the distal descending thoracic aorta (usually a few centimeters proximal to the origin of the celiac axis) or the femoral artery (most commonly the left), with a closed-circuit in-line centrifugal pump (Fig. 49-7C). The left atrial cannula is placed via an opening in the inferior pulmonary vein (Fig. 49-7C). When we first began using LHB, cannulation of the distal descending thoracic aorta (usually at the level of the diaphragm) was used solely as an alternative to femoral artery cannulation in patients with femoral or iliac artery occlusive disease. However, because this technique causes few complications and eliminates the

need for femoral artery exposure and repair, distal aortic cannulation has become our preferred approach. Careful examination of CT or MR images assists selection of an appropriate site for direct aortic cannulation. Areas with intraluminal thrombus (Fig. 49-4) are avoided because cannulation could lead to distal embolization. Bypass flows are adjusted to maintain normal proximal arterial and venous filling pressures. Flows between 1500 and 2500 mL/min are generally used. LHB facilitates rapid adjustment of proximal arterial pressure and cardiac preload, thereby reducing the need for pharmacologic intervention. Because LHB effectively unloads the left ventricle, it is useful in patients with suboptimal cardiac reserve.

### SPINAL CORD PROTECTION

Paraplegia remains an index complication specific to both distal aortic surgery and endovascular repair. Historically, rates for spinal cord deficits (paraplegia or paraparesis) have been as high as 30% for extent II aortic replacements.<sup>54</sup> Although the mechanism of developing paraplegia following spinal cord ischemia as part of open aortic repair is imperfectly understood, it is generally associated with interrupted distal aortic blood flow following proximal aortic clamping and the intraoperative loss of intercostal and lumbar arteries; additional factors include the role of the left subclavian and hypogastric arteries in perfusing the spinal cord (which tends to vary by patient), reperfusion injury, and the possible dissemination of embolic debris.<sup>60,61</sup> With modern operative techniques and spinal adjuncts, paraplegia rates in aortic centers are currently 1 to 5%.<sup>44,56,62,63</sup> Because multiple adjuncts are used in combination and are continuously evolving,<sup>64</sup> it is difficult to attribute the improvements in outcome to one technique.

**Cerebrospinal Fluid Drainage.** The drainage of cerebrospinal fluid (CSF) in the context of aortic surgery for spinal cord protection was tested in animal models in the early 1960s.<sup>65</sup> The rationale for CSF drainage was that it would enhance spinal perfusion by decreasing the pressure on the cord during aortic cross-clamping. Today, its use is widespread and specifically recommended by current US practice guidelines during both open and endovascular repairs in patients at high risk of developing paraplegia (Class I recommendation, level of evidence B).<sup>24</sup> In our study of 145 patients who underwent extent I or II TAAA repair, patients were randomly assigned to receive CSF drainage or no CSF drainage. Postoperatively, paraplegia or paraparesis developed in 9 patients (13%) in the control group but in only 2 patients (2.6%) in the CSF drainage group ( $p = .03$ ).<sup>66</sup> Although the safety of CSF drainage has been shown clinically,<sup>67</sup> known risks include intracranial bleeding, perispinal hematoma, meningitis, and spinal headaches.<sup>68</sup>

We routinely use CSF drainage in patients undergoing Crawford extent I or II TAAA repairs because of the higher risks of paraplegia in these extensive TAAA repairs. We selectively use CSF drainage during less extensive repairs, such as

DTAA or extent III or IV TAAA repairs, depending upon the individual risk factors involved; for example, we would use CSF drainage in a redo aortic operation in which the spinal collateral is compromised and a long cross-clamp time is anticipated because of the complex configuration of the aneurysm. The intrathecal catheter is placed through the second or third lumbar space preoperatively after induction of anesthesia and is maintained 1 to 2 days postoperatively in the intensive care unit. The catheter allows both monitoring of the CSF pressure and therapeutic drainage of the fluid. The CSF is allowed to drain passively from the catheter and can be aspirated with a closed collection system as needed to keep the CSF pressure between 8 and 10 mm Hg during the operation and between 10 and 12 mm Hg during the early postoperative period. Once the patients are awake and neurologic examinations confirm that they are able to move their legs, the CSF pressures are allowed to rise to a higher range of 15 to 18 mm Hg. To prevent intracranial hemorrhage, we avoid draining more than 25 mL per hour.

**Left Heart Bypass for Spinal Protection.** LHB appears to provide the greatest benefit to patients who undergo the more extensive repairs. Our own retrospective review of 1250 consecutive extent I or extent II TAAA repairs found that using LHB (in 666 cases) reduced the incidence of spinal cord deficits only in patients who underwent extent II repairs.<sup>69</sup> In patients who underwent extent I repairs, the incidence of paraplegia was similar in the LHB and no-LHB groups, even though the LHB group had significantly longer aortic clamp times. This finding suggests that, by providing spinal cord protection, LHB gives the surgeon more time to create secure anastomoses. A propensity-score analysis of 387 of our patients who underwent DTAA repair with (n = 46) or without (n = 341) LHB during the construction of the proximal anastomosis found no effect of LHB on postoperative paraplegia and paraparesis rates.<sup>70</sup> Because patients who undergo extensive TAAA repairs (extents I and II) are at greatest risk of postoperative paraplegia or paraparesis, we routinely use LHB to provide distal aortic perfusion during the proximal portion of the aortic repair.

**Segmental Artery Reattachment and Sequential Graft Clamping.** Because of the often tenuous nature of the blood supply to the spinal cord, we take an aggressive approach to reattaching patent segmental arteries. Intimal atherosclerosis, particularly in medial degenerative fusiform aneurysms, obliterates many intercostal and lumbar arteries and complicates matters anatomically. Pairs of patent segmental arteries from T8 to L1 are selectively reattached as patches to one or more openings made in the graft (Fig. 49-7E). Large arteries with little or no back-bleeding are considered particularly important. When none of these arteries is patent, endarterectomy of the aortic wall and removal of calcified intimal disease can be considered as a means of identifying arteries suitable for reattachment. Infrequently, a small-diameter graft may be used to facilitate bypass reattachment of selected arteries. After intercostal arteries are

reattached, the proximal clamp is often moved down the graft to restore intercostal perfusion. Sequential clamping restores perfusion to the proximal branch vessels and will decrease the ischemic time to the spinal cord. However, this benefit needs to be weighed against the additional time needed to control the potential bleeding from the proximal aortic anastomosis, the intercostal patch, and the collateral intercostal and lumbar branches that often results when the clamp is moved below the intercostal patch. In addition, the possibility of dislodging emboli that could lodge in branching arteries and create localized ischemia should be considered. The reattachment of intercostal arteries appears most significant in extent II TAAA repair; recently, we identified such reattachment independently predicted a 54% reduction in the risk of developing permanent paraplegia in such repairs.<sup>51</sup>

**Spinal Cord Monitoring.** Somatosensory evoked potential (SSEP), motor evoked potential (MEP), and near-infrared spectroscopy (NIRS) monitoring have been used for intraoperative assessment of spinal cord function. MEP monitoring involves electrical excitation of the motor cortex or motor neurons and measuring the amplitude of the resulting motor response in the peripheral muscles of the arms and legs. Monitoring MEPs allows real-time assessment of spinal cord motor function and was approved for this use during surgical TAAA repair by the FDA in 2003. Because the motor function of the anterior horn of the spinal cord is more susceptible than the posterior horn to ischemia and infarction, MEP changes are a sensitive indicator of spinal cord ischemia and are predictive of adverse neurological events. In contrast, SSEP monitoring is less sensitive because the sensory pathways on the dorsal horn are more resistant to injury and are sometimes spared when ischemic injury occurs. Irreversible loss of either MEPs or SSEPs is predictive of immediate neurologic deficit on recovery.<sup>60</sup> Less is known about the effectiveness of NIRS as applied to distal aortic repair, but it appears to have promising sensitivity and response time.<sup>60,71</sup> Importantly, monitoring MEPs precludes the use of neuromuscular paralytic agents during repair, adding complexity to anesthetic management. Although we have used MEP monitoring in the past for extent II and other selective TAAA repairs, we no longer use this approach in part because of the risk of false positive results; however, in expert hands, this remains a valuable approach.<sup>72</sup>

**Regional Spinal Hypothermia.** Regional spinal cord hypothermia can be accomplished by direct infusion of cold perfusate into the epidural or intrathecal space and by intravascular cold perfusion of isolated thoracic aortic segments (with the expectation that the intercostal vessels will deliver the cold perfusate to the spinal cord). A series of 337 TAAA repairs reported by Cambria and colleagues<sup>73</sup> showed that, in patients who underwent extent I, II, or III TAAA repairs, the incidence of spinal cord ischemic injury was reduced from 19.8 to 10.6% after the introduction of epidural cooling at their institution in 1993. Using an epidural catheter containing cold saline, Inoue et al<sup>74</sup> demonstrated its effectiveness in

reducing epidural temperature in a leporine model; in clinical application, it was used in 37 distal aortic repairs without any postoperative spinal cord deficits.<sup>75</sup> A similar technique, cold perfusion into isolated aortic segments, has been tested in animal models to show that cord temperature and, consequently, the extent of ischemic spinal cord injury can be effectively reduced by this method.<sup>76</sup>

**Collateral Network Concepts.** Collateral network concepts refute the existence of dominant intercostal and lumbar arteries (eg, the artery of Adamkiewicz) and imply that reattaching select intercostal arteries is largely unnecessary;<sup>77</sup> instead, the network of small arteries that perfuse the spinal cord may readily remodel following ischemic insult to provide sufficient perfusion of the spinal cord.<sup>78</sup> Efforts to further develop this approach have led to emerging endovascular-spinal-cord preconditioning techniques by selectively coiling segmental arteries to promote remodeling and better tolerate subsequent open distal aortic repair.<sup>79</sup> Staged distal aortic repair is also being developed as a method to facilitate remodeling of the spinal cord between repairs, and porcine models showed this to be effective at preventing paraplegia after extensive aortic repair if the two stages were separated by 7 days.<sup>80</sup> While staged repair may prove difficult in extensive open distal aortic repairs, this approach is not dissimilar from current approaches to extensive distal aortic dissection—typically only the dilated section is repaired, and thus, often a DTAA or an extent I repair is followed by an extent III or IV repair.<sup>62</sup>

**Rescue Measures for Spinal Cord Deficit.** Postoperative management remains critical to spinal cord protection. Adequate blood pressure, preload, and cardiac inotropic state are carefully maintained to keep spinal perfusion sufficient. In the absence of postoperative bleeding, blood pressure should be kept near its preoperative baseline level. Delayed paraplegia can arise hours to days after aortic surgery.<sup>81</sup> In the immediate postoperative period, strategies to reverse paraplegia and paraparesis include inducing systemic hypertension; placing a CSF drain, if one is not already present; decreasing CSF pressure; administering cardiac inotropes, mannitol, or steroids; correcting anemia; and preventing fever. Recovery from paraplegia is possible, but if cord function does not return promptly after these measures are taken, such a recovery is not likely.

## RENAL PROTECTION

Postoperative renal failure after DTAA and TAAA remains an important complication and is predictive of mortality.<sup>82</sup> Although distal aortic perfusion with LHB provides renal perfusion during proximal anastomosis, the ability to provide continued renal protection is valuable. Our approach to renal protection for repair of TAAA has evolved from the results of two of our randomized clinical trials.<sup>83,84</sup> Once the renal vessels are exposed during distal repair, the renal arteries can be directly perfused with cold (4°C) perfusate (Fig. 49-7E). Our current technique is to provide an initial

bolus of 200 to 300 mL of cold crystalloid perfusate that is administered to each kidney, followed by the intermittent infusion of 100 to 150 mL per kidney, which is delivered every 10 to 15 minutes until arterial flow is restored. The volume and frequency of perfusate delivery are adjusted to avoid fluid overload or hypothermia (a systemic temperature of 32°C is targeted). First, we reported on a group of patients who underwent Crawford extent II TAAA repair with LHB and who were randomly assigned to receive either renal artery perfusion of cold LR solution for renal cooling or to isothermic blood perfusion from the LHB circuit. Multivariate analysis confirmed that cold crystalloid perfusion was independently protective against acute renal dysfunction.<sup>84</sup> Second, we reported on a group of patients who underwent Crawford extent II or III TAAA repair and compared the outcomes of cold blood to cold crystalloid for renal protection. Although we found no significant difference between patients regarding renal failure or early death, a trend toward less paraplegia was observed in the cold crystalloid group.<sup>83</sup> Wynn and colleagues<sup>85</sup> were able to demonstrate the effectiveness of moderate systemic hypothermia and cold (4°C) renal perfusion using a similar approach in a retrospective review of 455 patients who underwent TAAA repair. Among aortic centers, there is considerable variation in perfusate; some centers have shifted from lactated Ringer's solution to histidine-tryptophan-ketoglutarate (HTK) solution.<sup>86</sup> Current US aortic guidelines recommend the use of cold renal perfusion (class IIB, level of evidence B).<sup>24</sup> Other groups continue to selectively perfuse the renal arteries with blood from the LHB circuit.

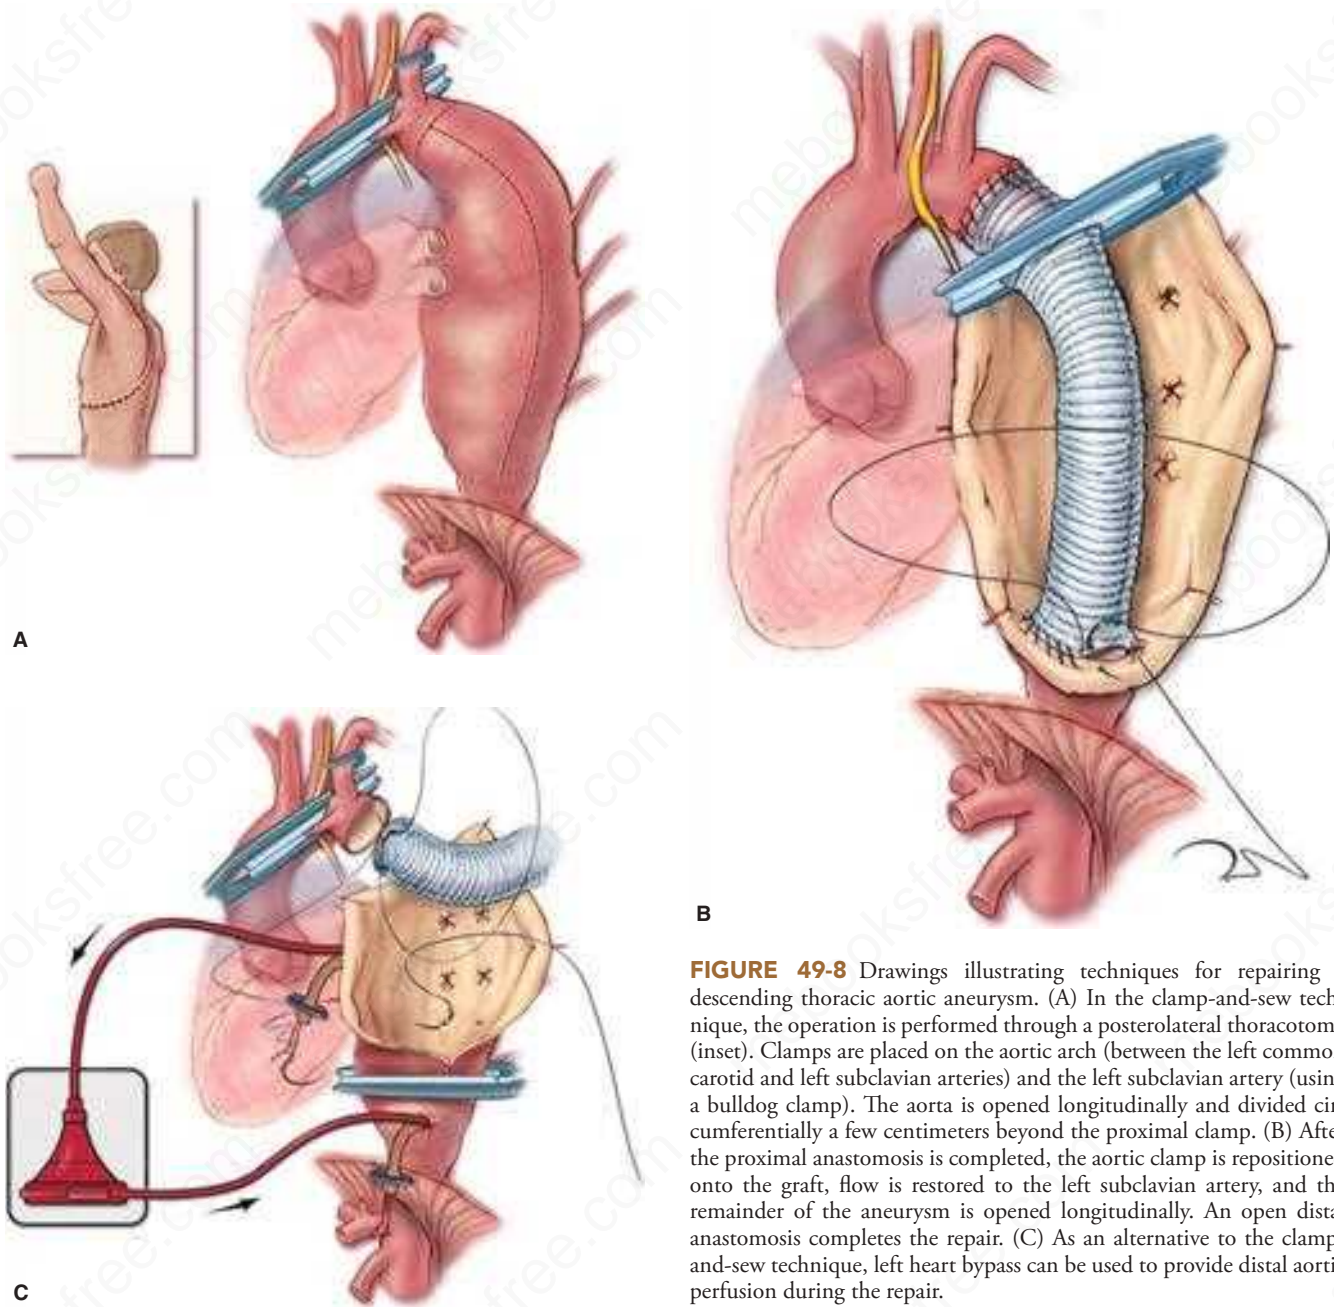

## VISCERAL PROTECTION

Similarly, distal aortic perfusion by LHB provides flow to the mesenteric branches during the initial portion of a TAAA repair. Once the visceral origins are exposed, selective visceral perfusion can be delivered through separate balloon perfusion catheters that are placed within the origins of the celiac and superior mesenteric arteries; these catheters are attached to the LHB circuit via a Y-line from the arterial perfusion line (Fig. 49-7C). This system provides oxygenated blood to the abdominal viscera while the intercostal and visceral branches are being reattached to the graft (Figs. 49-7E-F). Reducing hepatic ischemia in this fashion may decrease the risk of postoperative coagulopathy, and reducing bowel ischemia may decrease the risk of bacterial translocation.

## Operative Techniques

### INCISIONS AND AORTIC EXPOSURE

Aneurysms limited to the descending thoracic aorta are approached through a full posterolateral thoracotomy (Fig. 49-8A). In most cases, the left pleural space is entered through the sixth intercostal space; however, if the aneurysm predominantly involves the upper portion of the descending thoracic aorta, the fifth intercostal space provides better access to the distal aortic arch. Exposure of the distal descending

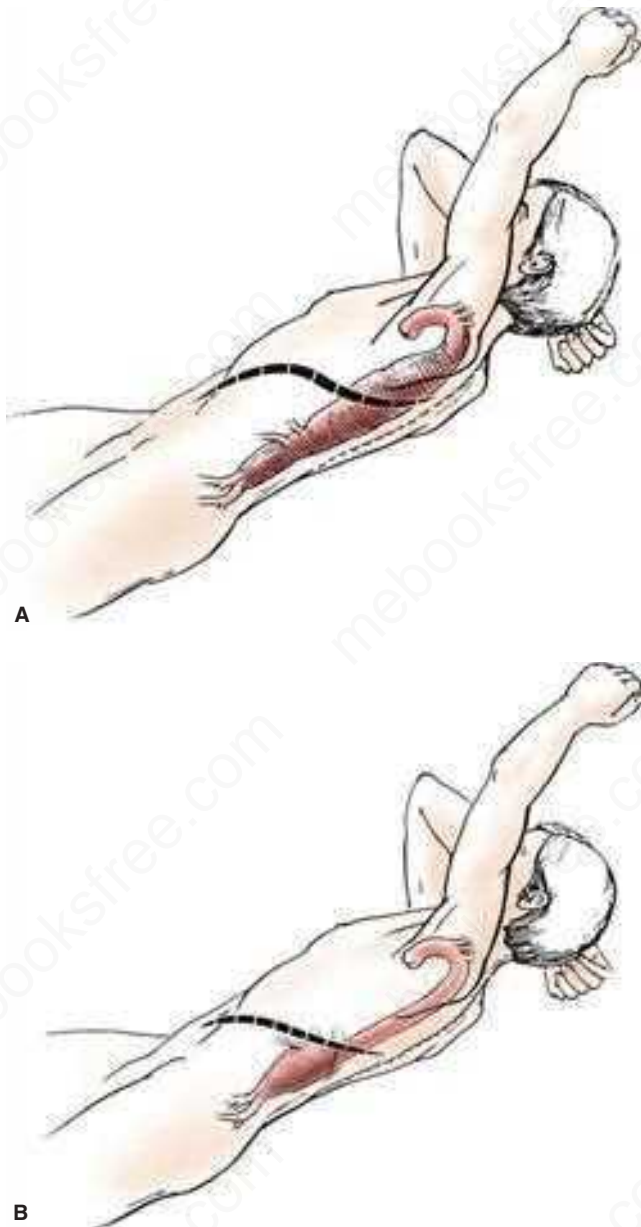

**FIGURE 49-8** Drawings illustrating techniques for repairing a descending thoracic aortic aneurysm. (A) In the clamp-and-sew technique, the operation is performed through a posterolateral thoracotomy (inset). Clamps are placed on the aortic arch (between the left common carotid and left subclavian arteries) and the left subclavian artery (using a bulldog clamp). The aorta is opened longitudinally and divided circumferentially a few centimeters beyond the proximal clamp. (B) After the proximal anastomosis is completed, the aortic clamp is repositioned onto the graft, flow is restored to the left subclavian artery, and the remainder of the aneurysm is opened longitudinally. An open distal anastomosis completes the repair. (C) As an alternative to the clamp-and-sew technique, left heart bypass can be used to provide distal aortic perfusion during the repair.

thoracic aorta is enhanced by dividing the costal margin without dividing the diaphragm.

The full thoracoabdominal incision extends from the left posterior chest (between the scapula and the spine), crosses the costal margin, and traverses obliquely to the umbilicus. The length and level varies according to the anatomy of the aneurysm. The incision is gently curved as it crosses the costal margin to reduce the risk of tissue necrosis at the apex of the lower portion of the musculoskeletal tissue flap (Fig. 49-9A). Stabilized on a bean bag, the patient is placed in a modified right lateral decubitus position with the shoulders placed at 60° to 80° and the hips rotated to 30° to 40° from

horizontal. In extent I and II repairs, which require access to the left subclavian artery and distal arch in the upper chest, our standard approach is through the sixth intercostal space. Rarely, the upper or lower ribs may be divided posteriorly to achieve additional proximal or distal exposure, respectively. For extent III aneurysm repairs, entering through the seventh or eighth intercostal space will allow adequate access. Extent IV aneurysms are approached via a straight oblique incision through the ninth or tenth interspace (Fig. 49-9B). Ending the incision distally at the level of the umbilicus will allow access to the aortic bifurcation. The incision can be extended toward the pubis if iliac aneurysms also require repair.

**FIGURE 49-9** Drawings of the typical incisions used in thoracoabdominal aortic aneurysm repairs. (A) A curvilinear incision is used to approach the aorta in extents I, II, and III thoracoabdominal aneurysm repairs. (B) A straighter, oblique incision is used to approach extent IV thoracoabdominal aortic aneurysm repairs.

For thoracoabdominal access, the diaphragm is divided partially or completely in a circular fashion to protect the phrenic nerve and to preserve as much diaphragm as possible. The crus of the diaphragm is divided at the hiatus, and a 3- to 4-cm rim of diaphragmatic tissue is left posterolaterally on the chest wall to facilitate closure when the operation is complete. Below the diaphragm, the retroperitoneum is entered lateral to the left colon, and medial visceral rotation is performed to expose the aorta. A dissection plane is developed anterior to the psoas muscle, and the left kidney, left colon,

spleen, and left ureter are retracted anteriorly and to the right. The abdominal aortic segment is approached transperitoneally; opening the peritoneum permits direct inspection of the abdominal viscera and its blood supply after aortic reconstruction is completed. An entirely retroperitoneal approach can be used in patients with a “hostile abdomen,” that is, patients with multiple prior abdominal operations or a history of extensive adhesions, peritonitis, or both.

The left renal artery is identified but generally does not require mobilization. The aorta is approached laterally to avoid injury to the mesenteric vessels and the abdominal organs. Commonly, a large lumbar branch of the left renal vein courses posteriorly around the aorta. This branch may be ligated and divided as needed. An anomalous retroaortic left renal vein is occasionally encountered and should be preserved. If the retroaortic renal vein or its tributaries require division for exposure, direct reanastomosis or interposition grafting to the inferior vena cava can be performed if the left kidney appears congested and shows distended collaterals.

### PROXIMAL ANASTOMOSIS

For DTAA and extent I and II TAAA repairs, options for establishing proximal control include applying a proximal aortic clamp distal to the left subclavian artery; applying an aortic clamp between the left subclavian and the left carotid artery and applying a separate bulldog clamp to the left subclavian artery; applying an aortic clamp to an existing graft during an elephant trunk operation; or open anastomosis under hypothermic circulatory arrest with full cardiopulmonary bypass when an aortic clamp cannot be safely applied. The decision is based on the anatomy of the aneurysm. We use aortic clamping distal to the left subclavian artery whenever possible, although others have advocated using circulatory arrest routinely.<sup>56</sup>

In aneurysms suitable for aortic clamping, the distal aortic arch is gently mobilized by dividing the remnant of the ductus arteriosus. The vagus and recurrent laryngeal nerves are identified. The vagus nerve may be divided below the recurrent nerve to provide additional mobility, thereby protecting the recurrent nerve from injury. Preserving the recurrent laryngeal nerve is particularly important in patients with chronic obstructive pulmonary disease and reduced pulmonary function. If the aneurysm encroaches upon the left subclavian artery, clamping proximal to the left subclavian artery should be anticipated; the left subclavian artery is then circumferentially mobilized to enable placement of a bulldog clamp.

After heparin is administered, the proximal clamp is applied to the proximal descending thoracic aorta or the distal transverse aortic arch between the left common carotid and left subclavian arteries (Figs. 49-7B and 49-8A). When LHB is used, it is initiated at a flow rate of 500 mL/min just before the proximal aorta is clamped. After the proximal clamp is applied, LHB flow is increased to 2 L/min and a second distal aortic clamp is placed between T4 and T7 (Fig. 49-7C). After the aorta is opened, patent upper

intercostal arteries are oversewn (Fig. 49-8C). In cases of chronic dissection, the septum between the true and false lumens is completely removed. The aorta is transected 2 to 3 cm beyond the proximal clamp and is separated from the esophagus to allow the surgeon to place full-thickness sutures in the aortic wall without injuring the esophagus. A 22- or 24-mm, gelatin-impregnated woven Dacron graft is used in most patients. The proximal anastomosis is performed with continuous polypropylene suture (Fig. 49-7D). Most anastomoses are made with 3-0 polypropylene suture; however, in patients with particularly fragile aortic tissues, such as patients with acute aortic dissection or Marfan syndrome, 4-0 polypropylene sutures are commonly used. Felt strips are generally not used; instead, intermittent polypropylene mattress sutures with felt pledgets are used to reinforce selected portions of the anastomoses. The use of surgical adhesives is avoided in these operations.

### Open Anastomosis Under Hypothermic Circulatory Arrest.

In repairs of large aneurysms at the distal arch or aneurysms with enormous size, contained rupture, or in redo operations in which safe dissection and clamping are not possible, an alternative strategy is total cardiopulmonary bypass with hypothermic circulatory arrest. Arterial inflow is established by placing a cannula in the distal aorta or the femoral artery, depending on patient-specific factors. Venous drainage is usually established by inserting a long, multiholed cannula into the left femoral vein and advancing it into the right atrium with transesophageal echocardiographic guidance. The left atrium or left ventricle can be vented via a right-angled sump cannula placed in the left pulmonary vein to prevent cardiac distension. Total cardiopulmonary bypass is initiated, and the patient is cooled to electrocerebral silence. Circulatory arrest is initiated, and the aneurysm is opened. Direct antegrade cerebral perfusion into the left carotid artery can be accomplished via a separate balloon catheter arising from the arterial limb of the circuit. An open proximal anastomosis is performed. After this anastomosis is completed, a Y-limb from the arterial line is connected to a side branch of the graft. The graft is deaired and clamped, pump flow to the upper body is resumed, and the remainder of the aortic repair is performed.

**Elephant Trunk Repairs.** A staged operative procedure is preferred in patients who present with extensive aneurysmal disease involving the ascending aorta, aortic arch, and descending thoracic or thoracoabdominal aorta (Fig. 49-10A). When the DTAA or TAAA is not causing symptoms and is not substantially larger than the ascending aorta, the proximal aortic repair is performed first. This allows treatment of valvular and coronary artery occlusive disease during the first operation.

Our current preference for reconstruction of the innominate, left carotid, and left subclavian artery is separate end-to-end anastomoses with a branched trifurcated graft (Fig. 49-10B). The bypass to the left subclavian artery during the first stage is not critical, and the left subclavian artery origin

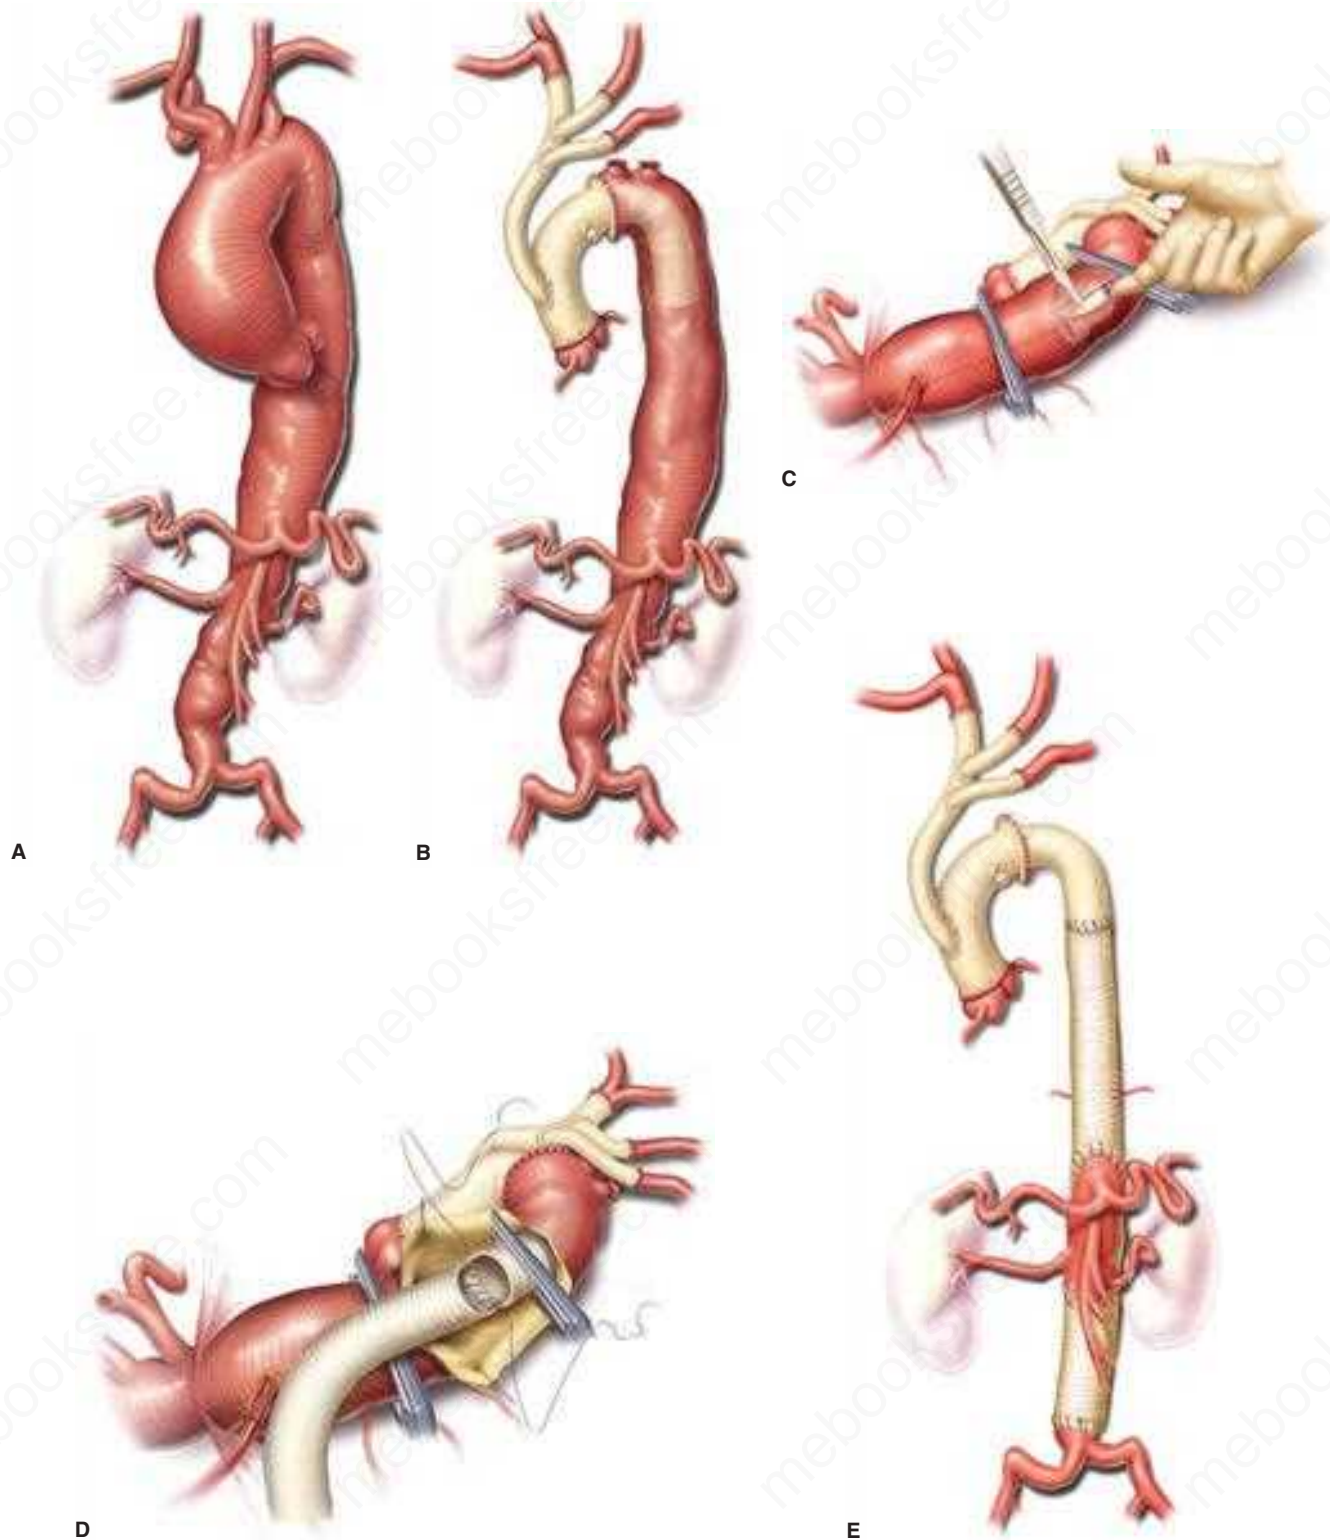

can remain intact on the native aorta. The aorta itself can be replaced with a skirted elephant trunk graft, which facilitates the distal aortic anastomosis to aneurysmal tissue, because the skirt accommodates any size discrepancy between the graft and native aorta. The proximal aortic anastomosis is placed to the supra-avalvular ascending aorta, and the distal skirt anastomosis can be placed fairly anteriorly on the aortic arch at the level of the innominate artery, facilitating hemostasis. The proximal end of the trifurcated graft is then anastomosed to an opening in the mid-ascending aspect of the aortic graft. The distal aortic anastomosis later becomes unimportant when the elephant trunk anastomosis to the descending aorta is completed at the second stage (Fig. 49-10D). The presence of the elephant trunk graft within the descending aorta allows secure clamping of even very large aneurysms distal to the left subclavian artery. If the left subclavian artery was not bypassed during the arch vessel reconstruction, a side branch from the descending aorta can be anastomosed to the subclavian artery from the left chest during the second stage. During the second stage repair, an ultrasound probe may be used to identify the distal end of the elephant trunk before incision.

**Reversed Elephant Trunk Repairs.** Conversely, in patients with similarly extensive aneurysmal disease who present with a DTAA or TAAA that has ruptured, causes symptoms (eg, back pain), or is considerably larger than the ascending aorta (Fig. 49-11A), the DTAA or TAAA is treated during the initial operation, and the ascending aorta and transverse aortic arch are repaired in a second procedure. During this “reversed” elephant trunk repair (Fig. 49-11B), a portion of the proximal end of the aortic graft is inverted down into the lumen during the first operation and is later used to facilitate second-stage repair of the ascending and transverse aortic arch.<sup>87</sup>

### INTERCOSTAL PATCH ANASTOMOSIS AND COMPLETION OF THE DTAA REPAIR

After the proximal anastomosis is completed, LHB is discontinued and the distal aortic clamp is removed. The remainder of the aneurysm is opened longitudinally to its distal extent (Fig. 49-7E). The blood in the open aorta is scavenged via cell saver and returned as whole blood by a rapid infuser system. When intraluminal thrombus is present, it is evacuated by hand. If the aneurysm was clamped proximal to the left subclavian artery, the aortic clamp is moved down onto the graft and the left subclavian artery clamp is removed; this restores blood flow to the left vertebral artery and to spinal collaterals. For repairs that extend to the diaphragm or beyond, patent lower intercostal arteries are selected and reattached to an opening cut in the side of the graft. If the aortic tissue is particularly friable, a separate, 8-mm graft can be attached in an end-to-end fashion to the selected intercostal vessels. In DTAA repairs, the distal anastomosis is then performed (Fig. 49-8B) as an open distal anastomosis. For aneurysms arising from chronic dissections, the membrane between the true and false lumen is fenestrated distally to ensure that both lumens are perfused.

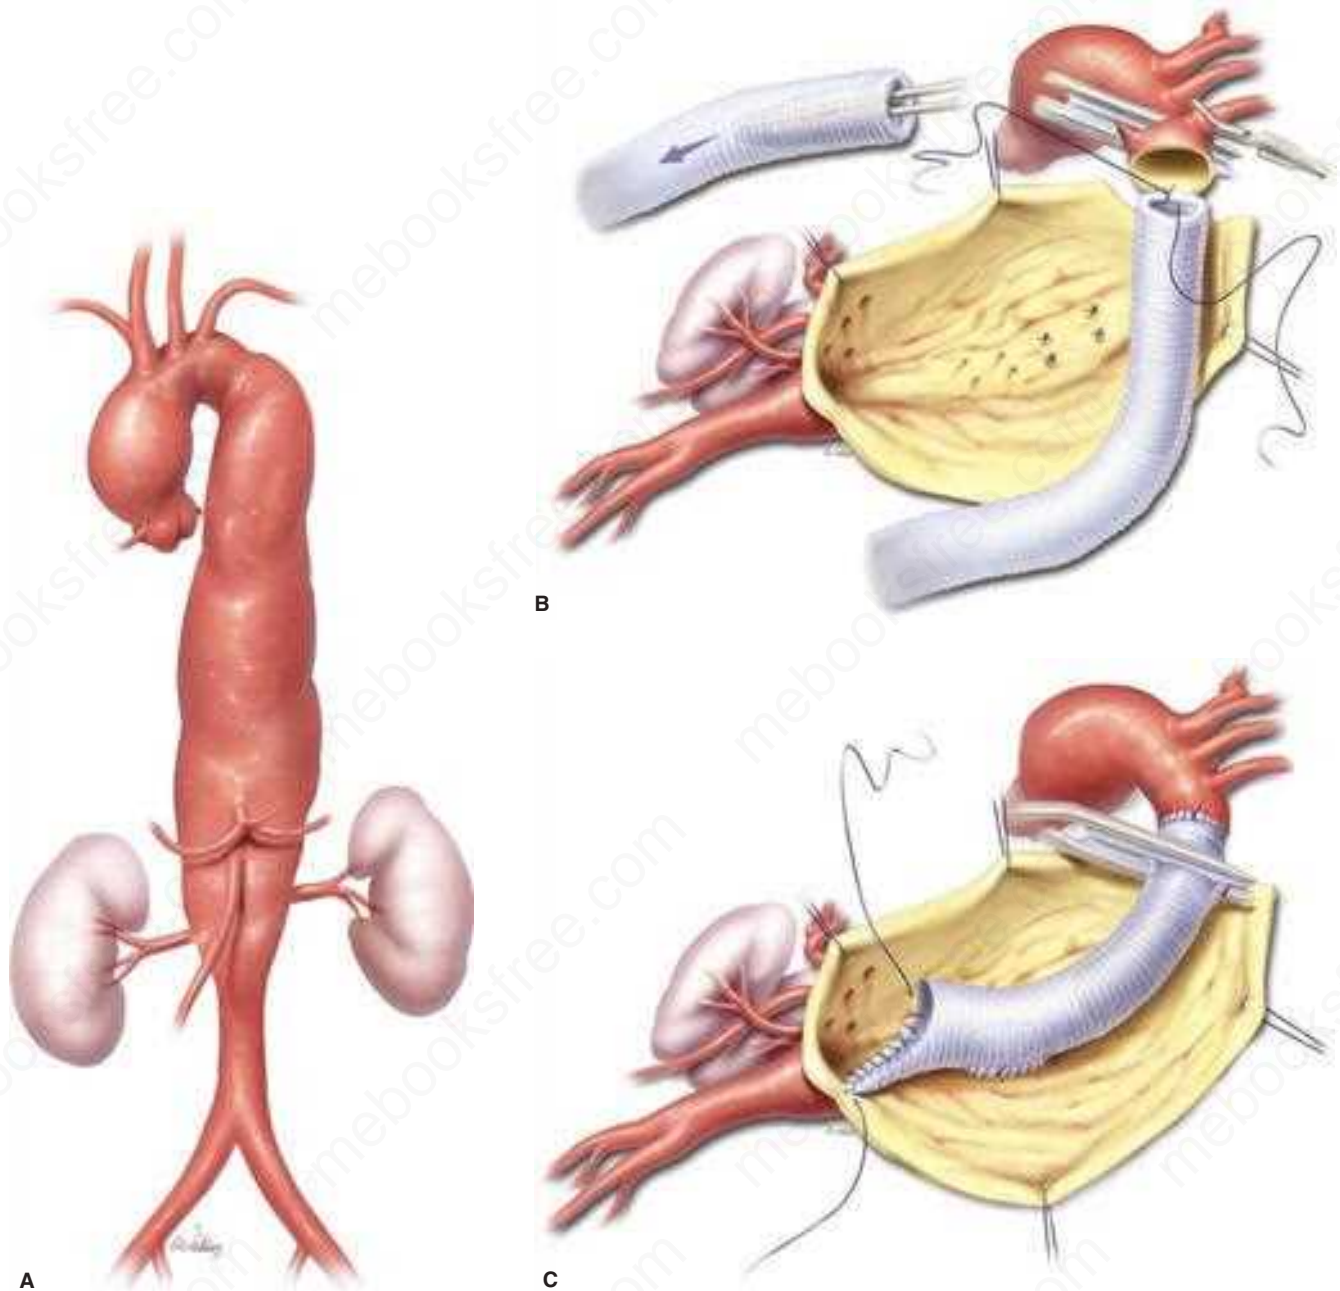

**FIGURE 49-10** Drawings illustrating the two-stage elephant trunk repair of an extensive aneurysm (A) involving the ascending, transverse arch, and entire thoracoabdominal aorta. (B) The first stage includes graft replacement of the ascending aorta and transverse aortic arch. A segment of the graft (the elephant trunk) is left suspended within the aneurysmal descending thoracic aorta. (C) During the second stage, the elephant trunk is retrieved and (D) used for the proximal anastomosis. (E) The completed repair includes reattachment patches for a pair of intercostal arteries and the visceral arteries. (Figures B-D reproduced with permission from Baylor College of Medicine. Figure E reproduced with permission from LeMaire SA, Price MD, Parenti JL, et al: Early outcomes after aortic arch replacement by using the Y-graft technique, *Ann Thorac Surg.* 2011 Mar; 91(3):700-707.)

### VISCERAL BRANCH VESSEL ANASTOMOSES

In patients with TAAAs, after the descending thoracic aortic repair is completed, the remainder of the aneurysm is opened longitudinally (Fig. 49-7E). This incision runs posterior to the origin of the left renal artery and continues to the distal extent of the aneurysm. When present, the remaining dissecting membrane is excised. The origins of the visceral and renal branches are identified. Cold

perfusate is intermittently delivered to the renal arteries via balloon catheters. In patients receiving LHB, balloon cannulas are also placed in the celiac and superior mesenteric arteries so that selective visceral perfusion can be delivered from the pump circuit. Subsequently, the celiac, superior mesenteric, and renal arteries are reattached. In extent I repairs, the reattachment of the visceral arteries is often incorporated into a beveled distal anastomosis

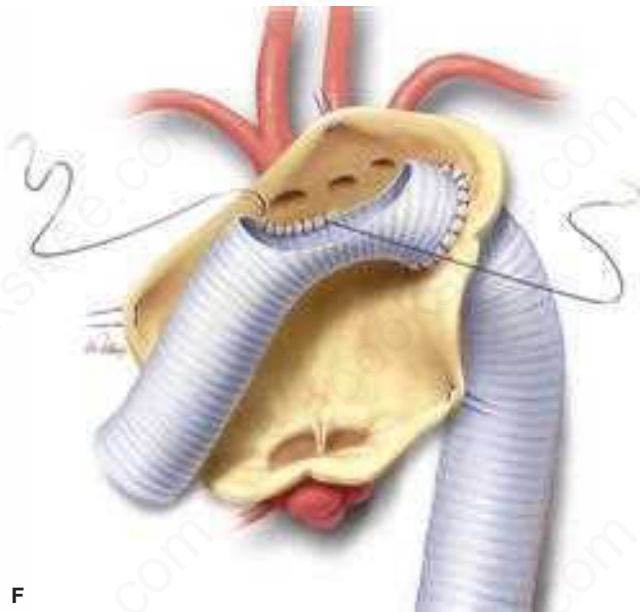

**FIGURE 49-11** Drawings illustrating the two-stage reversed elephant trunk repair of an extensive aneurysm (A) involving the ascending, transverse arch, and thoracoabdominal aorta. (B) The first stage involves graft replacement of the thoracoabdominal aorta. The proximal portion of the graft is invaginated, and the folded edge is used to create the proximal anastomosis. (C) After reattachment of intercostal arteries, a beveled distal anastomosis is performed behind the visceral ostia.

D

E

F

G

**FIGURE 49-11** (Continued) (D) After the first stage is completed, a segment of graft (the elephant trunk) is left suspended within the descending thoracic aortic graft. (E) During the second stage, the elephant trunk is retrieved through the open aortic arch and (F) used to replace the arch and ascending aorta, (G) which completes the repair.

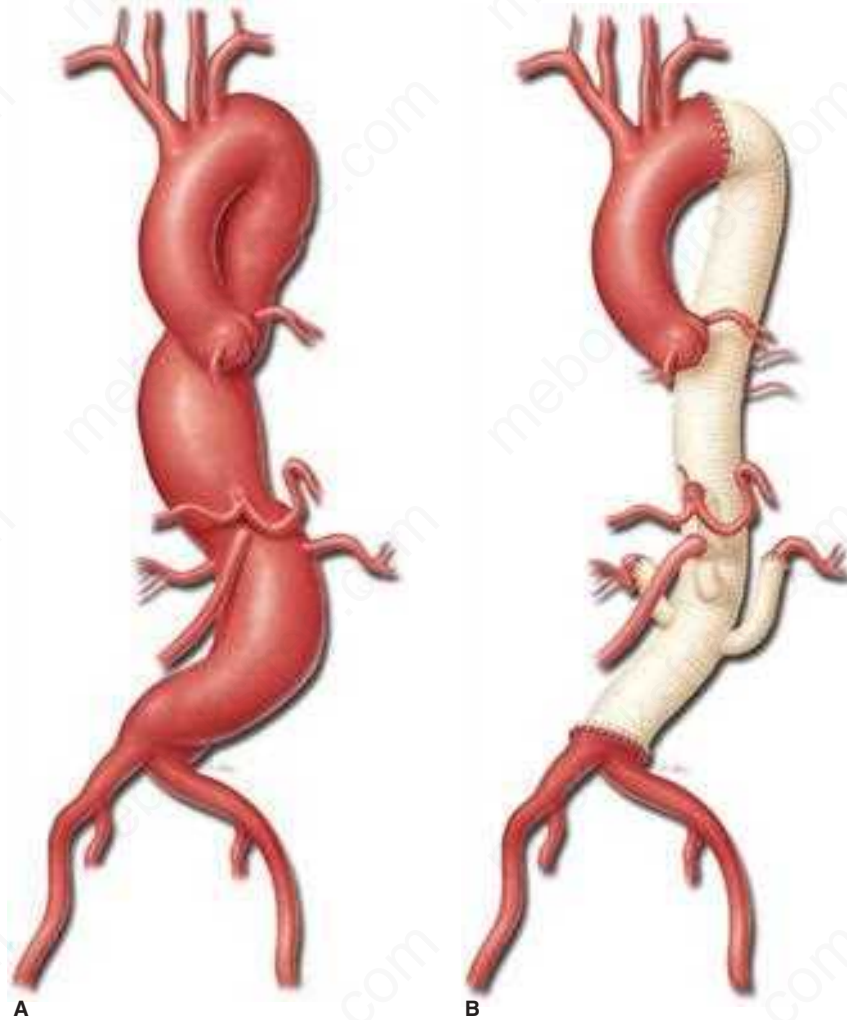

(Fig. 49-11C), but in extent II and III repairs, the visceral artery origins are reattached to one or more oval openings in the graft (Fig. 49-7F). Commonly, the origin of the left renal artery is displaced laterally and is best attached to a separate opening in the graft (Fig. 49-7H). Patients with genetic disorders such as Marfan or Loeys-Dietz syndrome are prone to aneurysms involving their visceral reattachment patch; a multibranch graft enables separate bypasses to each of the vessels, thereby minimizing the amount of remaining aortic tissue and reducing the risk of recurrent aneurysms. Multibranch grafts are also useful in patients with large aneurysms that have caused wide displacement of the celiac, superior mesenteric, and renal arterial ostia (Fig. 49-12). Visceral artery stenosis is typically encountered in at least 25% of cases and necessitates endarterectomy (if anatomically suitable), stenting, or interposition bypass grafting.<sup>54,88</sup>

### DISTAL AORTIC AND ILIAC ANASTOMOSES

When the TAAA extends below the renal arteries, a distal anastomosis is performed near the aortic bifurcation (Fig. 49-7H). In patients with iliac artery aneurysms, a bifurcation graft is sewn onto the end of the straight graft; the graft's limbs are then anastomosed to the common iliac, external iliac, or common femoral artery, depending on the extent of disease. The right limb of the bifurcation graft is tunneled retroperitoneally into the pelvis near the right iliac artery. Exposure of the left iliac artery is more straightforward from the left retroperitoneal incision. As needed for stenosis or extensive calcification, endarterectomy may be performed or stents may be used under direct vision to repair one or both iliac arteries.

### CLOSURE

After all clamps are removed, heparin is reversed with protamine sulfate. Hemostasis is achieved by surgically

**FIGURE 49-12** Drawings showing (A) a thoracoabdominal aortic aneurysm with wide displacement of the celiac, superior mesenteric, and both renal arterial ostia. (B) The aorta has been replaced with a multibranch graft that facilitates separate reattachment of each of the visceral arteries. (Printed with permission from Baylor College of Medicine.)

reinforcing the anastomoses and administering blood products as necessary. The renal, visceral, and peripheral circulations are assessed. To ensure that renal function is adequate, blue dye is administered intravenously, and transit time to urine output is measured. The bowel, spleen, and liver are all assessed for adequacy of perfusion. The spleen is examined for capsular injury; if a splenic hematoma is present, the spleen is removed to avoid postoperative bleeding and hypotension. The aneurysm wall is then loosely wrapped around the aortic graft. Two posteriorly located thoracic drainage tubes and a closed-suction retroperitoneal drain are placed before closure. The diaphragm is closed with continuous polypropylene suture; postoperative disruption of the diaphragmatic repair is exceedingly rare.

### EARLY POSTOPERATIVE CARE

Postoperative blood pressure management is critical and must be balanced between hypertension (which can cause bleeding) and hypotension (which can lead to paraplegia/paraparesis). Because aortic anastomoses are often extremely fragile during the early postoperative period, even brief episodes of hypertension may disrupt suture lines and cause severe bleeding or pseudoaneurysm formation. In most cases, we use nitroprusside, intravenous  $\beta$ -antagonists, and intravenous calcium-channel blockers to keep the mean arterial blood pressure between 80 and 90 mm Hg. In patients with severely friable aortic tissue, such as those with Marfan syndrome, we use a target range of 70 to 80 mm Hg.

### OUTCOMES

Since 1986, we have performed open surgical repair of 4040 DTAAAs and TAAAs. Combined hospital and 30-day operative mortality was 7.1% ( $n = 286$ ). Complications that are commonly associated with an increased risk of death include paraplegia, renal failure, respiratory failure, cardiac events, and bleeding. The incidence of paraplegia and paraparesis in our series was 4.8% ( $n = 195$ ), paraplegia alone was 2.7% ( $n = 111$ ), and the incidence of renal failure necessitating

hemodialysis was 5.7% ( $n = 231$ ). The rate of return to the operating room for bleeding has been 3.5% in our experience ( $n = 142$ ). Our most recent data (from 2009 to 2015), which reflect the results of our current organ-protection strategies, are shown in Table 49-2; for the majority of postoperative complications, operative risk varies by the extent of repair.

Pulmonary complications following distal aortic repair are quite common, affecting more than a third of patients and tending to occur more frequently after extensive repair (extents I and III TAAA repair) than less extensive repair (extent IV TAAA repair). Of note, vocal cord paralysis can contribute to respiratory complications; it should be suspected in patients with postoperative hoarseness and confirmed by direct examination. This complication can be treated effectively by direct cord medialization (ie, type 1 thyroplasty) or by polytetrafluoroethylene injection. In general, younger patients ( $\leq 50$  years) tend to have far fewer postoperative complications than older patients; however, extensive TAAA repair (extent II TAAA) in the elderly ( $> 80$  years) should be cautioned as patients do quite poorly.<sup>89</sup>

### SURVEILLANCE FOR ADDITIONAL AORTIC DISEASE

Patients who have undergone DTAA or TAAA repair remain at risk for developing new aneurysms in other aortic segments or in reattachment patches; this is especially true for patients with residual distal aortic dissection. Progressive weakening of aortic tissue at suture lines can lead to pseudoaneurysm formation—this late risk tends to be more pronounced in patients with uncontrolled hypertension or connective tissue disorder. If concerning symptoms develop (such as any ischemic complications or sudden onset of pain), patients should be made aware that they should seek urgent treatment. To detect new aortic disease before life-threatening complications occur, we recommend that all patients undergo annual CT or MR imaging of the chest and abdomen. This strategy of lifelong surveillance is especially important in patients with genetic disorders.<sup>8</sup> Subsequent aortic repairs can be performed with surprisingly low mortality and morbidity risk, particularly when done electively.<sup>90</sup>

**TABLE 49-2: Results of 705 Contemporary (2009-2015) Open Descending Thoracic or Thoracoabdominal Aortic Aneurysm Repairs-Baylor College of Medicine**

Extent of repair	No. of patients	30-day deaths	Paraplegia*	Stroke*	Renal Failure*
DTAA	51	2 (4%)	2 (4%)	1 (2%)	1 (2%)
TAAA I	161	5 (3%)	3 (2%)	4 (3%)	8 (5%)
TAAA II	226	16 (7%)	11 (5%)	4 (2%)	22 (10%)
TAAA III	118	4 (3%)	10 (8%)	0	16 (14%)
TAAA IV	149	5 (3%)	4 (3%)	3 (2%)	8 (5%)
Total	705	32 (5%)	30 (4%)	12 (2%)	55 (8%)

DTAA, descending thoracic aortic aneurysm; TAAA, thoracoabdominal aortic aneurysm.

\*Discharged as a persistent impairment or present at time of early death.

## ACKNOWLEDGMENTS

The authors thank Joseph Huh, MD, for his substantial contribution to the chapter published in the 4th edition of the textbook, on which this updated chapter is based; Scott A. Weldon, MA, CMI, and Carol P. Larson, BS, AMI, for their outstanding medical illustrations; and Stephen N. Palmer, PhD, ELS, Susan Y. Green, MPH, Eric K. Rachlin, and D'Arcy Wainwright for invaluable editorial support.

# Endovascular Therapy for the Treatment of Thoracic Aortic Disease

Susan D. Moffatt-Bruce • R. Scott Mitchell

Patients with thoracic aortic disease pose many challenges. Frequently, these patients are older and present with multiple comorbidities. Additionally, the posterior location of the descending thoracic aorta requires a large thoracotomy incision, with its own inherent morbidity.

The modern surgical treatment of thoracic aortic disease began in the 1950s, when successful treatment utilizing segmental resection and graft replacement was first reported by Swan, Lam, DeBakey, and Etheridge.<sup>1-3</sup> Soon thereafter, DeBakey and Cooley reported the first successful repair of an ascending aortic aneurysm using cardiopulmonary bypass.<sup>4</sup> Cardiopulmonary bypass and commercially available tube grafts were the mainstays of our surgical armamentarium for the next 30 years. Improved diagnostic capabilities, surgical techniques, and perioperative care have resulted in improved outcomes, even as the risk profile has worsened.<sup>5,6</sup> In an effort to limit the morbidity of these operations,<sup>7,8</sup> endovascular techniques emerged as an attractive alternative. Originally devised for high-risk patients, and following on developments directed toward aneurysms of the abdominal aorta, thoracic endovascular stent-graft technology has rapidly evolved. Although originally intended for repair of atherosclerotic thoracic aortic aneurysms,<sup>9-11</sup> thoracic stent-graft applications have been expanded to the treatment of multiple pathologies, including acute and chronic aortic dissections, penetrating atherosclerotic aortic ulcers, and thoracic aortic trauma.<sup>12-19</sup> Results have steadily improved, and long-term durability has been encouraging; however, the necessity for long-term follow-up remains,<sup>20-22</sup> with obvious financial implications.

## HISTORY

Endovascular stent-graft technology, initially targeting the abdominal aortic aneurysm, was introduced by Parodi.<sup>23</sup> Balloon-expandable stents, sewn inside the ends of a vascular tube graft, were placed within the aneurysmal aorta, excluding the aneurysm sac. Simultaneously, at Stanford University

Medical Center, a collaborative effort between interventional radiologists and cardiovascular surgeons proved highly synergistic and resulted in a homemade thoracic stent graft.

Self-expanding Gianturco Z stents (Cook Company, Bloomington, IN) were fastened together and covered with a woven Dacron graft (Meadox-Boston Scientific, Natick, MA; Fig. 50-1), and then compressed into a 28-French introducer sheath. The first homemade thoracic graft was implanted in the descending thoracic aorta in 1992 after Institutional Review Board (IRB) approval was obtained. Subsequently, a high-risk trial was approved for patients with thoracic aortic aneurysms who were deemed nonsurgical candidates.<sup>24</sup> Thirteen such patients were treated utilizing stent grafts, customized-designed for each patient. Placement of these stents was successful in all patients, with complete thrombosis of the aneurysm sac reported in 12 of the 13 patients. At 1 year, there were no deaths, paraplegia, strokes, or distal embolization.

Feasibility having been established, IRB approval was obtained for a subsequent trial of 103 patients, 60% of whom were deemed unfit for conventional open surgical repair.<sup>25</sup> Using the same "homemade" first-generation stent graft, complete aneurysm thrombosis was achieved in 83% of patients. Thirty-day mortality was 9% and was significantly associated with a history of cerebral vascular accidents and myocardial infarctions. Major perioperative morbidities included paraplegia in three patients, cerebrovascular accidents in seven patients, and respiratory insufficiency in 12 patients. Actuarial survival was 81% at 1 year and 73% at 2 years. Given the high-risk nature of this patient population, these first-generation results were deemed satisfactory. It was, however, recognized that mortality and morbidity occurred frequently and that long-term follow-up was necessary to establish the long-term efficacy. Subsequently, in 2004, mid-term results were reported for these initial 103 patients treated with first-generation stent grafts.<sup>26</sup> Overall actuarial survival was dismal; 82, 49, and 27% at 1, 5, and 8 years, respectively.

**FIGURE 50-1** First-generation stent graft assembled from articulated Z stents and covered with a woven Dacron tube graft.

However, for potentially operable candidates, survival was 93 and 78% at 1 and 5 years, respectively, as contrasted to a 74 and 31% survival at 1 and 5 years, respectively, in those patients deemed inoperable. Late rupture in 11 patients reinforced the mandate for continued lifelong follow-up.

This technology was extended to the treatment of complicated acute type B aortic dissections, as reported by Dake and associates in the *New England Journal of Medicine* in 1999.<sup>27</sup> Again, utilizing these first-generation homemade devices, stent grafts were placed across the primary entry tear, successfully excluding false lumen perfusion. Distal malperfusion was corrected, and false lumen thrombosis within the chest occurred in 79% of patients. Early mortality was 16%, which largely reflected very late referral. Favorable clinical results persisted out to a mean follow-up of 13 months.

## TECHNICAL DEVELOPMENT

Homemade stent-graft devices persisted for another 10 years, as commercial development was slow to evolve. Homemade devices were made in 10, 15, and 20 cm lengths, with diameters from 23 to 36 mm. Two-centimeter proximal and distal landing zones were recommended, and stent grafts were oversized to approximately 10 to 15%. These grafts were then loaded into 28-French delivery sheaths, which were advanced into the descending thoracic aorta, usually through a femoral artery cutdown. In addition to small iliofemoral vessels, additional anatomic constraints of these early first-generation stent grafts, which precluded either delivery or secure fixation, included acute angulation of the distal arch, a severe sigmoid-like tortuosity through the diaphragmatic crura, and excessive mural thrombus.

**FIGURE 50-2** Second-generation commercially manufactured thoracic aortic stent graft. The thoracic Excluder TAG system by W.L. Gore contains a thin-walled PTFE graft covered by a nitinol exoskeleton.

The advent of this new stent-graft technology required a new terminology for endoleaks, which allowed the aneurysmal sac to remain pressurized. Type I endoleaks occur at the proximal (A) or distal (B) attachment sites and signify a failure to achieve a hemostatic seal at these implant sites. Type II endoleaks denote a communication between a branch vessel and the excluded aneurysm sac, and are commonly seen with back-bleeding intercostal vessels. Type III endoleaks occur at graft to graft junctions, and Type IV endoleaks are characterized by increase in aneurysm sac size in the absence of an identifiable endoleak, variously referred to as endotension.

In 2005 and 2006, commercially produced stent grafts became available. Initially, the Gore Excluder TAG system (W.L. Gore, Sunnyvale, CA) was approved (Fig. 50-2), followed shortly thereafter by the Medtronic Talent Graft (Medtronic, Sunrise, FL) and the Cook Zenith (Cook Company, Bloomington, IN). These second- and third-generation endoprostheses addressed many of the deficiencies of the early homemade devices. The delivery systems have become increasingly smaller in diameter and more flexible. The exoskeleton has to provide high column strength and ductility and be compression- and kink-resistant. Nitinol is used predominantly, covered by either Dacron or polytetrafluoroethylene (PTFE) graft material.

## EARLY RESULTS

In January 2005, the phase II multicenter trial of the Gore Excluder TAG thoracic endoprosthesis was reported.<sup>28</sup> This multicenter, prospective, nonrandomized trial was conducted at 17 sites and compared the results of stent-graft repair of descending thoracic aortic aneurysms in 140 patients, with the results of open repair in 94 patients. Strict inclusion and

**FIGURE 50-3** (A) Angiogram of a descending thoracic aortic aneurysm suitable for stent-graft repair. (B) Angiogram illustrating successful exclusion of the aneurysm sac with a thoracic stent graft.

exclusion criteria were defined in an attempt to ensure comparability of both groups. Follow-up computed tomography (CT) scans were obtained at 1, 6, 12, and 24 months. For stent-graft patients, operative blood loss, renal failure, paraplegia, and mortality rates were all significantly less than for the open repair group (Fig. 50-3). Interestingly, stroke rates were approximately equal in both groups. ICU stay and total hospital stay and time to return to normal activity were approximately 50% shorter for the stent-graft group than for those with open repair. Although stent-graft patients had reduced aneurysm-related mortality out to 2 years (3% vs 10%), interestingly, all-cause mortality was similar between groups at 2 years, similar to the results of recent randomized trials in abdominal aortic aneurysm stent grafts.

## THORACIC AORTIC ANEURYSMS

Approximately 50% of all thoracic aortic aneurysms are located in the descending aorta; these aneurysms commonly arise at the level of the left subclavian artery and are often atherosclerotic in nature.<sup>29</sup> The size-rupture correlation has been demonstrated through the natural history of these aneurysms, as reported by Clouse and associates, using the Olmstead County database, in which thoracic aortic aneurysms have an overall 5-year rupture risk of 30%.<sup>30</sup> The Mount Sinai group has identified clinical variables that predict the risk for rupture, including increasing age, presence of chronic obstructive pulmonary disease, maximal thoracic and abdominal aneurysm diameter, and presence of pain.<sup>31</sup> The Yale Aortic Diseases Group has documented rupture and dissection of thoracic aortic aneurysms at a median diameter of 7.2 cm.<sup>6</sup> The Yale Group also reported the mean rate of rupture or dissection as 2% per year for smaller aneurysms, 3% for aneurysms 5.0 to 5.9 cm, and 6.9% for aneurysms 6.0 cm and larger.<sup>32</sup> Open surgical graft replacement has been the traditional mainstay of treatment for these patients, and mortality rates of 5 to 10% have been reported from experienced centers.<sup>33,34</sup> Similarly,

paraplegia rates have decreased to the 3 to 8% range, with increasing risk associated with increased extent of resection, emergency operation, and renal dysfunction. Utilization of distal circulatory support and cerebral spinal fluid drainage was protective.<sup>35-38</sup> However, in an ever-increasingly elderly population with multiple comorbidities, endovascular repair has become increasingly attractive, especially for patients with favorable anatomy.

Technological progress has also been very enabling. Smaller and more flexible delivery systems have assured access in most patients. Coverage of the left subclavian artery to create a satisfactory proximal landing zone has been frequently employed with few complications. Preoperative left subclavian-to-carotid transposition needs to be entertained only for extensive thoracic coverage, diminutive right vertebral artery, impaired perfusion of both left subclavian and hypogastric arteries, and for patients with previously repaired abdominal aortic aneurysms. Patients considered at high risk for paraplegia should receive a spinal drain preoperatively and hypotension assiduously avoided. Increasingly, percutaneous access is sufficient, even in obese patients. Lastly, much like abdominal aortic aneurysms, endograft technology can be very efficient for the management of ruptured thoracic aortic aneurysms.

## THORACIC AORTIC DISSECTION

Perhaps the greatest impact of this endovascular technology has been on the treatment of thoracic aortic dissections. Previously, open repair of complicated acute type B aortic dissections, defined as those dissections with rupture or impending rupture, rapid expansion, or malperfusion syndromes, was associated with high mortalities. Endovascular repair, because of its ability to cover the primary entry tear, thus redirecting flow into the true lumen and eliminating “dynamic malperfusion”; also allows treatment of “static malperfusion” during the same interventional setting.

Uncovered stents placed in branch vessel orifices occluded by an intimal flap are remarkably effective for these malperfused organ systems.<sup>39-42</sup>

For uncomplicated acute type B aortic dissections, there is increasing enthusiasm for prophylactic placement of stent grafts to allow aortic remodeling during the acute and subacute phases. Conventional medical therapy successes may still fail in the late follow-up due to aneurysmal expansion of the false lumen. Early stent-graft intervention, if it could be achieved with low morbidity and mortality, could allow positive aortic remodeling in the stented aorta, avoiding these very problematic late aneurysmal complications. Given the likely development of disease-specific stents, ideally, a covered segment in the proximal portions and uncovered stents for the more distal aorta, prophylactic stent grafting in the subacute stage could allow positive aortic remodeling for the entire thoracic aorta (Fig. 50-4).<sup>27</sup> Hopefully, genetic risk factors which place patients at increased risk for late aneurysmal changes could be identified, which would allow targeting those patients who would most benefit from such a prophylactic intervention.

Chronic aortic dissections are more problematic. Frequently, these patients are much older, with very large aneurysmal components, and multiple communications between true and false lumens. Open surgical repair has been associated with significant morbidity and mortality. Unfortunately, since the dissection frequently extends into the abdomen, and because of multiple fenestrations between the true and false lumens, exclusion of false lumen filling is difficult. Although aneurysmal dilation frequently involves only the proximal descending thoracic aorta, it is unknown whether endograft coverage of the entire thoracic aorta to the level of the celiac artery will be sufficient to provoke false lumen thrombosis. Recent publication of a select series by Hughes and the Duke aortic group has documented good results with low morbidity by stent grafting from the left subclavian artery to the celiac axis.<sup>43</sup> Complete exclusion of a patent false lumen distally, especially in the absence of multibranch grafts, can be very problematic, even with snorkel and chimney grafts and occluder devices. New technical advances should provide more tools to address these very problematic patients. Roselli and the Cleveland Clinic group recently reported surgical

**FIGURE 50-4** (A) Intravenous contrast-enhanced CT scan of the upper abdomen demonstrating an aortic dissection with compression of the true lumen. (B) Angiogram of the thoracic aorta demonstrating a type B dissection involving the descending thoracic aorta. (C) CT scan of the abdomen, and (D) angiogram of the descending thoracic aorta after stent-graft implantation into the true lumen in the proximal descending thoracic aorta.

and endovascular experience in this very challenging group of patients, highlighting the competing risks of death and intervention.<sup>44</sup>

## PENETRATING ATHEROSCLEROTIC ULCERS AND INTRAMURAL HEMATOMAS

Intramural hematoma (IMH) of the aorta is attracting growing interest as a variant of aortic dissection.<sup>45</sup> The exact pathophysiology is not well understood. Although by definition, pure IMH likely occurs from hemorrhage into the media from the vasa vasorum, many maintain that an intimal disruption is present in all cases.

Certainly, in the absence of any intimal disruption, there would be no indication for stent-graft repair. IMH, however, is often associated with or even precipitated by penetrating atherosclerotic ulcers (PAUs) of the descending thoracic aorta. Therefore, covering the PAU with a stent graft may limit the progression of the IMH and allow healing to occur.<sup>46-48</sup> Unfortunately, even with successful stent-graft implantation using both first- and second-generation grafts, retrograde aortic dissection, new ulcer formation, and endoleaks have been noted in a significant percentage of patients, emphasizing the diffuse and severe nature of this disease.<sup>49-52</sup>

The Stanford group has reported their mid-term results treating PAU of the descending thoracic aorta, with an average of 51 months of follow-up<sup>19</sup> (Fig. 50-5). Using both

**FIGURE 50-5** Three-dimensional CT scan of a giant penetrating ulcer involving the descending thoracic aorta that is perfectly suited to treatment with a thoracic stent graft.

first- and second-generation commercial devices, 26 patients were treated, 14 of whom were deemed nonoperative candidates. The primary success rate was 92%, with actuarial survival estimates of 85, 76, and 70% at 1, 3, and 5 years, respectively. Perioperative mortality was 12%. Increasing aortic diameter and female gender were determinants of treatment failure. These risk factors reflect the importance of careful patient selection based on anatomical criteria and clinical factors. In addition, long-term follow-up with serial CT angiography is necessary to detect late complications.

## THORACIC AORTIC TRAUMA

Aortic injuries secondary to nonpenetrating trauma are frequently lethal lesions, with 80 to 90% of patients dying in the hour after the accident.<sup>53</sup> Urgent surgical graft replacement of the aorta has been the conventional treatment, but these patients frequently have other major injuries, including closed head injuries, pulmonary contusions, myocardial contusions, and other solid organ injuries, which may limit options for surgical repair. Thoracic endografts would appear to be an invaluable addition to our surgical armamentarium. Initially, however, all available stent grafts were too large to be utilized inside the smaller aortas of these younger patients. Fortunately, smaller stent grafts, as well as tapered stent grafts, have become available, greatly facilitating repair of these traumatic injuries.<sup>54-58</sup>

Blunt aortic injuries have been classified in an SVS classification system. Class I injury involves only an intimal laceration with no other radiographic changes. Type II injury includes an intimal laceration and mild intramural hemorrhage without significant compromise of the vessel lumen or expansion of the adventitial diameter. Extent III denotes an intramural hemorrhage, sufficient to cause an increase in aortic diameter and compression of the intimal lumen, the classical pseudo-aneurysm. Class IV denotes rupture or impending rupture. For Class I and II injuries, most authors recommend no acute treatment, with repeat imaging in 24 to 48 hours. When anatomically feasible, stent-graft coverage for Class III and IV injuries has become the procedure of choice, limiting stent-graft length to that necessary to cover the injured area. Endografts longer than 15 cm may be associated with an increased risk of paraplegia. For type II injuries noted to progress and for type III injuries, delayed repair may be elected in a stable patient to allow recovery from other injuries. With an Extent III injury and with the necessity for permissive hypertension in the treatment of a closed head injury, early intervention may be warranted (Fig. 50-6). In patients for whom permissive hypertension is desirable, that is, patients with closed head injuries, early stent-graft placement may be indicated. Otherwise, for stable type III or minimally progressive Extent II injuries, delayed stent-graft placement may be most effective, allowing interval recovery from polytrauma. There is little data demonstrating the durability of these stent grafts in past 5 years, but it is expected that interval surveillance will allow safe and timely reintervention if necessary.

**FIGURE 50-6** (A) Thoracic angiogram demonstrating a contained rupture of the descending thoracic aorta in a trauma victim. (B) Thoracic angiogram revealing repair of the aortic rupture with a thoracic stent graft.

## FUTURE DIRECTIONS

Despite the many advances in the field of endovascular surgery, stent grafting of the thoracic aorta remains in a developmental phase.<sup>20,59</sup> Newer stent-graft technologies had been slow to become available in the United States, especially compared to China and Japan. Unibranched grafts may allow more proximal repairs into the aortic arch, and multibranched and fenestrated grafts may allow complex repair of thoracoabdominal aortic aneurysms. There are currently many new stent-graft and interventional technologies in the pipeline, which will facilitate aortic repairs in the future. Disease-specific endografts and combinations will also likely become available, further enabling endovascular repair.

Finally, it is important that these patients be followed longitudinally. Early success is no long-term guarantee, as we have seen even totally thrombosed aortic aneurysm sacs elongate with a late appearance of type I endoleaks. Serial imaging may allow timely reintervention, but obviously does incur added expense.

Diseases of the thoracic aorta pose a significant challenge to the surgeon because of complexity of the disease and the characteristics of an ever-aging patient population. Current literature supports increasing application of endovascular technology in well-suited patients, but further follow-up and additional trials may be necessary to further refine the exact role of endovascular repair for the future.

# Trauma to the Great Vessels

Tom P. Theruvath • Claudio J. Schonholz • John S. Ikonomidis

Injury to the aorta and great vessels of the thorax may occur secondary to penetrating or blunt trauma. The management strategy involves control of immediate hemorrhage with prevention of distal malperfusion or pseudoaneurysm development and rupture. Blunt thoracic aortic injury (BTAI) is the most common thoracic vascular injury and is the second leading cause of death in the United States from nonpenetrating trauma. Its incidence is estimated at 7500 to 8000 cases per year.<sup>1</sup> In 75 to 90% of cases, death occurs at the accident scene, typically in those with four or more serious injuries in addition to their aortic transection.<sup>2</sup> Current data suggest that approximately 4% of patients die during transport from the scene, and an additional 19% die during the initial trauma evaluation.<sup>3</sup> A meta-analysis in 2011 reported that in-hospital mortality of patients managed nonoperatively was as high as 46%, whereas mortality was 9% in patients treated by endovascular repair and 19% for open repair.<sup>4</sup> After aortic transection at the isthmus, aortic disruption at the base of the innominate artery is the most common site of injury, followed by the base of the left subclavian artery, and the base of the left carotid. Central venous structures are rarely injured with blunt trauma, but this can occur with penetrating trauma.<sup>5</sup> Traditionally, open surgical repair of these injuries has proved effective. Since the first endovascular thoracic aortic device became commercially available in the United States in 2005, the treatment of BTAI has rapidly evolved as high-volume trauma centers applied the principles of endovascular aneurysm repair to BTAI in an off-label manner. With the growing shift from open repair to thoracic endovascular aortic repair (TEVAR) as the primary treatment in patients with BTAI, outcomes have improved with significantly reduced mortality and morbidity, including procedure-related paraplegia.<sup>6</sup> This chapter describes the traumatic injuries to the thoracic aorta and its brachiocephalic branch vessels. The mechanism, clinical presentation, and treatment strategies are presented. The emphasis is directed to endovascular strategies which have emerged as the most commonly utilized intervention in blunt aortic and brachiocephalic branch vessel trauma.

The chapter is divided into the ascending, arch, and descending zones and both open surgical and endovascular approaches are described with regard to the specific zones.

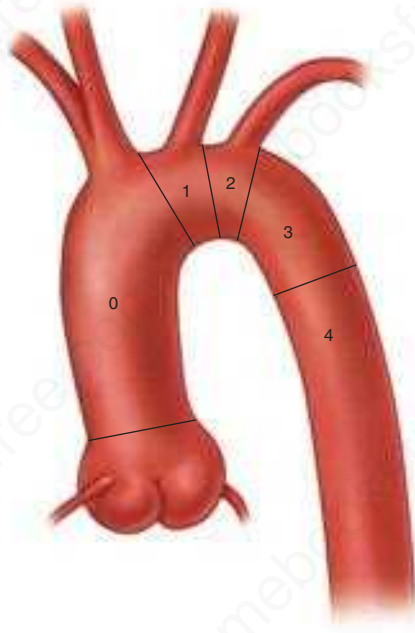

## GENERAL CONSIDERATIONS

### Zonal Divisions of the Thoracic Aorta

In order to facilitate international correspondence and a clinically more useful system with regard to anatomical identification of the thoracic aorta, an “anatomical endograft landing zone map” was advocated at the First International Summit on Thoracic Aortic Endografting held in Tokyo in 2001.<sup>7</sup> We suggest using this landing zone map to classify not only the proximal deployment site of an endograft but also extent of open surgical repairs. In 2002, this landing zone map was expanded to include the position of the distal end of the endograft. Since then, the map (Fig. 51-1) has achieved consensus as the standardized anatomical definition to evaluate outcomes.<sup>8</sup> On a more personal notation, we refer to the aortic root as the “double-0” site.

### Clinical Presentation

Patients presenting to the emergency department with injury to a great vessel should be evaluated according to standard advanced trauma life support (ATLS) protocols. Those suffering blunt trauma are often hemodynamically stable; therefore, a high index of suspicion for intrathoracic vascular disruption must be based on the mechanism and constellation of related injuries. In addition to high-speed collisions involving automobiles or motorcycles, crush injuries and falls often have sufficient force to rupture a thoracic vessel.<sup>9-12</sup> There are often clues evident in the initial evaluation of a trauma patient that can suggest aortic disruption. In contrast to blunt injury to the arch vessels, patients sustaining descending thoracic aortic rupture are often hemodynamically stable on presentation at the emergency department. Although patients may complain

**FIGURE 51-1** Zonal divisions of the thoracic aorta.

of dyspnea or back pain and display differential blood pressures in the upper versus lower extremities, specific signs or symptoms of aortic rupture have been identified in less than 50% of cases. Complete de-gloving injury may result in intussusception of the aortic media into the descending thoracic aorta, with resultant “pseudocoarctation” and subsequently variable degrees of distal malperfusion (Fig. 51-2). Commonly associated complaints include neck and chest pain, and physical examination may reveal ecchymosis across the chest and neck from the seatbelt shoulder harness.<sup>13,14</sup>

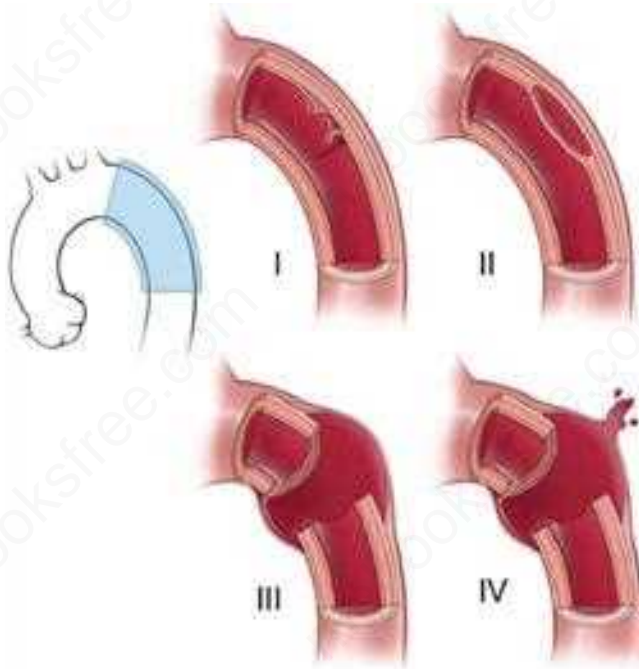

Physical examination findings concerning for rupture of a great vessel include supraclavicular swelling or bruit, diminished pulse in the ipsilateral upper extremity, neck hematoma with or without tracheal deviation, acute Horner’s syndrome, and an acute superior vena cava-like syndrome.<sup>11,14-16</sup> In a stable patient with evidence of a stab or gunshot wound located between the mid clavicular lines or in zone I of the neck, great vessel penetration should be suspected.<sup>17</sup> A precordial bruit suggesting arteriovenous fistula (AVF) formation may be noted in up to 30% of patients.<sup>18</sup> Penetrating distal subclavian injuries may demonstrate pulsatile bleeding during initial evaluation.<sup>19</sup> More commonly, patients suffering penetrating injury to the chest or neck will be hemodynamically unstable on arrival to the emergency department, possibly with evidence of cardiac tamponade, and those *in extremis* should undergo emergent thoracotomy. Hypotensive patients may proceed directly to the operating room without diagnostic imaging; the mortality of patients presenting with hypotension is nearly three times greater than that of stable patients.<sup>18,19</sup> Therefore, an organized, efficient, and effective evaluation of these patients is necessary to prevent unnecessary loss of life.

### Classification System for Traumatic Aortic Injury

The classification scheme for grading the severity of BTAI has been widely accepted and is shown in Fig. 51-3.<sup>20</sup> Grade I demonstrates an intimal tear or flap. Grade II demonstrates an intramural hematoma without significant change in the external contour of the aorta. Grade III demonstrates a contained pseudoaneurysm with extension beyond the normal contours of the aorta. Grade IV involves full-thickness aortic injury with extravasation. The Society of

**FIGURE 51-2** Pseudocoarctation of the aorta caused by circumferential transection of the aorta with the wall flap telescoping into the distal aorta. Blood flow between the proximal and distal aortic segments is maintained by the surrounding adventitia alone.

**FIGURE 51-3** Classification system for blunt thoracic aortic injury (BTAI). The different grades of BTAI are shown: Grade I—intimal tear/flap, Grade II—intramural hematoma, Grade III—pseudoaneurysm, Grade IV—rupture.

Vascular Surgery guidelines recommend TEVAR for grade II through IV BTAIs, given that grade I injuries typically heal spontaneously.

### Initial Evaluation

A multitrauma patient should be evaluated according to standard ATLS protocols regardless of whether aortic disruption is suspected. The primary and secondary survey, routine radiographs, and hemodynamic stabilization must be completed before the team can begin investigating specific injuries. The first step in diagnosing a blunt traumatic aortic injury is identifying the at-risk patient. Motor vehicle collisions, falls from height, explosions, and crush injuries have the impact and deceleration forces required to cause aortic transection; therefore these patients should undergo imaging directed at ruling out this potentially fatal injury.<sup>21-24</sup> Operative management of intracranial space-occupying lesions and intra-abdominal hemorrhage takes priority over nonbleeding aortic injuries. Hemodynamically unstable patients with signs of exsanguinating hemorrhage should go directly to the operating room for control of hemorrhage, and transesophageal ultrasound may be used to evaluate for aortic injury. Ninety-five percent of patients with aortic disruption have associated injuries. Data accrued from a trial which included approximately 50 trauma centers across the United States and Canada, the American Association for the Surgery of Trauma

### TABLE 51-1: Clues that Suggest Aortic Disruption

#### History

- Motor vehicle crash >50 km/h
- Motor vehicle crash into fixed barrier
- No seatbelt
- Ejection from vehicle
- Broken steering wheel
- Motorcycle or airplane crash
- Pedestrian hit by motor vehicle
- Falls greater than 3 m
- Crush or cave-in injuries
- Loss of consciousness

#### Physical signs

- Hemodynamic shock (systolic blood pressure < 90 mm Hg)
- Fracture of sternum, first rib, clavicle, scapula, or multiple ribs
- Steering wheel imprint on chest
- Cardiac murmurs
- Hoarseness
- Dyspnea
- Back pain
- Hemothorax
- Unequal extremity blood pressures
- Paraplegia or paraparesis

(AAST) trial,<sup>25</sup> demonstrated that current advancements in emergency medical resuscitation in the field have provided more patients the opportunity to reach the hospital and receive aggressive definitive care. There are often clues evident in the initial evaluation in these patients that can suggest aortic disruption (Table 51-1).

### CHEST X-RAY

In the majority of trauma patients, a supine chest radiograph is obtained as part of the initial evaluation, and the constellation of grossly widened mediastinum, hemothorax, and transient hemodynamic instability on arrival appear to be predictive of early in-hospital death from BTAI.<sup>26</sup> During the evaluation of a blunt trauma patient, an anteroposterior chest radiograph is routinely obtained and ought to be examined for one of the 15 signs that have been associated with aortic rupture (Table 51-2).<sup>27</sup> Widening of the mediastinum to a width exceeding 25% of the total chest width, obliteration of the aortic knob, apical pleural capping, and fractures of the sternum, scapula, clavicle, or first rib are some of the most common findings (Fig. 51-4). None of these signs have demonstrated sufficient sensitivity or specificity to effectively rule out aortic injury, however, and up to 40% of patients with aortic rupture have had chest x-ray findings interpreted as normal.<sup>22,23,28-32</sup> When abnormalities are identified, however, they can aid the practitioner in determining which patients require aggressive imaging to definitively rule out an aortic injury.

### TABLE 51-2: Chest X-ray Findings Associated with Blunt Aortic Disruption

Widened mediastinum (>8.0 cm)
Mediastinum-to-chest width ratio >0.25
Tracheal shift to the patient's right
Blurred aortic contour
Irregularity or loss of the aortic knob
Left apical cap
Depression of the left main bronchus
Opacification of the aortopulmonary window
Right deviation of the nasogastric tube
Wide paraspinal lines
First rib fracture
Any other rib fracture
Clavicle fracture
Pulmonary contusion
Thoracic spine fracture

Data from Cook AD, Klein JS, Rogers FB, et al: Chest radiographs of limited utility in the diagnosis of blunt traumatic aortic laceration, *J Trauma*. 2001 May; 50(5):843-847.

### COMPUTED TOMOGRAPHY

In the typical hemodynamically stable blunt trauma patient, head and abdominopelvic computed tomography (CT) should be conducted to identify closed-head or intra-abdominal injury. Those with an abnormal chest x-ray or a traumatic mechanism consistent with aortic injury should undergo helical CT scan of the chest with intravenous contrast at this time. Since its introduction in the early 1990s, CT has become the screening tool of choice at most medical institutions to detect traumatic aortic rupture due to its availability, speed, and ease of interpretation. Additionally, sensitivities and negative predictive values nearing 100% have

**FIGURE 51-4** Chest radiograph of an 18-year-old male victim of a motor vehicle collision showing a widened mediastinum.

**FIGURE 51-5** Helical computed tomography scan of the chest in a 30-year-old male after a high-speed motor vehicle collision demonstrating an intimal flap in the proximal descending thoracic aorta and periaortic hematoma.

been reported for volumetric helical or spiral CT.<sup>22,23,32-35</sup> Normal aorta portrays homogeneous enhancement, while filling defects, contrast extravasation, intimal flaps, periaortic hematoma, pseudoaneurysm, and mural thrombi may suggest the presence of an aortic injury (Fig. 51-5).<sup>34</sup> Moreover, the enhanced resolution of CT imaging has allowed identification of minimal aortic injuries, such as small intimal flaps with minimal or no mediastinal changes, that may be safely managed with anti-impulse therapy.<sup>23,34,36</sup>

### TRANSESOPHAGEAL ECHOCARDIOGRAPHY

Transesophageal echocardiography (TEE) has become a valuable tool in cardiothoracic surgery due to its ability to image the entire descending thoracic aorta along with portions of the ascending aorta arch and its portability. In unstable blunt trauma patients requiring laparotomy, TEE can be utilized to evaluate the descending aorta for evidence of rupture, such as a mural flap or a thickened vessel wall concerning for mural thrombus. Multiplanar TEE probes permit acquisition of cross-sectional images at different angles along a single rotational axis. The typical 5- or 7-MHz transducer permits adequate resolution of structures as small as 1 to 2 mm. Doppler mapping of turbulent blood flow near a vessel wall abnormality may be suggestive of blunt aortic disruption, and time-resolved imaging allows evaluation of the movement of anatomic structures, thereby enhancing the ability to define the physiologic consequences of such abnormalities. Chronic atheromatous disease of the aorta can complicate obtaining and interpreting TEE images; therefore observation of multiple-related signs of injury, such as mural flap with a surrounding mediastinal hematoma, is more reliable. A disadvantage of TEE, and potential inhibitor to its widespread use as a screening tool for aortic injury, is its operator-dependent nature with sensitivities as low as 63% documented for this modality.<sup>37</sup> A prospective comparison of imaging techniques

for diagnosis of blunt aortic trauma reported, however, sensitivity and specificity of 93 and 100% for TEE compared to 73 and 100% for helical CT.<sup>35</sup> Thoracoscopy has also been used to evaluate traumatic hemothoraces, however with experienced practitioners intraoperative TEE has superb sensitivity and specificity for aortic transection.<sup>38,39</sup> TEE is more invasive than helical CT, but overall the associated risk is low. Contraindications include concomitant injury to the cervical spine, oropharynx, esophagus, or maxillofacial structures.<sup>35</sup>

### MAGNETIC RESONANCE ANGIOGRAPHY

Vascular structures are well imaged by magnetic resonance angiography (MRA), particularly the thoracic aorta, and its utility in the diagnosis and follow-up of complex aortic disease including aortic dissections and aneurysms is firmly established.<sup>40-42</sup> The time required to capture images inhibits the utility of MRA in the acute evaluation of a trauma patient, however it may be effective in posttherapeutic surveillance of traumatic thoracic injuries.

### AORTOGRAPHY

Aortography may be useful when helical CT or TEE fail to definitively identify or adequately characterize an aortic injury. The role of aortography in evaluating blunt thoracic injuries was firmly established prior to the advent of noninvasive, sophisticated imaging techniques, and it may still be considered the gold standard. In experienced hands its sensitivity and specificity both approach 100%.<sup>43</sup> Intra-arterial digital subtraction is most often used because it allows rapid generation of images (Fig. 51-6). In the past, intravenous digital subtraction was used as well. After injecting intravenous

**FIGURE 51-6** Digital subtraction arteriogram of an acute traumatic aortic disruption near the isthmus.

contrast, time-delayed images of the arch and descending aorta were obtained, and although this technique greatly decreased the duration of the procedure, it was abandoned because the diagnostic accuracy for aortic disruption was less than 70%.<sup>40</sup> With the availability and speed of helical CT, aortography is now rarely used for diagnosis, but routinely utilized for endovascular stent graft placement. This intervention requires a highly trained team of endovascular specialists and can be time-consuming; therefore trauma patients with additional life or limb threatening injuries should be otherwise stabilized before entering the endovascular suite. Rates of exsanguination and death of up to 10% have previously been reported during diagnostic aortography, but this incidence has decreased significantly as endovascular proficiency has improved.<sup>40,44,45</sup> In fact, complication rates attributed directly to aortography are low, but patients may suffer contrast reactions, contrast nephropathy, groin hematomas, or femoral artery pseudoaneurysms. False-positive studies are usually attributed to atheromata or ductal diverticula.

### Decision to Repair Versus Expectant Management

Uniformly, hemodynamically unstable blunt trauma patients should bypass diagnostic imaging and be taken to the operating room immediately. During a damage control exploratory laparotomy or thoracotomy, TEE may be conducted to diagnose contained aortic rupture.<sup>35</sup> Operative repair of the aorta should not be attempted at this time, however, as this group of patients benefit from immediate transfer to the intensive care unit for further resuscitation. Once hemodynamic stability is achieved, anti-impulse therapy with beta-blockade should be initiated to minimize aortic wall stress. Hemodynamically stable patients diagnosed with blunt aortic injury, and lacking severe associated injuries requiring interventions, warrant immediate repair. Treatment of all nonlife-threatening injuries should be delayed until after definitive aortic repair. As such, delayed management has demonstrated to be safe and effective in carefully selected patients with severe associated injuries or comorbidities.<sup>46-57</sup> Patients with thoracic, intraperitoneal or retroperitoneal hemorrhage, or intracranial bleeding that cause mass effect should be managed with aggressive anti-impulse therapy to minimize the risk of aortic rupture while these injuries are addressed.<sup>55</sup> The goal of anti-impulse therapy should be to maintain a systolic blood pressure less than 120 mm Hg and/or a mean arterial pressure less than 80 mm Hg.<sup>23</sup> The aortic insult should also be monitored by TEE during surgical repair of concomitant injuries, and routinely imaged with CT during the delayed management period. The mortality rate of patients awaiting aortic repair has ranged from 30 to 50%, but the majority of deaths have not been related to the aortic injury.<sup>49,50,55</sup> In the AAST trial, those presenting in extremis or with evidence of free aortic rupture were excluded, and the mortality rate of patients with associated injuries that precluded initial aortic repair was 55%.<sup>25</sup> Therefore, evidence supports operative delay

or even nonoperative management in select patients with blunt aortic injury who may be considered poor operative candidates. Even in carefully selected patient with BTAIs deliberate nonoperative management has been shown to be a reasonable alternative in the polytrauma patient.<sup>58</sup> Anti-impulse therapy with beta-blockers should be initiated in patients proceeding directly to the operating room for aortic repair, as well as in those selected for delayed repair, to reduce blood pressure and thereby reduce aortic wall stress.<sup>23,24,59</sup> In-hospital aortic rupture rates have been reduced through aggressive beta-blockade without adversely affecting the outcome of associated injuries.<sup>23</sup>

## THE ASCENDING AORTA

### Mechanism of Injury

Descending thoracic aortic transection is the most common vascular injury resulting from blunt thoracic force. The ascending aorta and arch vessels, however, may also be disrupted, commonly leading to dissection or pseudoaneurysm formation.<sup>11,14</sup> Mechanistically, the transmission of force through the thoracic cavity from blunt injury is believed to cause torsion of the ascending aorta, leading to disruption of the wall with an associated shearing effect on the heart.<sup>60</sup> Additionally, a water-hammer effect is described in which an aortic occlusion at the diaphragm occurs with impact and a high pressure wave is reflected back to the ascending aorta and aortic arch.<sup>61</sup>

### Operative Repair

Pseudoaneurysm of the ascending aorta should be repaired using cardiopulmonary bypass. Femorofemoral or axillofemoral cannulation and commencement of cardiopulmonary bypass before sternotomy may decompress the ascending aorta and decrease the risk of pseudoaneurysm rupture on opening the chest.<sup>16</sup> After entering the pericardium, the pseudoaneurysm should be carefully mobilized, if possible, to gain proximal and distal control. Depending on the nature and extent of the injury, repair may be conducted by primary repair, patch angioplasty, or prosthetic replacement of aortic segment. If aortic valve insufficiency is encountered, prosthetic valve replacement may be warranted.<sup>62</sup> Occasionally, deep hypothermic circulatory arrest is required, especially if proximal and distal control cannot be comfortably obtained or the pseudoaneurysm extends into the proximal aortic arch. This will allow for excision of the pseudoaneurysm and closure of the aortic defect with a prosthetic patch.<sup>60</sup> As with descending thoracic aortic injuries, a delay in operative management may be considered in hemodynamically stable patients with associated injuries at high risk for bleeding, especially intracranial lesions.<sup>60</sup> The application of this delayed approach depends on the nature of the ascending aortic injury. For instance, it must be a discrete lesion without evidence of circumferential involvement or compromised adjacent structures. Safe observation entails maintaining a mean arterial pressure less than 80 mm Hg

and cerebral perfusion pressure greater than 50 mm Hg, typically through short-acting intravenous beta-blockade.<sup>63</sup> Conservative management must be accompanied by regular assessment of the aortic lesion through serial CT scans of the thorax and a low threshold for operative intervention if enlargement of the pseudoaneurysm is identified.<sup>63</sup>

## Endovascular Interventions

Several studies have reported safety and effectiveness of TEVAR of the descending aorta, but the role of TEVAR for treating ascending aortic pathology is less well known. Especially the role of ascending TEVAR (or A-TEVAR) in the setting of trauma has not been evaluated and reported to date. Only a small number of studies have described outcomes with this approach.<sup>64-66</sup> The reported experience demonstrates that endovascular repair of the ascending aorta is technically feasible in settings of chronic aneurysms or acute aortic dissections and can be accomplished with promising early results. Currently there are no commercially available endovascular devices specifically designed to treat the ascending aorta. Compared with TEVAR of the descending thoracic aorta, endovascular therapy for the ascending aorta is challenged by more complex pathology, hemodynamic characteristics, and anatomy. As such, the proximity of the aortic valve and coronary arteries to the ascending aorta makes it particularly challenging to obtain seal and fixation within the proximal landing zone. Thus far the only intervention is the open surgical approach via median sternotomy and cardiopulmonary bypass as described in the previous section.

## THE AORTIC ARCH BRANCH VESSELS

### Mechanism of Injury

The pathogenesis of blunt innominate artery rupture has been postulated to be the result of anteroposterior compression of the mediastinum between the sternum and vertebrae, displacing the heart posteriorly and to the left, thereby increasing the curvature of the aortic arch and increasing tension on all of its outflow vessels.<sup>67</sup> Hyperextension of the cervical spine with head rotation provides additional tension on the right carotid artery, which is transmitted to the innominate artery, and can lead to rupture.<sup>67</sup> The left carotid artery undergoes stretching injury with rapid deceleration, producing an intimal tear and subsequent dissection.<sup>11</sup> Additional mechanisms of carotid artery injury include hyperflexion of the neck to cause compression between the mandible and cervical spine, basilar skull fracture transecting the artery, and strangulation injury.<sup>11</sup> Blunt subclavian artery injuries are more common in the middle and distal third of the artery and are theorized to be caused by downward forces fracturing the first rib with the anterior scalene acting as a fulcrum so that the subclavian artery is pinched between the first rib and clavicle.<sup>9</sup> The abrupt deceleration of the shoulder, owing to the seatbelt shoulder harness, is also believed to cause subclavian artery shearing injuries.<sup>9</sup>

## Operative Repair

### INNOMINATE ARTERY

The innominate artery is the second most common site of thoracic vascular injury following blunt trauma. In a review of 117 reported cases of blunt innominate artery rupture, 83% were in the proximal vessel, 3% were in the middle, 9% were distal, and the remaining injuries involved multiple sections.<sup>10</sup> The most common finding was disruption of the intima and media with pseudoaneurysm formation (Fig. 51-7).<sup>10</sup> Although primary repair may be possible in some cases, surgical repair of an innominate artery rupture has traditionally been performed by a prosthetic aorto-innominate bypass graft from the aortic arch to healthy distal vessels through a full or upper median sternotomy with extension of the incision along the anterior border of the right sternocleidomastoid as necessary.<sup>17,68</sup> Operative repair of a penetrating innominate artery injury is approached in the same manner.<sup>17</sup> The entire length of the innominate artery should be mobilized to achieve distal control and the pericardium opened to gain proximal control at the level of the aortic arch.<sup>69</sup> After systemic administration of heparin, a partial occlusion clamp is applied to the aortic arch and the proximal anastomosis of the prosthetic graft performed end-to-side with polypropylene suture.<sup>69</sup> Depending on the location and extent of the injury, the distal end-to-end anastomosis may involve only the innominate artery or a Y-graft may be required to reconstruct the proximal portions of the right carotid and right subclavian arteries individually.<sup>10</sup> The origin of the innominate artery should then be fully exposed and oversewn with pledgeted nonabsorbable sutures.<sup>69</sup> Healthy patients typically tolerate temporary

**FIGURE 51-7** Arteriogram showing rupture of proximal segment of innominate artery and pseudoaneurysm at the site of rupture. (Reproduced with permission of Symbas JD, Halkos ME, Symbas PN: Rupture of the innominate artery from blunt trauma: current options for management, *J Card Surg* 2005 Sep-Oct;20(5):455-459.)

innominate artery occlusion caused by adequate collateral flow through the contralateral carotid and vertebral arteries.<sup>69</sup> Cerebral protection, cardiopulmonary bypass, electroencephalogram monitoring, hypothermia with circulatory arrest, or carotid shunting (for stump pressure < 50 mm Hg) should be employed in patients with neurologic abnormalities or suspicion of a contralateral carotid artery injury.<sup>68,69</sup> Long-term patency of prosthetic aorto-innominate artery bypass grafts has been reported to be greater than 96% at 10 years.<sup>70</sup>

### CAROTID ARTERY

Therapeutic management of blunt carotid artery injury must be directed at preventing cerebral ischemia and surgical intervention should be weighed against observation and anticoagulation.<sup>71</sup> Small intimal flaps may resolve, whereas larger flaps can lead to thrombosis and therefore require anticoagulation to prevent thromboembolism.<sup>72</sup> Arterial dissection may progress to luminal narrowing, placing the patient at risk for thrombosis, and anticoagulation therapy is especially important in patients with bilateral carotid artery dissection owing to the morbidity and mortality associated with bilateral thrombosis.<sup>73</sup> When operative intervention is indicated because of pseudoaneurysm formation (Fig. 51-8), the surgeon may bypass the lesion, but reconstruction or ligation of the artery can also be employed.<sup>11</sup> Open repair of an intrathoracic carotid artery injury should occur through a median sternotomy with extension along the anterior border of the ipsilateral sternocleidomastoid muscle as necessary to gain adequate exposure.<sup>18</sup> After gaining proximal and distal control, arterial repair may be accomplished by primary repair or interposition grafting with saphenous vein or prosthetic material.<sup>18</sup>

## SUBCLAVIAN ARTERY

Injury to the subclavian artery, from blunt or penetrating trauma, carries a mortality rate of 5 to 30% resulting from the inability to obtain adequate hemorrhagic control through direct pressure.<sup>74,75</sup> Additionally, because of the close proximity of the trachea, esophagus, subclavian vein, and brachial plexus, subclavian artery injuries are associated with 40% morbidity.<sup>74</sup> Operative exposure may be achieved by median sternotomy, limited sternotomy, supraclavicular incision, infraclavicular incision, thoracotomy, or a combination of these depending on the location of the injury.<sup>76</sup> Left-sided lesions are often managed through an anterolateral thoracotomy with either an infraclavicular or supraclavicular counter incision; however, some surgeons perform a median sternotomy for a proximal injury.<sup>9,76</sup> Right-sided injuries, on the other hand, require median sternotomy with supraclavicular extension.<sup>9</sup> In cases in which the defect involves a long segment of the subclavian artery, a portion of the clavicle may be resected to optimize exposure, although this procedure carries considerable postoperative morbidity.<sup>19,76</sup> Once establishing proximal and distal control of the subclavian artery, the damaged arterial segment may be excised and arterial reconstruction accomplished with an interposition graft using a saphenous vein or prosthetic material.<sup>9</sup> In cases in which minimal arterial debridement is required, primary repair is often attained.<sup>77</sup> Ligation of the subclavian artery may be performed on critically ill patients unable to tolerate an extensive operative repair, and minimal short-term morbidity in the affected limb has been reported.<sup>19,76,77</sup> When planning operative repair of the subclavian artery, concomitant injuries to nearby structures such as the subclavian vein and brachial plexus should be considered.

## Endovascular Interventions

Arteriography is considered the gold standard for diagnosis and characterization of an intrathoracic vascular injury, and as endovascular stent technology and surgeon proficiency continue to advance, arteriography may become the preferred method of treatment in hemodynamically stable patients. The literature is currently populated with small case series and case reports documenting the feasibility of this approach and minimal short-term morbidity and mortality, but very little long-term data exist. Similar to other minimally invasive techniques, endovascular management of a traumatic injury to an intrathoracic vessel can provide an opportunity for patients to avoid sternotomy or thoracotomy and the associated pain, prolonged recovery time, and infection risk.<sup>78,79</sup> An analysis of endovascular versus open procedures in the National Trauma Database revealed a survival advantage for endovascular repair when controlling for injury severity score, associated injuries, and age.<sup>80</sup> Widespread application of endovascular techniques to manage great vessel trauma in hemodynamically stable patients is constrained by lesion anatomy. With regard to accessing the injury, the relationship of the vascular defect to the aortic arch is rarely an issue because brachial and carotid artery approaches, with or without a concomitant femoral approach, are increasingly

employed.<sup>79</sup> However, the likelihood that the adjacent healthy vessel segments will provide adequate landing zones and the preservation of branch vessels are important considerations.<sup>81</sup> Therefore, critical assessment of each individual lesion is required to assure appropriate use of this technology. Common endovascular modalities such as bare-metal or covered stents (stent grafts) and coil embolization have been employed in vascular trauma. Stent grafts were not commercially available before 2000; therefore, case reports published in that timeframe described use of home-made devices in which the surgeon affixed autologous tissue, expanded polytetrafluoroethylene (ePTFE), or polyester to a bare-metal stent and then repackaged the device for endovascular deployment across an AVF or pseudoaneurysm.<sup>82</sup> There are currently a number of self-expandable and balloon-expandable stent grafts approved for coronary or peripheral vascular interventions that have been successfully used in the aortic arch vessels, specifically the wall-stent endoprosthesis (Boston Scientific, Natick, MA), the Gore Viabahn endoprosthesis (W.L. Gore & Associates, Flagstaff, AZ), and the Jostent stent-graft coronary or peripheral (Abbott Vascular, Redwood City, CA).<sup>83</sup>

## INNOMINATE ARTERY

Stable patients who have suffered either a blunt or penetrating injury to the innominate artery have benefited from endovascular repair with a stent graft, without reported complications.<sup>13,78,84-86</sup> One technical consideration when approaching an innominate artery pseudoaneurysm is whether the distal landing zone of the stent graft will occlude the carotid artery. This situation can potentially be avoided by realignment of the guidewire such that the orifice of the subclavian artery is covered instead, a lesion that is typically asymptomatic owing to the extensive collateralization of the upper extremity around the shoulder.<sup>78,87</sup> Alternatively, if the stent graft must traverse the origin of the right common carotid, a subclavian-carotid bypass may be performed before deployment.<sup>78</sup> Appropriate follow-up for these endovascular repairs has yet to be defined, but biannual duplex ultrasound examinations or CT scans have been proposed. The duration of antiplatelet therapy after stent graft deployment is also unclear; however, the majority of patients are discharged from the hospital on daily aspirin therapy with or without Plavix (Bristol-Myers Squibb, Princeton, NJ).<sup>13,88,89</sup>

## CAROTID ARTERY

Trauma to the intrathoracic carotid artery is rare, but cases of successful stent-graft exclusion of pseudoaneurysms have been reported.<sup>90-96</sup> Embolic risk should be considered when assessing whether the lesion is suitable for endovascular intervention, and many surgeons advocate for delayed stenting of carotid injuries to minimize arterial manipulation and the potential embolic sequelae.<sup>97</sup> Safely anticoagulating the trauma patient with concomitant intracranial or solid organ injuries can be difficult, but maintaining a partial thromboplastic time between 40 and 50 seconds has been shown to effectively cover carotid

artery injuries without significantly increasing the bleeding risk.<sup>73</sup> Full heparinization is vital during the stent-graft deployment procedure, however, and should be followed by antiplatelet therapy with Plavix for at least 2 weeks with subsequent conversion to lifelong aspirin therapy.<sup>91</sup> Although patients should be monitored for alterations in neurologic function as a marker of stent stenosis or occlusion, serial duplex ultrasounds ought to be employed to identify subclinical luminal narrowing.<sup>97</sup>

### SUBCLAVIAN ARTERY

Endovascular repair of subclavian artery injuries has been relatively well described in the literature because of the obvious benefits of this procedure compared with the morbidity of open subclavian artery exposure.<sup>83,87,94,98-104</sup> Stent grafts have effectively treated pseudoaneurysms, lacerations, AVFs, and complete transections of the subclavian artery and theoretically reduce the incidence of brachial plexus injury since dissection of the traumatized field has been eliminated.<sup>81,101,105</sup> An interventional consideration unique to the subclavian artery has been the presence of branch vessels that may be covered by the stent graft and provide a source for endoleak. If contralateral vertebral artery patency and antegrade flow have been visualized, these branch vessels may often be coil embolized.<sup>81</sup> If the vertebral artery cannot be safely occluded, however, a vertebral-carotid transposition should be completed before deployment of the stent graft.<sup>104</sup> Alternatively, stent-graft repair of the subclavian artery may cover an internal thoracic artery that has been used as a pedicled graft for coronary artery bypass grafting, placing the patient at risk for significant cardiac ischemia. Postprocedure antiplatelet therapy has consisted of Plavix for 1 to 3 months followed by lifelong aspirin therapy.<sup>104</sup> Repetitive compression of the stent graft between the clavicle and first rib over the lifespan of a young trauma patient creates the risk of stent fracture (Fig. 51-9). Therefore, long-term follow-up with serial imaging is required.<sup>87</sup> Both stenosis and stent fracture, although often asymptomatic, have been treated with balloon dilation and deployment of an additional stent such that open intervention may still be avoided.<sup>81,102</sup>

## THE DESCENDING THORACIC AORTA

### Mechanism of Injury

Traumatic aortic disruptions typically occur in motor vehicle drivers, passengers, or pedestrians hit by vehicles.<sup>25,106,107</sup> Alcohol or other substance abuse is involved in greater than 40% of these motor vehicle accidents.<sup>107</sup> Patients ejected from the vehicle are twice as likely to sustain traumatic aortic injury, and seatbelt use can decrease this risk fourfold.<sup>107</sup> Overall, seatbelts have been demonstrated to be more effective than airbags at preventing blunt aortic injury, and aortic rupture of both the ascending and descending aorta has been attributed to the deployment of an airbag.<sup>108-110</sup> Falls from significant height, crush injuries, and airplane accidents have also caused aortic rupture.<sup>22,25,106,111</sup> The pathogenesis of aortic transection remains controversial and no integrated understanding of these forces has been achieved. The “whiplash” theory proposes that a combination of traction, torsion, shear, and bursting forces interact owing to differential deceleration of tissues within the mediastinum, thereby causing adequate stress to rupture the aorta at the isthmus.<sup>107,112-116</sup> The ligamentum arteriosum, the left main stem bronchus, and the paired intercostal arteries limit aortic mobility. Investigations have shown that displacement of the aorta in a longitudinal direction may cause a tear at the isthmus.<sup>114</sup> Alternatively, the “osseous pinch” mechanism has been proposed based on quantifiable thoracic compression.<sup>117,118</sup> With this mechanism, anterior thoracic osseous structures (manubrium, first rib, and clavicular heads) rotate posteriorly and inferiorly and may impact the vertebral column, pinching the aortic isthmus and proximal descending thoracic aorta.<sup>118</sup> This pinch is theorized to cause shearing of the aorta and some clinical data do support the osseous pinch mechanism.<sup>119</sup> Overall, diversity among the direction and magnitude of forces generated by a blunt traumatic event in patients suffering descending thoracic aortic rupture have prohibited identification of a single pathogenetic mechanism. Traumatic aortic disruptions in the descending thoracic aorta occur most commonly at the aortic isthmus, and an autopsy series identified 54% at this site, with 8% in the ascending aorta, 2% in the arch, and 11% in the distal descending aorta.<sup>120</sup> In those who survive, the periadventitial tissues around the isthmus appear to provide protection against free rupture and allow time for transfer to a hospital; consequently, surgical case series have reported 84 to 97% of aortic ruptures occurring at the isthmus.<sup>25,121-125</sup> The strength of the aortic wall is in its adventitial layer, and despite the increased incidence of transection at the aortic isthmus, there is no evidence to suggest that the adventitia in this area is deficient.<sup>126</sup> Additionally, the structure of the aortic wall surrounding the transection has not demonstrated any defect and atherosclerotic disease does not play a role in this injury.<sup>106,107,120</sup> The transverse transection caused by blunt aortic trauma typically involves all three layers of the wall and the edges may be separated by several centimeters.<sup>106,120</sup> Occasionally, noncircumferential or partial aortic wall disruptions have been described, particularly posteriorly, and

under these circumstances intramural hematomas and focal dissections may occur.<sup>106,120,127</sup>

## Operative Strategies

BTAI has traditionally undergone open repair with interposition graft placement, and this approach has proved to be safe, effective, and durable, thereby establishing it as the standard with which new repair strategies should be compared. Mortality after an open repair has been approximated at 20%, and the morbidity rate may be as high as 14%, largely attributable to the incidence of spinal cord ischemia.<sup>128</sup> The popularity of endovascular stent grafting (EVSG) or TEVAR of traumatic aortic disruptions has grown immensely in the current era because of expected decreases in operating room time, complication rate, morbidity, and mortality.<sup>129,130</sup> A prospective, nonrandomized, multicenter trial of endovascular aortic repair using Valiant Captivia for BTAI (RESCUE) reports on 50 patients with BTAI. These patients were enrolled between April 2010 and January 2012. All-cause mortality within 1 year was 12%. There were no conversions to open repair. There were no device-related adverse events. This study demonstrated that TEVAR has favorable early midterm outcomes in the treatment of BTAI. The authors conclude that TEVAR remains the treatment modality of choice; however, the longevity of the stent grafts in this patient population has yet to be established.<sup>129</sup> As such this approach is particularly attractive in multitrauma patients, and several institution series have reported good short-term outcomes.<sup>131-139</sup> Many anatomical details must be considered when pursuing TEVAR for traumatic aortic rupture in a young, otherwise healthy patient with a normal-caliber thoracic aorta. The landing zones may not coincide with those expected when the commercially available stent graft was designed for the treatment of aneurysm disease; therefore, successful placement of the stent graft relies on individual surgeon ingenuity and long-term durability of these repairs remains unknown.<sup>129</sup> TEVAR techniques continue to evolve, however, and are not uniformly applicable; therefore, surgeons treating thoracic aortic disruption must be comfortable with conventional open repair techniques.

### OPEN REPAIR

The major controversy regarding open operative repair of blunt aortic trauma involves spinal cord protection. Some still report safety and efficacy with a “clamp-and-sew” technique, whereas the majority of surgeons have successfully reduced the historical 10% paraplegia rate through some form of lower body perfusion to minimize spinal cord and visceral organ ischemia.<sup>25,121,123-125,140,141</sup>

### ARTERIAL SUPPLY TO THE SPINAL CORD

Blood supply to the spinal cord relies on three longitudinal arteries, the anterior spinal artery located in the anterior-median position and supplying 75% of the spinal cord, and the paired posterior spinal arteries located near the nerve roots. Segmental intercostal and lumbar arteries originating from the posterior aspect of the aorta supply a series of unpaired

radicular arteries that subsequently contribute flow to the anterior spinal artery. The vertebral arteries also provide radicular branches to supply the anterior spinal artery; therefore, in addition to the risk of cord ischemia during aortic cross-clamp at the isthmus and associated paraplegia rates, clamping proximal to the left subclavian compromises flow into the left vertebral and further threatens the integrity of the spinal cord. The posterior spinal arteries are supplied by smaller radicular arteries that originate from the aorta at nearly every spinal level. The largest and most significant radicular artery, typically originating at the level of T10 and entering the vertebral column at the first lumbar vertebrae, is the arteria radicularis magna (or artery of Adamkiewicz) and this vessel is essential for spinal cord perfusion in nearly 25% of patients.

### AORTIC CROSS-CLAMP

Some groups report low paraplegia rates exclusively using a “clamp-and-sew” technique; however, these results are not widely reproducible and rely on cross-clamp times of less than 30 minutes.<sup>124</sup> Because of its simplicity, this technique may be preferentially employed by the noncardiothoracic surgeon confronted with repair of a blunt aortic injury. Fragility of the aortic wall, anatomical distortion by the periaortic hematoma, and extension of the defect into the left subclavian artery pose significant obstacles and the average cross-clamp time reported in the literature is 41 minutes.<sup>125</sup> Paraplegia rates are greatly reduced and may even approach zero when extracorporeal lower body perfusion techniques are paired with short cross-clamp times (Tables 51-3, 51-4, and Fig. 51-10).<sup>25,140-142</sup>

### ADJUVANT PERFUSION TECHNIQUES

Elective repair of thoracic or thoracoabdominal aneurysms allows employment of several techniques to minimize spinal cord ischemia, but the preoperative preparation required to monitor somatosensory evoked potentials, provide lumbar cerebrospinal fluid drainage, or achieve epidural cooling is typically not available in the trauma setting.<sup>141,143-145</sup> Hypothermic circulatory arrest techniques have been successfully applied to injuries involving the arch, but are not

practical when partial bypass systems are employed.<sup>146,147</sup> The system used by any one group should be routine; however, it is important to be well versed in the various lower body perfusion systems because distinct circumstances may require alterations in practice. Intra-arterial blood pressure monitoring of both the upper and lower limbs should be performed with a goal perfusion pressure of 60 to 70 mm Hg.<sup>148</sup> Systemic heparinization poses a significant risk of hemorrhage in the trauma patient, particularly in those with severe lung or intracranial injuries. Use of a centrifugal pump with heparin-bonded tubing and active partial left heart bypass or use of a heparin-bonded passive shunt is an option that does not require systemic heparinization.<sup>148,149</sup> Alternatively, safe use of partial left heart bypass with full systemic heparinization has been reported as well.<sup>150,151</sup> For partial left heart bypass, pump inflow is established by cannulating the left atrium through the left inferior pulmonary vein using a small single- or dual-stage cannula (Fig. 51-11). Pulmonary

**FIGURE 51-11** Diagram showing a typical setup for partial left heart bypass in a patient with aortic disruption at the isthmus.

venous cannulation near its confluence with the left atrium has demonstrated a lower complication rate than cannulation of the left atrial appendage.<sup>152</sup> Arterial cannulation may occur through the distal descending aorta or the femoral artery. Distal aortic cannulation has the advantage of convenience and speed. Partial left heart bypass serves several purposes: (1) to unload the left heart and control proximal hypertension at the time of cross-clamping; (2) to maintain lower body perfusion; (3) to allow rapid infusion of volume; and (4) to control (remove) intravascular volume. Lower body mean arterial pressure should be maintained

**FIGURE 51-10** Probability of paraplegia in relation to aortic cross-clamp time with and without lower body perfusion in patients with traumatic aortic disruption at the isthmus. (Reproduced with permission from Katz NM, Blackstone EH, Kirklin JW, et al: Incremental risk factors for spinal cord injury following operation for acute traumatic aortic transection, *J Thorac Cardiovasc Surg*. 1981 May;81(5):669-674.)

at 60 to 70 mm Hg and this can typically be accomplished with a perfusion flow rate of 2 to 3 L/min. Mean arterial pressures from 70 to 80 mm Hg are generated in the upper body by the native heart and ventricular arrhythmias remain a significant risk. The pump reservoir and/or cell saver are employed to return blood from the field and a heat exchanger can be used to maintain core temperatures above 35°C. If the system is used without systemic heparinization, however, heat exchangers and oxygenators should be removed from the circuit to minimize surface area and thrombotic risks.

In full or partial cardiopulmonary bypass, a long venous catheter with multiple side holes may be introduced through the left common femoral vein and placed in the right atrium with a guidewire. Alternatively, direct right atrial cannulation at the inferior vena cava-right atrial junction may be accomplished from a left thoracotomy by simple, transverse, inferior pericardiotomy below the left phrenic nerve. Right atrial-femoral arterial bypass has also been used with or without an oxygenator-like partial left heart bypass. A partial arterial oxygen pressure of 40 mm Hg has been reported in non-oxygenated circuits, a level shown to be sufficient for lower body tissue oxygenation when the hemoglobin is maintained at 10 g/dL.<sup>153</sup> In cases of aortic arch injury, full cardiopulmonary bypass is beneficial.<sup>154,155</sup> Partial or complete bypass may be established before entering the chest by pursuing right femoral venous to arterial bypass, a technique particularly advantageous when a concomitant right lung contusion inhibits oxygenation. In cases of aortic arch transection in proximity to the innominate or left common carotid, anterior exposure via sternotomy or thoracosternotomy may offer better exposure for total arch replacement under deep hypothermic circulatory arrest (HCA).<sup>154,155</sup> Use of HCA in trauma patients poses significant bleeding risks; therefore, aortic injuries requiring this technique may be appropriate for anti-impulse therapy and a delay in repair until other concomitant injuries have been addressed. Additionally, aortic valvular insufficiency must be ruled out. When HCA is used within the left chest, the left ventricle should be vented through the left atrium. A passive (Gott) shunt has been described where the proximal and distal ends of a heparin-coated polyvinyl tube are placed in the ascending aorta or arch and the descending aorta or femoral artery, respectively. Ventricular cannulation had been used in the past; however, it was abandoned because of a high rate of ventricular dysrhythmias, reduced shunt flows, and a higher rate of paraplegia.<sup>156,157</sup> Flow through this fixed tube is dependent on a pressure gradient and this inability to control flow is the main disadvantage of the Gott shunt.<sup>157</sup> Moreover, it offers no left ventricular unloading or loading advantage, as partial bypass systems do; therefore, blood pressure control is left to pharmacology alone.

## Operative Techniques

The patient is positioned in the right lateral decubitus position with the left groin prepped for arterial and venous access.

A right radial arterial line is preferred to avoid losing arterial pressure tracing if occlusion of the left subclavian artery is required during the repair. Use of a pulmonary arterial catheter is optional. Selective ventilation of the right lung is required. A standard fourth interspace posterolateral thoracotomy with or without fifth rib notching usually provides excellent exposure to the aortic isthmus and proximal descending aorta. The incision should be long enough to facilitate dissection of the descending aorta below the level of the inferior pulmonary vein and dissection of the arch of the aorta between the left common carotid and left subclavian arteries. In a patient with a prior left thoracotomy, the associated scarring offers both an advantage and disadvantage to the patient. The adhesions between the lung and mediastinum help contain the rupture, making it less likely to exsanguinate. Dissection near the isthmus or tear should be avoided until both proximal and distal aortic control is established. Depending on the stability of the patient, lower body perfusion can be established before aortic exposure by gaining access to the left groin. If cannulation is planned in the chest, the left inferior pulmonary vein-left atrial junction is dissected and cannulated, in addition to arterial cannulation of the distal descending thoracic aorta or left common femoral vein. Excessive compression or traction of the lung should be avoided, particularly when dissecting out the aortic arch, because the left pulmonary artery may be easily disrupted at this location. Distal control is obtained first, usually by fairly simple passage of a blunt instrument or finger around the descending aorta at the distal margin of the hematoma. Care must be taken not to avulse intercostal arterial branches with this maneuver. The subclavian artery is isolated next. Great care is taken to avoid injury to either the phrenic or vagus nerves as they pass over the aortic arch, which can be difficult because they are often obscured by the hematoma. They should be reflected off the aorta with the overlying pleura and retracted medially by attaching stay sutures to the pleura just lateral to the vagus nerve. Loops around the nerves themselves should be avoided, as even stretch of these nerves can result in paresis. This reflection exposes the arch of the aorta between the left common carotid and left subclavian arteries, which is the point needed for proximal aortic control in the majority of cases. Inferiorly, the vagus nerve and its branching left recurrent laryngeal nerve are reflected medially as well. This exposes the ligamentum arteriosum, which can be sharply divided, but usually this step is not required. Careful dissection is then undertaken between the left common carotid artery and left subclavian artery using a combination of sharp and gentle finger dissection to completely encircle the aortic arch with an umbilical tape. As with distal aortic control, the periaortic hematoma facilitates this dissection considerably. There should be no dissection distal to either the left subclavian or the ligamentum in order to avoid free disruption of the hematoma. Lower body perfusion is initiated, and once systemic blood pressure is stabilized the left subclavian artery is clamped (if necessary) followed by the proximal aorta. With modern imaging techniques, it is usually possible to predict, to the millimeter, exactly where the aortic tear is in order to avoid involving it in

the proximal clamp. The distal aorta is clamped last. Traumatic aortic disruptions that occur in close proximity (<1 cm) from the left subclavian artery portend a higher mortality risk and greater operative difficulty than injuries further away from the left subclavian ostium.<sup>154</sup> Upper and lower body pressures are stabilized with the bypass circuit to maintain upper body mean arterial pressures of 70 to 80 mm Hg and a lower body pressure of 60 to 70 mm Hg with flows of 2 to 3 L/min. The periaortic hematoma is then entered, and the edges of the transected aorta are identified. Usually the aorta is completely transected, and the edges are separated by 2 to 4 cm.<sup>106,120</sup> Less frequently, the transection is partial. Some authors advocate primary repair at this point.<sup>156,158</sup> However, we advocate placing a short interposition graft after debridement of the torn edges in all cases.<sup>151,159,160</sup> Collagen-coated woven polyester grafts or gelatin-impregnated grafts are used most commonly. Use of intraluminal prostheses has been abandoned by most groups.<sup>161</sup> Grafts are sewn using a running polypropylene suture with the proximal anastomosis performed first, followed by the distal. Generous amounts of adventitial tissue are included in each bite. If the proximal anastomosis is done under HCA, cardiopulmonary bypass and reperfusion of the arch should be reinstated immediately after completion of the proximal anastomosis for optimal neurocerebral protection. This requires cannulation of the graft just beyond the proximal anastomosis (branched grafts are useful here for recannulation), and then the distal anastomosis is completed using a dual arterial-inflow perfusion setup perfusing the arch and lower body simultaneously. The left subclavian can either be incorporated into the proximal anastomosis or grafted separately as appropriate. If it is discovered that the tear extends above the proximal aortic clamp, an attempt can be made to dissect more proximally and place a second clamp provided the left common carotid artery is not compromised. If this is not possible, the best recourse is to cannulate the aortic arch in addition to the distal arterial cannula, commence full cardiopulmonary bypass through both arterial routes, and perform the proximal anastomosis during a brief period of profound HCA. We cool to 20°C and use cerebral protection adjuncts, including packing the head in ice and 15 mg/kg sodium thiopental intravenously. One must be prepared to vent the left ventricular apex if distention occurs as a result of cooling induced ventricular fibrillation. A continuous short-axis view by transesophageal echocardiography is very useful in this circumstance. If the aorta is already ruptured with bleeding into the hemithorax, proximal aortic dissection between the left carotid and subclavian arteries is rapidly performed, and a cross-clamp quickly applied. The descending aorta is then clamped below the injury, and the hematoma opened. No attempt is made to establish lower body perfusion, but every attempt is made at maintaining adequate mean arterial pressure during clamping. The aortic repair is done as expeditiously as possible to minimize clamp time. Repair sutures are placed accordingly after clamps are removed. Hemostasis is achieved after continuity of the aorta is re-established. Occasionally, the aortic tear will extend into the left subclavian orifice. In this case the proximal clamp may have to partially or totally occlude the left common carotid. The left subclavian

can then be completely detached from the aorta, the proximal anastomosis completed, and the clamp then moved distally onto the graft. The left subclavian is then reattached to the aortic graft with an interposition graft after completing the distal aortic anastomosis. The left subclavian interposition graft is fashioned with an end-to-end anastomosis distally and an end-to-side anastomosis proximally.

## Endovascular Stent Grafting/Thoracic Endovascular Aortic Repair

Use of endovascular techniques to treat abdominal aortic aneurysms began in 1991 and has subsequently been expanded to degenerative thoracic aortic aneurysms. In trauma patients with blunt aortic injury, this technology was initially applied to patients considered extremely high risk for open repair, such as those with a head injury, abdominal visceral injury, or severe pulmonary contusions.<sup>53,54,137,162</sup> The safety and efficacy of this procedure has since been demonstrated and EVSG is considered the preferred method of treatment by many groups.<sup>52,131,132,134-139,162-170</sup> Theoretical advantages of stent grafting include avoidance of thoracotomy, one-lung ventilation, the systemic effects of cardiopulmonary bypass, aortic cross-clamping, and spinal cord ischemia, which should decrease perioperative mortality and complications.<sup>6,129,132,134,135,137-139,162,171-175</sup>

In patients with stable aortic injuries (grade II or III), the timing of intervention is usually dictated by the severity of associated nonaortic injuries. With proper anti-impulse control, delayed management of BTAI until life-threatening nonaortic injuries have been treated has been shown to be a safe and beneficial approach.<sup>47,176</sup> The optimal timing of aortic repair has continued to evolve as the treatment of BTAI has shifted from open aortic repair to TEVAR. The minimally invasive nature of TEVAR has allowed for earlier aortic repair in stable patients, emergent treatment of unstable patients, and easier concomitant management of both aortic and non-aortic injuries. In patients without other serious injuries, the trend has been to treat grade II or III injuries within 24 hours of admission to avoid progression to rupture (grade IV) and the potential deleterious effects of aggressive impulse control in certain patient populations.

Several anatomical considerations must be addressed when deciding whether a patient is a candidate for TEVAR of a blunt aortic transection. A proximal landing zone of at least 1.5 cm is considered necessary to achieve a reliable seal, raising the concern of left arm ischemia if the left subclavian artery needs to be covered; however, this has not been observed.<sup>136,165</sup> In the rare case of symptomatic left arm ischemia, elective carotid to subclavian bypass may be performed.<sup>165</sup> A recent study from Texas demonstrated no statistically significant difference in physical health scores between left subclavian artery coverage and uncovered TEVAR for traumatic aortic injury and hence coverage of the left subclavian artery appears safe and does not impair normal activities.<sup>166</sup> The left subclavian artery origin is also a good marker for an area of acute angulation of the proximal descending aorta and the wall stents used

in early TEVAR procedures often became distorted in this region.<sup>177,178</sup> Newer flexible stents have overcome this issue. Additionally, the graft diameter should be oversized 10 to 20% for appropriate seating.<sup>133,136</sup> The size of the chosen graft will determine the route of placement. Early procedures used grafts designed as extension cuffs for abdominal aortic grafts, and these devices had delivery systems 65 cm in length, necessitating iliac or distal aortic access.<sup>133,138</sup> Those frequently reported in the literature include the Gore Excluder (W.L. Gore and Associates, Flagstaff, AZ), AneuRx (Medtronic, Santa Rosa, CA), and Zenith (Cook, Inc., Indianapolis, IN). These cuff diameters range from 18 to 28 mm, and the lengths range from 3.3 to 3.75 cm, necessitating placement of several cuffs to achieve adequate coverage.<sup>79</sup> Commercially available thoracic aortic stent grafts have been designed for treatment of aneurysm disease. Therefore, the diameters are often too large for the otherwise healthy aorta encountered in a patient with traumatic aortic transection. The Gore TAG (W.L. Gore and Associates, Flagstaff, AZ) fits vessels 23 to 37 mm, and the Talent Valiant (Medtronic, Santa Rosa, CA) may be applied to vessels 20 to 42 mm in diameter, excluding a large percentage of blunt aortic transection victims.<sup>177</sup> The ideal device for repair of traumatic aortic injury would be 16 to 40 mm in diameter, be available in 5-, 10-, and 15-cm lengths, and conform to a 90-degree curvature without deformation. Additionally, the delivery system should be distally flexible and approximately 80 to 90 cm in length.<sup>79</sup> A recent study by Canaud and colleagues compared the conformability of the four commercially available thoracic devices with increasing aortic arch angulation and oversizing. All second-generation devices performed significantly better than their respective predecessors. Both the Valiant and the C-TAG devices performed well, with complete wall apposition and arch angulation up to 140° and 120°, respectively.<sup>179</sup>

Patients who will undergo TEVAR for traumatic aortic disruption should be positioned supine in a hybrid operating room/angi suite or conventional operating room table with fluoroscopic capabilities. General endotracheal anesthesia is typically employed. Conversion to open repair is rare, but has occurred because of postdeployment stent migration; therefore, the operative team must be prepared for rapid conversion.<sup>180</sup> Retrograde aortic access is accomplished percutaneously or by cutdown on the femoral or iliac artery depending on the chosen stent graft. A floppy tipped J-wire should be advanced into the aorta under fluoroscopic guidance with subsequent placement of marked catheter. An aortogram should be obtained in steep left anterior oblique projection to clearly visualize the arch. The details of the aortic injury and device measurements are obtained from a computed tomography angiography (CTA) during operative planning, but the intraoperative aortogram is vital to confirming appropriate anatomy for TEVAR and selection of the correct device. Additionally, the length of graft coverage is determined by this intraoperative image. Deployments of stent grafts have been successful with and without administration of systemic heparin (Fig. 51-12).<sup>181</sup> Intravascular ultrasound may be a useful adjunct when determining coverage length

**FIGURE 51-12** Endovascular stent graft repair of a blunt traumatic aortic injury demonstrating coverage of the left subclavian artery.

and graft diameter.<sup>182,183</sup> Based on the proximity to the aortic injury, the left subclavian artery may need to be covered, and if covered, it may need to be embolized and bypassed or transposed to the left common carotid artery to ensure a proximal graft seal and avoid problems of ischemia to the left arm or vertebrobasilar system.<sup>138,184-186</sup> Despite whether single or multiple graft devices have been deployed, successful exclusion of the pseudoaneurysm has been accomplished in 90 to 100% of patients reported in the literature.<sup>136-138,187</sup> Decreased operating room time, diminished physiologic derangement and hypothermia, decreased transfusion rates, and shorter intensive care unit and overall hospital stays have been documented in series directly comparing open and endovascular repair of blunt traumatic aortic injury.<sup>137,138,180</sup> Procedure-related paraplegia and mortality rates are also markedly reduced to nearly zero.<sup>137,138,180</sup> Long-term surveillance is recommended to evaluate for endoleak, stent migration, or delayed pseudoaneurysm formation with annual CTA. The optimal follow-up strategy is evolving as imaging technology continues to improve. Also long-term experience grows. In general, CTA is utilized at 1, 3, and 12 months. The individual follow-up strategy is usually tailored to the patient. In the absence of endoleak or endograft collapse or migration on those initial studies, repeat imaging is usually performed every 3 to 5 years.

## The Future

With the development of newer-generation devices leading to improved outcomes and less endograft-related complications, TEVAR has established itself as the primary treatment for

most patients with thoracic aortic injuries. Future iterations of devices should include shorter lengths and smaller and more precise deployment mechanisms. The potential ability to redeploy the same endograft will make this a very adaptable technique. The use of TEVAR in traumatically injured patients continues to evolve, and TEVAR has supplanted open surgical repair as the primary treatment for BTAs in most centers. Since the release of the Society of Vascular Surgery clinical guidelines,<sup>4</sup> many issues have been resolved. Other problems associated with TEVAR for thoracic aortic injuries are evolving as this chapter is being written, with improved newer-generation devices. Soon enough, a time will come where most interventions for treatment of acute injuries to the aorta and its great vessels are undertaken by TEVAR with open surgical techniques being discussed in historical chapters.

# Pulmonary Embolism and Pulmonary Thromboendarterectomy

Stuart W. Jamieson • Michael M. Madani

Pulmonary embolism (PE) results in at least 630,000 symptomatic episodes in the United States yearly, making it about half as common as acute myocardial infarction, and three times as common as cerebrovascular accidents.<sup>1</sup> Acute PE is the third most common cause of death (after heart disease and cancer). Estimates of PE are probably low because approximately 75% of autopsy-proved PE are not detected clinically<sup>2</sup> and in 70 to 80% of the patients in whom the primary cause of death was PE, premortem diagnosis was completely unsuspected.<sup>3,4</sup> Of all hospitalized patients who develop PE, 12 to 21% die in the hospital, and another 24 to 39% die within 12 months.<sup>5-7</sup> Thus, approximately 36 to 60% of patients who survive the initial episode live beyond 12 months, and may present later in life with a wide variety of symptoms.

In addition, approximately 2.5 million Americans develop deep vein thrombosis (DVT) each year, and more than 90% of clinically detected pulmonary emboli are associated with lower extremity DVT. However, in two-thirds of patients with DVT and PE, the DVT is asymptomatic.<sup>8-10</sup>

For the most part, DVT and acute PE are managed medically. Cardiac surgeons rarely become involved in management of acute PE, unless it is in a hospitalized patient who survives a massive embolus that causes life-threatening acute right heart failure with low cardiac output, with a large clot burden. On the other hand, the mainstay of treatment for patients with chronic pulmonary thromboembolic disease<sup>11</sup> is the surgical removal of the disease by means of pulmonary thromboendarterectomy. Medical management for this condition is only palliative, and surgery by means of transplantation is an inappropriate use of resources with outcomes inferior to thromboendarterectomy.

## DEEP VEIN THROMBOSIS

Deep vein thrombosis primarily affects the veins of the lower extremity or pelvis. It is most common in hospitalized patients but may occur in ambulatory patients outside

the hospital.<sup>12,13</sup> The process may involve superficial as well as deep veins, but superficial venous thrombosis does not generally propagate beyond the saphenofemoral junction and therefore very rarely causes PE.<sup>9,14,15</sup> Venous thrombosis of the upper extremity is almost always associated with trauma, indwelling catheters, or other pathologic states and is an uncommon cause of PE, but can be fatal. Pulmonary emboli that do not originate from the deep venous system of the legs, pelvis, or arms are thought to come from a diseased right atrium or ventricle or retroperitoneal and hepatic systems.<sup>12,13</sup>

## Pathogenesis

In 1856, Rudolf Virchow made the association between DVT and PE and suggested that the causes of DVT were related to venous stasis, vein wall injury, and hypercoagulopathy. This triad of etiologic factors remains relevant today and is supported by an ever-growing body of evidence.

Immobilization is by far the most important cause of venous stasis in hospitalized patients. Injections of contrast material in foot veins require up to 1 hour to clear from the venous valves in the soleus muscle of immobilized patients.<sup>16</sup> Venous stasis may also be produced by mechanical obstruction of proximal veins, by low cardiac output, by venous dilatation, and by increased blood viscosity.<sup>17</sup> Some pelvic tumors, bulky inguinal adenopathy, the gravid uterus, previous caval or iliac venous disease, and elevated central venous pressures from cardiac causes also enhance venous stasis.

The role of vein wall injury is less clear because DVT often begins in the absence of mechanical trauma. Recent work shows that subtle vein wall injuries may occur during operation in veins remote from the operative field.<sup>18,19</sup> In animals, endothelial cell tears have been found at junctions of small veins with larger veins at remote sites during hip replacement (Fig. 52-1).

**FIGURE 52-1** Scanning electron photomicrograph of a canine jugular vein after total hip replacement with significant operative venous dilatation. An endothelial cell tear (t) is visible near a valve cusp (V). (Reproduced with permission from Cometra AJ, Stewart GJ, White JV: Combined dihydroergotamine and heparin prophylaxis of postoperative deep vein thrombosis: proposed mechanism of action, *Am J Surg* 1985 Oct 8;150(4A):39-44.)

Three uncommon familial deficiencies associated with venous thrombosis are seen in antithrombin, protein C, and protein S. Antithrombin is a natural plasma protease that inhibits thrombin after it is formed, and to a lesser extent before it is formed. Antithrombin is also the cofactor that is accelerated 1000-fold by heparin. Protein C is a potent inhibitor of factor V and platelet-bound factor VII and requires protein S as a cofactor for anticoagulant activity. Both protein C and S are vitamin-K-dependent zymogens that are activated by thrombin and accelerated by thrombomodulin produced by endothelial cells.<sup>20,21</sup>

A much more common coagulation deficiency, resulting from a mutation of factor V (factor V Leiden) that prevents its degradation by protein C, has been described and is present in approximately 6 to 7% of study populations of Swedes and North American males.<sup>22-24</sup> Both the homozygous and heterozygous mutants are strongly associated with venous thrombosis and PE but are not associated with manifestations of arterial thrombosis.<sup>24,25</sup>

The presence of the lupus anticoagulant, which is an acquired IgG or IgM antibody against prothrombinase, increases the likelihood of venous thrombosis by poorly understood mechanisms.<sup>25</sup> The disease may be associated with lupus-like syndromes, immunosuppression, or intake of specific drugs, such as procainamide.

### Risk Factors for Deep Vein Thrombosis

Table 52-1 presents a list of major risk factors for the development of DVT or PE. Previous thromboembolism, older age,

**TABLE 52-1: Major Risk Factors for Venous Thromboembolism**

Previous venous thromboembolism	Age over 45 years
Major hip or knee surgery	Bed rest 7 days or longer
Recent major surgery	Cancer
Congestive heart failure	Paralysis of lower extremity
Pelvis, hip, or leg fracture	Multiple trauma
High-dose estrogen therapy	

immobilization for more than 1 week, orthopedic surgery of the hip or knee, recent surgery, multiple trauma, and cancer are strong risk factors. In patients with a history of venous thromboembolism the risk of developing a new episode during hospitalization is nearly eight times that of someone without a history.<sup>9,26-29</sup> Up to 10% of patients with a first episode of DVT or PE and up to 20% of those with a recurrent event develop a new episode of venous thromboembolism within 6 months.<sup>30</sup>

The incidence of DVT and PE increases exponentially with age (Fig. 52-2). Males are at greater risk than females. Prolonged bed rest or immobility from any cause are major risk factors. Although usually other risk factors are present, the incidence of autopsy-proved venous thrombosis rises from 15 to 80% in patients at bed rest for more than 1 week.<sup>30,31</sup>

The incidence of venous thromboembolism increases threefold in patients who have operations for cancer.<sup>9</sup> Of particular interest to cardiac surgeons and cardiologists is the observation that clinically silent DVT develops during hospitalization in nearly 50% of patients after myocardial revascularization.<sup>32</sup>

**FIGURE 52-2** Annual incidence of venous thromboembolism in the United States stratified for age. Males have a significantly higher incidence rate of venous thromboembolism than females. Both curves fit an exponential function.

A follow-up study<sup>33</sup> found that the incidence of PE in hospital after coronary arterial bypass operations was 3.2% and hospital mortality in patients with PE was 18.7%. Interestingly, valvular surgery was not associated with the development of PE. In a retrospective study of 5694 patients who had open heart surgery, Gillinov and colleagues found the risk of PE proved by V/Q scan (20 patients), angiography (four patients), or autopsy (eight patients) was 0.56% within 60 days. The mortality was 34% in patients with PE.<sup>34</sup>

## Diagnosis

Approximately two-thirds of patients with DVT do not have clinical symptoms;<sup>9</sup> therefore, the diagnosis depends on a high degree of clinical suspicion and a variety of objective diagnostic tests. Venography remains the most reliable test for detecting thrombus in calf veins, but is invasive, not suitable for serial studies, and the contrast material may be thrombogenic if allowed to remain within the deep venous system.<sup>10</sup>

The most popular noninvasive test, which can be done at the bedside, is a combination of ultrasound and color flow Doppler mapping, widely referred to as *duplex scanning*. The method does not detect fresh thrombi directly but infers the presence of clot by flow patterns and the inability to compress the vessel in specific locations.<sup>10</sup> In the hands of skilled examiners duplex scanning is highly accurate for the detection of thrombus in popliteal, deep femoral, and superficial femoral veins and has a sensitivity between 89 and 100% against venography in symptomatic patients. Magnetic resonance imaging (MRI) is a noninvasive method that can image the entire venous system, including upper extremity veins and mediastinum.<sup>35</sup> Against MRI duplex scanning has a sensitivity of 70% for pelvic veins and a specificity of nearly 100%.<sup>36</sup> Impedance plethysmography assesses volume changes in the leg after occlusion of the vein with calf electrodes and a thigh cuff. It is clinically useful in symptomatic patients but has relatively low sensitivity and specificity in asymptomatic patients and calf thrombosis.<sup>36</sup> Injection of iodine 125-labeled fibrinogen with subsequent leg scanning is a sensitive test for detecting calf vein thrombus but does not detect iliofemoral vein thrombosis. The combination of these two tests improves sensitivity and specificity, but in most hospitals duplex scanning, venography, and MRI have superseded both tests.

## Prophylaxis

The prevalence of DVT, its strong association with PE, and the identification of risk factors in the pathogenesis of the disease provide the basis and rationale for prophylactic measures that are recommended in patients with two or more major risk factors, such as age over 40 years and major surgery.<sup>9</sup> Innocuous measures such as compression stockings probably should be prescribed more often and be used in most nonambulating patients in the hospital. Intermittent pneumatic compression is more expensive and more

cumbersome but is effective. Both methods reduce the incidence of DVT after general surgery to approximately 40% of control patients.<sup>9</sup> Low-dose subcutaneous heparin and low-molecular-weight heparin given once a day reduce the incidence of DVT to approximately 35 and 18% of controls, respectively.<sup>9,31,37</sup> The reduction in PE with subcutaneous standard heparin or low-molecular-weight heparin is similar.<sup>31,37</sup>

Calf vein DVT that does not propagate has a low risk of PE, and controversy exists as to whether or not these patients should be anticoagulated.<sup>15</sup> Of patients who have DVT diagnosed in hospital without PE, the probability of clinically diagnosed PE within the next 12 months is 1.7%.<sup>5</sup> If PE occurs, the probability of recurrent PE is 8.0%.<sup>5</sup> Six months of warfarin anticoagulation is recommended for patients who have DVT with or without PE, as prophylaxis against recurrent disease.<sup>38</sup>

## PULMONARY EMBOLISM

### Pathology and Pathogenesis

The only firm attachment of leg thrombus is at the site of origin, usually a venous sacculi or venous valve pocket.<sup>26</sup> The degree of organization within the thrombus varies, but recent clots are more likely to migrate than older thrombi that are more firmly attached to the vessel wall.

Detached venous thrombi are carried in the bloodstream through the right heart into the pulmonary circulation. In autopsy series the percentage of emboli that obstruct two or more lobar arteries (major) ranges between 25 and 67% of all emboli;<sup>39</sup> but this figure varies with the thoroughness of the examination. In clinical trials based on angiographic data the percentage of major emboli is similar and ranges from 30 to 64%.<sup>40</sup> The majority of pulmonary emboli lodge in the lower lobes,<sup>12</sup> and are slightly more common in the right lung than the left. This is probably the result of relative flow to those areas of the lung. Soon after reaching the lungs emboli become coated with a layer of platelets and fibrin.<sup>12</sup>

Simple mechanical obstruction of one or more pulmonary arteries does not entirely explain the often devastating hemodynamic consequences of major or massive emboli. Humoral factors, specifically serotonin, adenosine diphosphate (ADP), platelet-derived growth factor (PDGF), thromboxane from platelets coating the thrombus, platelet-activating factor (PAF), and leukotrienes from neutrophils are also involved.<sup>41,42</sup> Anoxia and tissue ischemia downstream from the emboli inhibit endothelium-derived relaxing factor (EDRF) production and enhance release of superoxide anions by activated neutrophils. The combination of these effects contributes to increased pulmonary vasoconstriction.<sup>41</sup>

### Natural History

The mortality of a large, untreated PE is 18 to 33%, but can be reduced to about 8% if diagnosed and treated.<sup>7,43,44</sup> Seventy-five to ninety percent of patients who die of pulmonary

emboli do so within the first few hours of the primary event.<sup>45</sup> In patients who have sufficient cardiopulmonary reserve and right ventricular strength to survive the initial few hours, autolysis of emboli occurs over the next few days and weeks.<sup>46</sup> On average, approximately 20% of the clot disappears by 7 days, and complete resolution may occur by 14 days.<sup>44,46,47</sup> For many patients, up to 30 days are needed to dissolve small emboli and up to 60 days for massive clots.<sup>48</sup> As the natural fibrinolytic system dissolves the embolic mass, the available cross-sectional area of the pulmonary arterial tree progressively increases, and pulmonary vascular resistance and right ventricular afterload decreases. In the vast majority of patients, pulmonary emboli continue to resolve and thus an immediate interventional therapy, particularly surgical embolectomy, is not necessary for survival except in a minority of patients.

In an unknown but small percentage of patients with acute PE the clot will not lyse, and chronic thromboembolic obstruction of the pulmonary vasculature develops. The reasons for failure of emboli to dissolve are unknown. Patients often are asymptomatic until symptoms of dyspnea, exercise intolerance, or right heart failure develop, mostly secondary to the pulmonary hypertension that ensues. Asymptomatic patients may have partial or complete chronic thrombotic occlusion of one or more segmental or lobar arteries. Symptomatic patients usually have more than 40% of their pulmonary vasculature obstructed by organized and fresh thrombi; however, significant pulmonary hypertension can develop in patients despite lesser degrees of vascular obstruction.

## Clinical Presentation

Acute PE usually presents suddenly. Symptoms and signs vary with the extent of blockage, the magnitude of the humoral response, and the pre-embolus reserve of the cardiac and pulmonary systems of the patient.<sup>49</sup> Symptoms and signs vary widely, and in autopsy series of proven emboli only 16 to 38% of patients were diagnosed during life.<sup>39</sup>

The acute disease is conveniently stratified into minor, major (submassive), or massive embolism on the basis of hemodynamic stability, arterial blood gases, and lung scan or angiographic assessment of the blocked pulmonary arteries.<sup>40,49,50</sup> Most pulmonary emboli are minor. These patients present with sudden, unexplained anxiety, tachypnea or dyspnea, pleuritic chest pain, cough, and occasionally streak hemoptysis.<sup>39,45,50</sup> Examination may reveal tachycardia, rales, low-grade fever, and sometimes a pleural rub. Heart sounds and systemic blood pressure are often normal; sometimes the pulmonary second sound is increased. Interestingly less than one-third of the patients will have evidence of clinical DVT.<sup>39</sup> Room air arterial blood gases indicate a PaO<sub>2</sub> between 65 and 80 torr and a normal PaCO<sub>2</sub> around 35 torr.<sup>45</sup> Pulmonary angiograms show less than 30% occlusion of the pulmonary arterial vasculature.

Major PE is associated with dyspnea, tachypnea, dull chest pain, and some degree of hemodynamic instability

manifested by tachycardia, mild to moderate hypotension, and elevation of the central venous pressure.<sup>45,50</sup> Some patients may present with syncope rather than dyspnea or chest pain. In contrast to massive PE, patients with major embolism (at least two lobar pulmonary arteries obstructed) are hemodynamically stable and have adequate cardiac output.<sup>40</sup> Room air blood gases reveal moderate hypoxia (PaO<sub>2</sub> <65, >50 torr) and mild hypocarbia (PaCO<sub>2</sub> <30 torr).<sup>50</sup> Echocardiograms may show right ventricular dilatation. Pulmonary angiograms indicate that 30 to 50% of the pulmonary vasculature is blocked.

Massive PE is truly life-threatening and it causes hemodynamic instability.<sup>40</sup> It is usually associated with occlusion of more than 50% of the pulmonary vasculature, but may occur with much smaller occlusions, particularly in patients with preexisting cardiac or pulmonary disease. The diagnosis is clinical, not anatomical. Patients develop acute dyspnea, tachypnea, tachycardia, and diaphoresis; and sometimes may lose consciousness. Both hypotension and low cardiac output (<1.8 L/m<sup>2</sup>/min) are present. Cardiac arrest may occur. Neck veins are distended; central venous pressure is elevated, and a right ventricular impulse may be present. Room air blood gases show severe hypoxia (PaO<sub>2</sub> < 50 torr), hypocarbia (PaCO<sub>2</sub> < 30 torr), and sometimes acidosis.<sup>40,45,50</sup> Urine output falls; peripheral pulses are decreased and perfusion is poor.

## Diagnosis

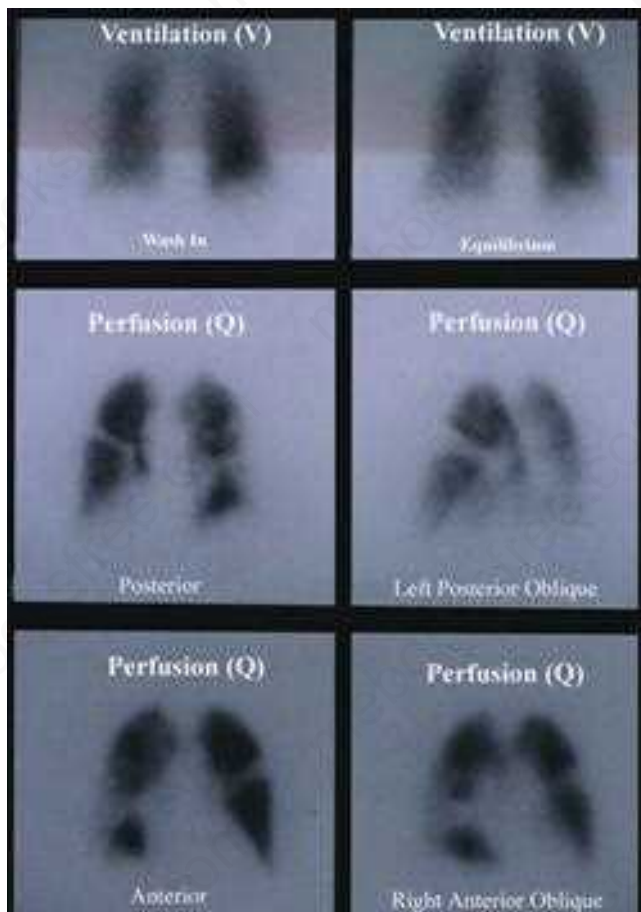

The clinical diagnosis of acute major or massive PE is wrong in 70 to 80% of patients who subsequently have angiography.<sup>49,51</sup> Even in postoperative patients and those with additional major risk factors for DVT, differentiation of major or massive PE from acute myocardial infarction, aortic dissection, septic shock, and other catastrophic states is difficult and uncertain.

The chest film may be normal but usually shows some combination of parenchymal infiltrate, atelectasis, and pleural effusion. A zone of hypovascularity or a wedge-shaped pleural-based density raises the possibility of PE. Usually, the ECG shows nonspecific T-wave or ST segment changes with PE. A minority of patients with massive embolism (26%) may show evidence of cor pulmonale, right axis deviation, or right bundle branch block.<sup>49</sup> An echocardiogram showing right heart dilatation raises the possibility of major or massive PE. A Swan-Ganz catheter generally shows pulmonary arterial desaturation (PaO<sub>2</sub> < 25 torr), but usually does not show pulmonary hypertension over 40 mm Hg because of low cardiac output and cor pulmonale (the unprepared right ventricle cannot generate pulmonary hypertension).

Ventilation-perfusion (V/Q) scans will provide confirmatory evidence, but these studies may be unreliable because pneumonia, atelectasis, previous pulmonary emboli, and other conditions may cause a mismatch in ventilation and perfusion and mimic positive results. In general, negative V/Q scans essentially exclude the diagnosis of clinically

significant PE. V/Q scans usually are interpreted as high, intermediate, or low probability of PE to emphasize the lack of specificity but high sensitivity of the test (Fig. 52-3). Pulmonary angiograms provide the most definitive diagnosis, but collapse of the circulation may not allow time for this procedure, and pulmonary angiograms should not be performed if the patient's circulation cannot be stabilized by pharmacologic or mechanical means.<sup>52,53</sup>

MRI and CT angiography are better noninvasive methods for the diagnosis of pulmonary emboli and provide specific information regarding flow within the pulmonary vasculature.<sup>54</sup> Unfortunately, these methods are expensive, somewhat time consuming, and not widely available. Furthermore, they are not generally suitable for hemodynamically unstable patients. Transthoracic (TTE) or transesophageal (TEE) echocardiography with color flow Doppler mapping can provide reliable information about the presence or absence of major thrombi obstructing right-sided chambers or the main pulmonary artery. More than 80% of patients with clinically significant PE have abnormalities of right ventricular volume or contractility, or acute tricuspid regurgitation by TTE (Fig. 52-4).<sup>55</sup> In some patients,

**FIGURE 52-3** Anterior and posterior views from a radionuclide perfusion scan in a patient with chronic thromboembolic disease. Note the large punched out defects.

**FIGURE 52-4** Appearance of echocardiography before and after the operation. The top pictures represent pre-PTE and bottom pictures represent post-PTE. Note the shift of the intraventricular septum toward the left in the systole before the operation, together with the relatively small left atrial and left ventricular chambers. After the operation, the septum has normalized, and the right-sided chambers are no longer massively enlarged. LA, left atrium; LV, left ventricle; PTE, pulmonary thromboendarterectomy; RA, right atrium; RV, right ventricle.

abnormal flow patterns can be discerned in major pulmonary arteries during TEE.

### Management of Acute Major Pulmonary Embolism

For the purposes of this chapter, major or submassive PE is defined as an acute episode that causes hypoxia and mild hypotension (systolic arterial pressure > 90 mm Hg), but does not cause cardiac arrest or sustained low cardiac output and cardiogenic shock. By definition there is sufficient time in these patients to definitely establish the diagnosis and to attempt pharmacologic therapy and possibly remove the embolic material by catheter suction.

The first priority after sudden collapse of any patient is to establish adequate ventilation and circulation. The first may require intubation and mechanical ventilation. Pharmacologic agents, including cardiovascular pressors and vasoactive agents, are then used to help stabilize the patient's hemodynamics. If the patient's circulation can be stabilized, intravenous heparin is started with an initial bolus of 70 U/kg followed by 18 to 20 U/kg/h if there are no contraindications. Heparin will prevent propagation and formation of new thromboemboli, but does not dissolve the existing clot. In most instances the patient's own fibrinolytic system lyses fresh thrombi over a period of days or weeks.<sup>46</sup>

The addition of lytic therapy, that is, streptokinase, urokinase, or recombinant tissue plasminogen activator (rt-PA), increases the rate of lysis of fresh thrombi and is recommended in patients with a stable circulation and no contraindications. This increases the rate of lysis of fresh pulmonary clots over that of heparin alone during treatment,<sup>56</sup> but there is little

difference in the amount of residual thrombus between the two treatments at 5 days or thereafter.<sup>57-60</sup> There is also no statistical difference in mortality or in the incidence of recurrent PE, but more recent experience shows a trend toward better results with thrombolytic therapy because of a more rapid reduction in right ventricular afterload and dysfunction.<sup>56</sup> Furthermore, there are no data that indicate that thrombolysis reduces the subsequent development of chronic pulmonary thromboembolism and pulmonary hypertension. Compared with Heparin therapy alone, thrombolytic agents carry a higher risk of bleeding complications, and despite precautions, bleeding complications occur in approximately 20% of patients.<sup>56,61,62</sup>

Mechanical removal of pulmonary thrombi is possible by a catheter device inserted under local anesthesia into the femoral (preferred) or jugular vein.<sup>50,63-66</sup> Successful extraction of clot with meaningful reduction in pulmonary arterial pressure varies between 61 and 84%.<sup>64,66</sup>

## Management of Acute Massive Pulmonary Embolism

If the circulation cannot be stabilized at survival levels within several minutes or if cardiac arrest occurs after a massive PE, time becomes of paramount importance. Eleven percent of patients with fatal PE die within the first hour, 43 to 80% within 2 hours, and 85% within 6 hours.<sup>67</sup> To a great extent, circumstances and the timely availability of necessary equipment and personnel determine therapeutic options. A decision to treat medically in an effort to stabilize the circulation at a survival level may preempt life-saving surgery, but also may make surgery unnecessary. The relative infrequency of treatment opportunities in massive PE, mitigating factors, and the lack of clear criteria for prescribing medical or surgical therapy leave the management of massive PE unsettled.

When surgery is not immediately available, in patients who may not be surgical candidates, or in whom an alternate diagnosis seems more likely, emergency extracorporeal life support (ECLS) using peripheral cannulation is an attractive alternative.<sup>68,69</sup> In prepared institutions ECLS can be instituted rapidly outside the operating room. ECLS compensates for acute cor pulmonale and hypoxia and sustains the circulation until the clot partially lyses, pulmonary vascular resistance falls, and pulmonary blood flow becomes adequate.

## Emergency Pulmonary Thromboembolectomy

Emergency pulmonary thromboembolectomy is indicated for suitable patients with life-threatening circulatory insufficiency, but should not be done without a definitive diagnosis because a clinical diagnosis of PE is often wrong.<sup>47,58,65,70</sup> If a patient has been taken directly to the operating room without a definitive diagnosis, TEE and color Doppler mapping can confirm or refute the diagnosis in the operating room. TEE will indicate increased right ventricular volume, poor right ventricular contractility, and tricuspid

regurgitation, which are strongly associated with massive PE and acute cor pulmonale.<sup>71</sup> Echocardiographic detection of a large clot trapped within the right atrium or ventricle in a hemodynamically compromised patient with massive acute PE is another indication for emergency pulmonary thromboembolectomy.<sup>72-74</sup>

A midline sternotomy incision is used and cardiopulmonary bypass is initiated. The heart may be electrically fibrillated or arrested with cold cardioplegic solution. The main pulmonary artery is then opened 1 to 2 cm downstream to the valve, and the incision is extended into the proximal left pulmonary artery. Forceps and suction catheters are used to remove the clot from the left pulmonary artery and behind the aorta to the right pulmonary artery. If necessary the right pulmonary artery can also be exposed and opened between the aorta and superior vena cava to allow better exposure in the distal segments. If a sterile pediatric bronchoscope is available, the surgeon can use this instrument to locate and remove thrombi in tertiary and quaternary pulmonary vessels. Alternatively, the pleural spaces are entered, and each lung is gently compressed to dislodge small clots into larger vessels and suctioned out. Greenfield recommends placement of an inferior vena caval filter before closing the chest.<sup>10,66,75,76</sup> European surgeons generally clip the intrapericardial vena cava at the end of pulmonary thromboembolectomy to prevent migration of large clots into the pulmonary circulation.<sup>74</sup> However, this clip increases venous pressure and stagnant flow in the lower half of the body and causes considerable morbidity in more than 60% of patients.<sup>72,74,75</sup>

Anticoagulation for 6 months is recommended for most patients with PE, but an inferior vena caval filter is recommended for patients with contraindications to anticoagulation or with recurrent PE, or those who will require pulmonary thromboendarterectomy. The cone-shaped Greenfield filter is the one most widely used and is associated with a lifetime recurrent embolism rate of 5% and has a 97% patency rate.<sup>77</sup>

## Extracorporeal Life Support

The wider availability of long-term extracorporeal perfusion (termed *extracorporeal life support*, ECLS) using peripheral vessel cannulation to stabilize the circulation offers a compromise position because most massive pulmonary emboli will dissolve in time. ECLS can be implemented outside the operating room within 15 to 30 minutes by an equipped team of trained personnel.<sup>68,69</sup>

ECLS should not be needed beyond 1 to 2 days because clot lysis proceeds rapidly. Once pulmonary vascular resistance is adequately reduced, ECLS should be discontinued in the operating room as the femoral vessels will need to be surgically repaired because of the need for heparin and long-term anticoagulation.

## Results

Mortality rates for emergency pulmonary thromboembolectomy vary widely between 40 and 92%.<sup>66,72-75,78</sup>

Results are best if cardiopulmonary bypass is used to support the circulation during pulmonary arteriotomy.<sup>73</sup> The eventual outcome depends largely upon the preoperative condition and circulatory status of the patient. If cardiac arrest occurs and external massage cannot be stopped without ECLS, the mortality ranges between 45 and 75%. Without cardiac arrest mortality ranges between 8 and 36%.<sup>72-74</sup> ECLS instituted during cardiac resuscitation is associated with survival rates between 43 and 56%.<sup>70,72</sup> Recurrent embolism is uncommon,<sup>75,79</sup> and approximately 80% of survivors maintain normal pulmonary arterial pressures and exercise tolerance. In these patients postoperative angiograms are normal or show less than 10% obstructed vessels. A minority of patients have 40 to 50% of the pulmonary vessels obstructed and have significantly reduced exercise tolerance and pulmonary function.<sup>79</sup>

## CHRONIC THROMBOEMBOLIC PULMONARY HYPERTENSION

### Incidence

The incidence of pulmonary hypertension caused by chronic PE is even more difficult to determine than that of acute PE. Twenty-five years ago, it was estimated that there were more than 500,000 survivors per year of acute *symptomatic* episodes of acute pulmonary embolization in the United States alone.<sup>11,76,80</sup> The population has increased since then, and of course many cases of PE are asymptomatic. The incidence of chronic thrombotic occlusion in the population depends on what percentage of patients fails to resolve acute embolic material. One estimate is that chronic thromboembolic disease develops in only 0.5% of patients with a clinically recognized acute PE.<sup>76</sup> If these figures are correct and counting only patients with symptomatic acute pulmonary emboli, approximately 2500 individuals would progress to chronic thromboembolic pulmonary hypertension (CTEPH) in the United States each year. However, because most patients diagnosed with chronic thromboembolic disease have no antecedent history of acute embolism, the true incidence of this disorder is probably much higher; we estimate on the order of five to ten times this number.

Regardless of the exact incidence or the circumstances, it is clear that acute embolism and its chronic relation, fixed chronic thromboembolic occlusive disease, are both much more common than generally appreciated and are seriously underdiagnosed. Houk and colleagues<sup>81</sup> in 1963 reviewed the literature of 240 reported cases of chronic thromboembolic obstruction of major pulmonary arteries but found that only six cases had been diagnosed correctly before death. Calculations extrapolated from mortality rates and the random incidence of major thrombotic occlusion found at autopsy would support a postulate that more than 100,000 people in the United States currently have pulmonary hypertension that could be relieved by operation.

## Pathology and Pathogenesis

Although most individuals with chronic pulmonary thromboembolic disease are unaware of a past thromboembolic event and give no history of DVT, the origin of most cases of unresolved pulmonary emboli are from acute embolic episodes. Why some patients have unresolved emboli is not certain, but a variety of factors must play a role, alone or in combination.

The volume of acute embolic material may simply overwhelm the lytic mechanisms. Total occlusion of a major arterial branch may prevent lytic material from reaching, and therefore dissolving, the embolus completely. Repetitive emboli may not be able to be resolved. The emboli may be made of substances that cannot be resolved by normal mechanisms (already well-organized fibrous thrombus, fat, or tumor). The lytic mechanisms themselves may be abnormal, or some patients may actually have a propensity for thrombus or a hypercoagulable state. In addition, there are other special circumstances. Chronic indwelling central venous catheters and pacemaker leads are sometimes associated with pulmonary emboli. More rare causes include tumor emboli; tumor fragments from stomach, breast, and kidney malignancies have been demonstrated to cause chronic pulmonary arterial occlusion. Right atrial myxomas may also fragment and embolize.

After the clot becomes wedged in the pulmonary artery, one of two processes occurs:<sup>82</sup>

1. Organization of the clot proceeds to canalization, producing multiple small endothelialized channels separated by fibrous septa (ie, bands and webs) or
2. Complete fibrous organization of the fibrin clot without canalization may result, leading to a solid mass of dense fibrous connective tissue totally obstructing the arterial lumen.

As previously described and discussed, in addition to the embolic material, a propensity for thrombosis or a hypercoagulable state may be present in a few patients. This abnormality may result in spontaneous thrombosis within the pulmonary vascular bed, encourage embolization, or be responsible for proximal propagation of thrombus after an embolus. But, whatever the predisposing factors to residual thrombus within the vessels, the final genesis of the resultant pulmonary vascular hypertension may be complex. With the passage of time, the increased pressure and flow as a result of redirected pulmonary blood flow in the previously normal pulmonary vascular bed can create a vasculopathy in the small precapillary blood vessels similar to the Eisenmenger's syndrome.

Factors other than the simple hemodynamic consequences of redirected blood flow are probably also involved in this process. For example, after a pneumonectomy, 100% of the right ventricular output flows to one lung, yet little increase in pulmonary pressure occurs, even with follow-up to 11 years.<sup>83</sup> In patients with thromboembolic disease, however, we frequently detect pulmonary hypertension even when less

than 50% of the vascular bed is occluded by thrombus. It thus appears that sympathetic neural connections, hormonal changes, or both might initiate pulmonary hypertension in the initially unaffected pulmonary vascular bed. This process can occur with the initial occlusion either being in the same or the contralateral lung.

Regardless of the cause, the evolution of pulmonary hypertension as a result of changes in the previously unobstructed bed is serious, because this process may lead to an inoperable situation. Consequently, with accumulating experience in patients with thrombotic pulmonary hypertension, we have increasingly been inclined toward early operation so as to avoid these changes.

## Clinical Presentation

Chronic thromboembolic pulmonary hypertension is a frequently under-recognized but treatable cause of pulmonary hypertension. There are no signs or symptoms specific for chronic thromboembolism. The most common symptom associated with thromboembolic pulmonary hypertension, as with all other causes of pulmonary hypertension, is exertional dyspnea. This dyspnea is characteristically out of proportion to any abnormalities found in clinical examination.

Nonspecific chest pains or tightness occur in approximately 50% of patients with more severe pulmonary hypertension. Hemoptysis can occur in all forms of pulmonary hypertension and probably results from abnormally dilated vessels distended by increased intravascular pressures. Peripheral edema, early satiety, and epigastric or right upper quadrant fullness or discomfort may develop as the right heart fails (*cor pulmonale*). Some patients with chronic pulmonary thromboembolic disease present with right heart failure after a relatively small PE, superimposed on chronic disease.

The physical signs of pulmonary hypertension are the same no matter what the underlying pathophysiology. Initially the jugular venous pulse is characterized by a large A-wave. As the right heart fails, the V-wave becomes predominant. The right ventricle is usually palpable near the lower left sternal border, and pulmonary valve closure may be audible in the second intercostal space. Occasional patients with advanced disease are hypoxic and slightly cyanotic. Clubbing is an uncommon finding.

The second heart sound is often narrowly split and varies normally with respiration; P2 is accentuated. A sharp systolic ejection click may be heard over the pulmonary artery. As the right heart fails, a right atrial gallop usually is present, and tricuspid insufficiency develops. Because of the large pressure gradient across the tricuspid valve in pulmonary hypertension, the murmur is high pitched and may not exhibit respiratory variation. These findings are quite different from those usually observed in tricuspid valvular disease. A murmur of pulmonic regurgitation may also be detected.

Pulmonary function tests reveal minimal changes in lung volume and ventilation; patients generally have normal or slightly restricted pulmonary mechanics. Diffusing capacity

(DLCO) is often reduced and may be the only abnormality on pulmonary function testing. Pulmonary arterial pressures are elevated and suprasystemic pulmonary pressures are not uncommon. Resting cardiac outputs are lower than the normal range, and pulmonary arterial oxygen saturations are reduced. Most patients are hypoxic; room air arterial oxygen tension ranges between 50 and 83 torr, the average being 65 torr.<sup>84</sup> CO<sub>2</sub> tension is slightly reduced and is compensated by reduced bicarbonate. Dead space ventilation is increased. Ventilation-perfusion studies show moderate mismatch with some heterogeneity among various respirator units within the lung and correlate poorly with the degree of pulmonary obstruction.<sup>85</sup>

## Diagnosis

To ensure accurate diagnosis in patients with chronic pulmonary thromboembolism, a standardized evaluation is recommended for all patients who present with unexplained pulmonary hypertension. This workup includes a chest radiograph, which may show either apparent vessel cutoffs of the lobar or segmental pulmonary arteries or regions, or oligemia suggesting vascular occlusion. The central pulmonary arteries are enlarged, and the right ventricle may also be enlarged without enlargement of the left atrium or ventricle (Fig. 52-5). Despite these classic findings, many patients present with a relatively normal chest radiograph, even in

**FIGURE 52-5** Chest radiograph of a patient with chronic thromboembolic pulmonary disease, and evidence of pulmonary hypertension. Note the enlarged right atrium and right ventricle, disparity of size between the left and right pulmonary arteries, and the hypoperfusion in several areas of the lung fields.

the setting of high degrees of pulmonary hypertension. The electrocardiogram demonstrates findings of right ventricular hypertrophy (right axis deviation, dominant R-wave in V1). Pulmonary function tests are necessary to exclude obstructive or restrictive intrinsic pulmonary parenchymal disease as the cause of pulmonary hypertension.

The ventilation-perfusion lung scan is the essential test for establishing the diagnosis of unresolved pulmonary thromboembolism. An entirely normal lung scan excludes the diagnosis of both acute or chronic, unresolved thromboembolism. The usual lung scan pattern in most patients with pulmonary hypertension either is relatively normal or shows a diffuse nonuniform perfusion.<sup>84,85-87</sup> When subsegmental or larger perfusion defects are noted on the scan, even when matched with ventilatory defects, pulmonary angiography is appropriate to confirm or rule out thromboembolic disease.

Currently, pulmonary angiography still remains the gold standard for the diagnosis of CTEPH. Organized thromboembolic lesions do not have the appearance of the intravascular filling defects seen with acute pulmonary emboli, and experience is essential for the proper interpretation of pulmonary angiograms in patients with unresolved, chronic embolic disease. Organized thrombi appear as unusual filling defects, webs, or bands, or completely thrombosed vessels that may resemble congenital absence of the vessel<sup>87</sup> (Fig. 52-6). Organized material along the wall of a recanalized vessel produces a scalloped or serrated luminal edge. Because of both vessel wall thickening and dilatation of proximal vessels, the contrast-filled lumen may appear relatively normal in diameter.

Distal vessels demonstrate the rapid tapering and pruning characteristic of pulmonary hypertension (see Fig. 52-6).

Pulmonary angiography should be performed whenever there is a possibility that chronic thromboembolism is the etiology of pulmonary hypertension. Many thousands of angiograms in pulmonary hypertensive patients have now been performed at our institution without mortality.

In addition to pulmonary angiography, patients over 40 undergo coronary arteriography and other cardiac investigation as necessary. If significant disease is found, additional cardiac surgery is performed at the time of pulmonary thromboendarterectomy.

## Medical Treatment

Chronic anticoagulation represents the mainstay of a medical regimen. This is primarily used to prevent future embolic episodes, but also serves to limit the development of thrombus in regions of low flow within the pulmonary vasculature. Inferior vena caval filters are used routinely to prevent recurrent embolization. If caval filtration and anticoagulation fail to prevent recurrent emboli, immediate thrombolysis may be beneficial, but lytic agents are incapable of altering the chronic component of the disease.

Right ventricular failure is treated with diuretics and vasodilators, and although some improvement may result, the effect is generally transient because the failure is owing to a mechanical obstruction and will not resolve until the obstruction is removed. Similarly, the prognosis is unaffected by medical therapy,<sup>88,89</sup> which should be regarded as only supportive.

**FIGURE 52-6** Right and left pulmonary angiograms demonstrate enlarged pulmonary arteries, poststenotic dilatation of vessels, lack of filling to the periphery in many areas, and abrupt cutoffs of branches. The arrow points to intraluminal filling defects representative of a web or band.

Because of the bronchial circulation, pulmonary embolization seldom results in tissue necrosis. Surgical endarterectomy therefore will allow distal pulmonary tissue to be used once more in gas exchange.

The only other surgical option for these patients is transplantation. However, transplantation is not appropriate for this disease because of the mortality and morbidity rates of patients on the waiting list, the higher risk of the operation, and the contrasted survival rate (approximately 80% at 1 year at experienced centers for transplantation vs more than 95% for pulmonary endarterectomy). Furthermore, pulmonary endarterectomy is considered to be permanently curative, and the issues of a continuing risk of rejection and immunosuppression are not present.

## Natural History

The natural history of CTEPH is dismal, and nearly all patients die of progressive right heart failure.<sup>11</sup> Because of the insidious onset, the diagnosis is usually made relatively late in the progression of the disease when dyspnea and/or early symptoms of right heart failure develop and pulmonary hypertension is severe ( $>40$  mm Hg mean). In Riedel's series of 13 patients, nine died a mean of 28 months after the diagnosis of right heart failure.<sup>11</sup> Seven of the 13 had recurrent episodes of fresh emboli demonstrated by new perfusion defects or by autopsy. The severity of pulmonary hypertension at the time of diagnosis inversely correlates with duration of survival.<sup>11</sup>

## Pulmonary Thromboendarterectomy

Although there were previous attempts, Allison et al<sup>90</sup> did the first successful pulmonary "thromboendarterectomy" through a sternotomy using surface hypothermia, but only fresh clots were removed. Since then, there have been many occasional surgical reports of the surgical treatment of chronic pulmonary thromboembolism,<sup>91-94</sup> but most of the surgical experience in pulmonary endarterectomy has been reported from the UCSD Medical Center. Braunwald commenced the UCSD experience with this operation in 1970, which now totals more than 3500 cases. The operation described in the following pages, using deep hypothermia and circulatory arrest, is the standard procedure and has now been adopted by other major centers.

### INDICATIONS

When the diagnosis of thromboembolic pulmonary hypertension has been firmly established, the decision for operation is based on the severity of symptoms and the general condition of the patient. Early in the pulmonary endarterectomy experience, Moser and colleagues<sup>92</sup> pointed out that there were three major reasons for considering thromboendarterectomy: hemodynamic, alveolo-respiratory, and prophylactic. The hemodynamic goal is to prevent or ameliorate right

ventricular compromise caused by pulmonary hypertension. The respiratory objective is to improve respiratory function by the removal of a large ventilated but unperfused physiologic dead space, regardless of the severity of pulmonary hypertension. The prophylactic goal is to prevent progressive right ventricular dysfunction or retrograde extension of the obstruction, which might result in further cardiorespiratory deterioration or death.<sup>92</sup> Our subsequent experience has added another prophylactic goal: the prevention of secondary arteriopathic changes in the remaining patent vessels.<sup>87</sup>

Most patients who undergo operation are within New York Heart Association (NYHA) class III or IV. The ages of the patients in our series have ranged from 3 to 85 years. A typical patient will have a severely elevated pulmonary vascular resistance (PVR) level at rest, the absence of significant comorbid disease unrelated to right heart failure, and the appearances of chronic thrombi on angiogram that appear to be relatively in balance with the measured PVR level. Exceptions to this general rule, of course, occur.

Although most patients have a PVR level in the range of 800 dynes/sec/cm<sup>-5</sup> and pulmonary artery pressures less than systemic, the hypertrophy of the right ventricle that occurs over time makes pulmonary hypertension to suprasystemic levels possible. Therefore many patients (approximately 20% in our practice) have a level of PVR in excess of 1000 dynes/sec/cm<sup>-5</sup> and suprasystemic pulmonary artery pressures. There is no upper limit of PVR level, pulmonary artery pressure, or degree of right ventricular dysfunction that excludes patients from operation.

We have become increasingly aware of the changes that can occur in the remaining patent (unaffected by clot) pulmonary vascular bed subjected to the higher pressures and flow that results from obstruction in other areas. Therefore, with the increasing experience and safety of the operation, we offer surgery to symptomatic patients whenever the angiogram demonstrates thromboembolic disease. A rare patient might have a PVR level that is normal at rest, although elevated with minimal exercise. This is usually a young patient with total unilateral pulmonary artery occlusion and unacceptable exertional dyspnea because of an elevation in dead space ventilation. Operation in this circumstance is performed not only to reperfuse lung tissue, but to re-establish a more normal ventilation perfusion relationship (thereby reducing minute ventilatory requirements during rest and exercise), and also to prevent the chronic arterial changes associated with long-term exposure to pulmonary hypertension, thus preserving the integrity of the contralateral circulation.

If not previously implanted, an inferior vena caval filter is routinely placed several days in advance of the operation.

### OPERATION

**Principles.** There are several guiding principles for the operation. The endarterectomy must be bilateral because this is a bilateral disease in the vast majority of our patients, and for pulmonary hypertension to be a major factor, both pulmonary vasculatures must be substantially involved. The only

reasonable approach to both pulmonary arteries is therefore through a median sternotomy incision. Historically, there were many reports of unilateral operation, and perhaps this is still performed occasionally in inexperienced centers, through a thoracotomy. However, the unilateral approach ignores the disease on the contralateral side, subjects the patient to hemodynamic jeopardy during the clamping of the pulmonary artery, does not allow good visibility because of the continued presence of bronchial blood flow, and exposes the patient to a repeat operation on the contralateral side. In addition, collateral channels develop in chronic thrombotic hypertension not only through the bronchial arteries but also from diaphragmatic, intercostal, and pleural vessels. The dissection of the lung in the pleural space via a thoracotomy incision can therefore be extremely bloody. The median sternotomy incision, apart from providing bilateral access, avoids entry into the pleural cavities, and allows the ready institution of cardiopulmonary bypass.

Cardiopulmonary bypass is essential to ensure cardiovascular stability when the operation is performed and to cool the patient to allow circulatory arrest. Excellent visibility is required, in a bloodless field, to define an adequate endarterectomy plane and then follow the pulmonary endarterectomy specimen deep into the subsegmental vessels. Because of the copious bronchial blood flow usually present in these cases, periods of circulatory arrest are necessary to ensure perfect visibility. Again, there have been sporadic reports of the performance of this operation without circulatory arrest. However, it should be emphasized that although endarterectomy is possible without circulatory arrest, a complete endarterectomy is not. We always initiate the procedure without circulatory arrest, and a variable amount of dissection is possible before the circulation is stopped, but never complete dissection. The circulatory arrest periods are limited to 20 minutes, with restoration of flow between each arrest. With experience, the endarterectomy usually can be performed with a single period of circulatory arrest on each side.

A true endarterectomy in the plane of the media must be accomplished. It is essential to appreciate that the removal of visible thrombus is largely incidental to this operation. Indeed, in most patients, no free thrombus is present; and on initial direct examination, the pulmonary vascular bed may appear normal. The early literature on this procedure indicates that thrombectomy was often performed without endarterectomy, and in these cases the pulmonary artery pressures did not improve, often with the resultant death of the patient.

**Preparation and Anesthetic Considerations.** Much of the preoperative preparation is common to any open heart procedure. Routine monitoring for anesthetic induction includes a surface electrocardiogram, cutaneous oximetry, and radial and pulmonary artery pressures. After anesthetic induction a femoral artery catheter, in addition to a radial arterial line, is also placed. This provides more accurate measurements during rewarming and on discontinuation of cardiopulmonary bypass because of the peripheral vasoconstriction that occurs

after hypothermic circulatory arrest. It is generally removed in the intensive care unit when the two readings correlate.

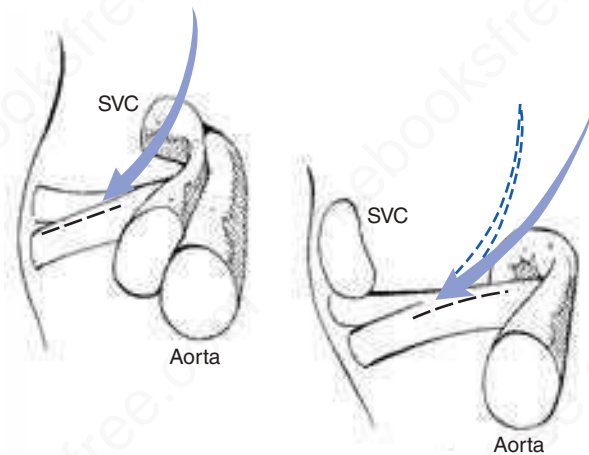

Electroencephalographic recording is performed to ensure the absence of cerebral activity before circulatory arrest is induced. The patient's head is enveloped in a cooling jacket, and cerebral cooling is begun after the initiation of bypass. Temperature measurements are made of the esophagus, tympanic membrane, urinary catheter, rectum, and blood (through the Swan-Ganz catheter). If the patient's condition is stable after the induction of anesthesia, up to 500 mL of autologous whole blood is withdrawn for later use, and the volume deficit is replaced with crystalloid solution.

**Surgical Technique.** After a median sternotomy incision, the pericardium is incised longitudinally and attached to the wound edges. Typically the right heart is enlarged, with a tense right atrium and a variable degree of tricuspid regurgitation. There is usually severe right ventricular hypertrophy, and with critical degrees of obstruction, the patient's condition may become unstable with the manipulation of the heart.

Anticoagulation with heparin (400 U/kg, intravenously) is administered to prolong the activated clotting time beyond 400 seconds. Full cardiopulmonary bypass is instituted with high ascending aortic cannulation and two caval cannulae. These cannulae must be inserted into the superior and inferior vena cavae sufficiently to enable subsequent opening of the right atrium if necessary. A temporary pulmonary artery vent is placed in the midline of the main pulmonary artery 1 cm distal to the pulmonary valve. After cardiopulmonary bypass is initiated, surface cooling with both the head jacket and the cooling blanket is begun. The blood is cooled with the pump-oxygenator. During cooling a 10°C gradient between arterial blood and bladder or rectal temperature is maintained.<sup>93</sup> Cooling generally takes 45 minutes to an hour. When ventricular fibrillation occurs, an additional vent is placed in the left atrium through the right superior pulmonary vein to prevent distention from the large amount of bronchial arterial blood flow that is common with these patients.

It is most convenient for the primary surgeon to stand initially on the patient's left side. During the cooling period, some preliminary dissection can be performed, with full mobilization of the right pulmonary artery from the ascending aorta. The superior vena cava is also fully mobilized. The approach to the right pulmonary artery is made medial, not lateral, to the superior vena cava. All dissection of the pulmonary arteries takes place intrapericardially, and neither pleural cavity should be entered. An incision is then made in the right pulmonary artery from beneath the ascending aorta out under the superior vena cava and entering the lower lobe branch of the pulmonary artery just after the take-off of the middle lobe artery (Fig. 52-7). The incision stays in the center of the vessel and continues into the lower rather than the middle lobe artery.

Any loose thrombus, if present, is now removed, to obtain good visualization. It is most important to recognize, however, that first, an embolectomy without subsequent endarterectomy is quite ineffective and, second, that in most

**FIGURE 52-7** Recommended surgical approach on the right side. This approach, medial to the superior vena cava (SVC), and between the SVC and aorta, provides a direct view into the right pulmonary artery. Note that an approach on the lateral side of the SVC will only provide a restricted view, and should be avoided.

patients with chronic thromboembolic hypertension, direct examination of the pulmonary vascular bed at operation generally shows no obvious embolic material. Therefore, to the inexperienced or cursory glance, if fresh thrombus is not present the pulmonary vascular bed may well appear normal even in patients with severe chronic embolic pulmonary hypertension.

If the bronchial circulation is not excessive, the endarterectomy plane can be found during this early dissection. However, although a small amount of dissection can be performed before the initiation of circulatory arrest, it is unwise to proceed unless perfect visibility is obtained, because the development of a correct plane is essential.

There are four broad types of pulmonary occlusive disease related to thrombus that can be appreciated, and we use the following classification<sup>87,94</sup>: Type I disease (approximately 15% of cases of thromboembolic pulmonary hypertension) (Fig. 52-8) refers to the situation in which major vessel clot is present and readily visible on the opening of the pulmonary arteries. All central thrombotic material has to be completely removed before the endarterectomy. In type II disease (approximately 55% of our cases; Fig. 52-9), no major vessel thrombus can be appreciated. In these cases only thickened intima can be seen, occasionally with webs, and the endarterectomy plane is raised in the main, lobar, or segmental vessels. Type III disease (approximately 30% of our cases; Fig. 52-10) presents the most challenging surgical situation. The disease is very distal and confined to the segmental and subsegmental branches. No occlusion of vessels can be seen initially. The endarterectomy plane must be carefully and painstakingly raised in each segmental and subsegmental branch. Type III disease is most often associated with presumed repetitive thrombi from indwelling catheters (such as pacemaker wires) or ventriculo-atrial shunts. It may also represent “burnt-out” disease, where the thrombotic obstruction developed years before, and has since resolved in many areas, but intrinsic

**FIGURE 52-8** Surgical specimen removed from a patient showing evidence of some fresh and some old thrombus in the main and both right and left pulmonary arteries. Note that simple removal of the gross disease initially encountered on pulmonary arteriotomy will not be therapeutic, and any meaningful outcome involves a full endarterectomy into all the distal segments.

vessel disease now contributes to the pulmonary hypertension. Type IV disease (Fig. 52-11) does not represent primary thromboembolic pulmonary hypertension and is inoperable. In this entity there is intrinsic small-vessel disease, although secondary thrombus may occur as a result of stasis. Small-vessel disease may be unrelated to thromboembolic events (“primary” pulmonary hypertension) or occur in relation to thromboembolic hypertension as a result of a high flow or high pressure state in previously unaffected vessels similar to the generation of Eisenmenger’s syndrome. We believe that there may also be sympathetic “cross-talk” from an affected contralateral side or stenotic areas in the same lung.

**FIGURE 52-9** Specimen removed in a patient with type II disease. Both pulmonary arteries have evidence of chronic thromboembolic material. Note the distal tails of the specimen in each branch. Full resolution of pulmonary hypertension is dependent on complete removal of all the distal tails.

**FIGURE 52-10** Specimen removed from a patient with type III disease. Note that the disease is distal, and the plane was raised at each segmental level.

When the patient's temperature reaches 20°C, the aorta is cross-clamped and a single dose of cold cardioplegic solution (1 L) is administered. Additional myocardial protection is obtained by the use of a cooling jacket. The entire procedure is now performed with a single aortic cross-clamp period with no further administration of cardioplegic solution.

A modified cerebellar retractor is placed between the aorta and superior vena cava. When blood obscures direct vision of the pulmonary vascular bed, thiopental is administered (500 mg-1 g) until the electroencephalogram becomes isoelectric. Circulatory arrest is then initiated, and the patient is exsanguinated. All monitoring lines to the patient are turned off to prevent the aspiration of air. Snares are tightened

**FIGURE 52-11** Note the absence of distal "tails" in this specimen removed from a patient with surgical classification type IV. All "tails" are replaced by "trousers." No clinical benefit was obtained from this procedure and the patient's postoperative hemodynamics was not improved, despite what appears to be an impressive endarterectomy specimen. The patient had primary pulmonary hypertension.

around the cannulae in the superior and inferior vena cavae. With experience it is rare that one 20-minute period for each side is exceeded. Although retrograde cerebral perfusion has been advocated for total circulatory arrest in other procedures, it is not helpful in this operation because it does not allow a completely bloodless field, and with the short arrest times that can be achieved with experience, it is not necessary.

Any residual loose, thrombotic debris encountered is removed. Then, a microtome knife is used to develop the endarterectomy plane posteriorly, because any inadvertent egress in this site could be repaired readily, or simply left alone. Dissection in the correct plane is critical because if the plane is too deep the pulmonary artery may perforate, with fatal results, and if the dissection plane is not deep enough, inadequate amounts of the chronically thromboembolic material will be removed. The plane should only be sought in the diseased parts of the artery; this often requires the initial dissection to begin quite distally.

The ideal layer is marked with a pearly white plane, which strips easily. There should be no residual yellow plaque. If the dissection is too deep, a reddish or pinkish color indicates the adventitia has been reached. A more superficial plane should be sought immediately.

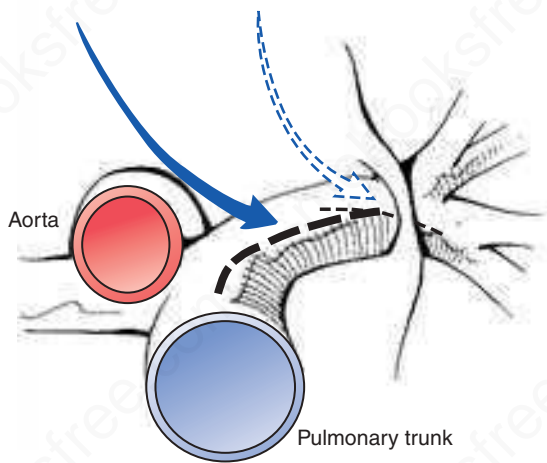

Once the plane is correctly developed, a full-thickness layer is left in the region of the incision to ease subsequent repair. The endarterectomy is then performed with an eversion technique, using a specially developed dissection instrument (Jamieson aspirator, Fehling Corp.). Because the vessel is partly everted and subsegmental branches are being worked on, a perforation here will become completely inaccessible and invisible later. This is why absolute visualization in a completely bloodless field provided by circulatory arrest is essential. It is important that each subsegmental branch is followed and freed individually until it ends in a "tail," beyond which there is no further obstruction.

Once the right-sided endarterectomy is completed, circulation is restarted, and the arteriotomy is repaired with a continuous 6-0 polypropylene suture. The hemostatic nature of this closure is aided by the nature of the initial dissection, with the full thickness of the pulmonary artery being preserved immediately adjacent to the incision.

The surgeon now moves to the patient's right side. The pulmonary vent catheter is withdrawn, and an arteriotomy is made either from the site of the pulmonary vent hole or adjacent to it, out laterally beneath the pericardial reflection, and again into the lower lobe, but avoiding entry into the left pleural space. Additional lateral dissection does not enhance intraluminal visibility, may endanger the left phrenic nerve, and makes subsequent repair of the left pulmonary artery more difficult (Fig. 52-12). There is often a lymphatic vessel encountered on the left pulmonary artery at the level of the pericardial reflection ("Jamieson's lymphatic"), and it is wise to clip this before it being divided with the pulmonary artery incision.

The left-sided dissection is virtually analogous in all respects to that accomplished on the right. By the time the circulation is arrested once more it will have been

**FIGURE 52-12** Surgical approach on the left side. The incision in the left pulmonary artery begins in the midpoint of the main pulmonary trunk, at the insertion site of the pulmonary artery vent. This incision provides better visibility than a more distal approach (*dotted line and arrow*). Care must be taken to avoid injury to the phrenic nerve.

reinitiated for at least 10 minutes, by which time the venous oxygen saturations are in excess of 90%. The duration of circulatory arrest intervals on the left side are again limited to 20 minutes.

After the completion of the endarterectomy, cardiopulmonary bypass is reinstated and warming is commenced. Methylprednisolone (500 mg, intravenously) and mannitol (12.5 g, intravenously) are administered, and during warming a 10°C temperature gradient is maintained between the perfusate and body temperature, with a maximum perfusate temperature of 37°C. If the systemic vascular resistance level is high, nitroprusside is administered to promote vasodilation and warming. The rewarming period generally takes approximately 90 to 120 minutes but varies according to the body mass of the patient.

When the left pulmonary arteriotomy has been repaired, the pulmonary artery vent is replaced. The right atrium is then opened and examined. Any intra-atrial communication is closed. Although tricuspid valve regurgitation is invariable in these patients and is often severe, tricuspid valve repair is not performed unless there is independent structural damage to the tricuspid valve itself. Right ventricular remodeling occurs within a few days, with the return of tricuspid competence. If other cardiac procedures are required, such as coronary artery or mitral or aortic valve surgery, these are conveniently performed during the systemic rewarming period. Myocardial cooling is discontinued once all cardiac procedures have been concluded. The left atrial vent is removed, and the vent site is repaired. All air is removed from the heart, and the aortic cross-clamp is removed.

When the patient has rewarmed, cardiopulmonary bypass is discontinued. Dopamine hydrochloride is generally administered at renal doses, and other inotropic agents and vasodilators are titrated as necessary to sustain acceptable

hemodynamics. The cardiac output is generally high, with a low systemic vascular resistance. Temporary pacing wires are placed.

Despite the duration of extracorporeal circulation, hemostasis is readily achieved, and blood products are generally unnecessary. Wound closure is routine. A vigorous diuresis is usual for the next few hours, also a result of the previous systemic hypothermia.

### POSTOPERATIVE CARE

Meticulous postoperative management is essential to the success of this operation. All patients are mechanically ventilated overnight, and subjected to a maintained diuresis with the goal of reaching the patient's preoperative weight within 24 hours. Although much of the postoperative care is common to more ordinary open-heart surgery patients, there are some important differences.

A higher minute ventilation is often required early after the operation to compensate for the temporary metabolic acidosis that develops after the long period of circulatory arrest, hypothermia, and cardiopulmonary bypass. Tidal volumes higher than those normally recommended after cardiac surgery are therefore generally used to obtain optimal gas exchange. The maximum inspiratory pressure is maintained below 30 cm of water if possible. Extubation should be performed on the first postoperative day, whenever possible.

**Diuresis.** Patients have considerable positive fluid balance after operation. After hypothermic circulatory arrest, patients initiate an early spontaneous aggressive diuresis for unknown reasons, but this may in part be related to the increased cardiac output related to a now lower PVR level, and improved RV function. This diuresis should be augmented with diuretics, however, with the aim of returning the patient to the preoperative fluid balance within 24 hours of operation. Because of the increased cardiac output, some degree of systemic hypotension is readily tolerated. Fluid administration is minimized, and the patient's hematocrit level should be maintained above 30% to increase oxygen-carrying capacity and to reduce the likelihood of the pulmonary reperfusion phenomenon.

**Arrhythmias.** The development of atrial arrhythmias, at approximately 10%, is no more common than that encountered in patients who undergo other types of non valvular heart surgery. When a small atrial septal defect or persistent foramen ovale is closed this is done with a small inferior atrial incision directly over the fossa ovalis, away from the conduction system of the atrium or its blood supply. The siting and size of this incision may be helpful in the reduction of the incidence of these arrhythmias.

**Transfusion.** Despite the requirement for the maintenance of an adequate hematocrit level, with careful blood conservation techniques used during operation, transfusion is required in a minority of patients.

**Inferior Vena Caval Filter and Anticoagulation.** A Greenfield filter is usually inserted before operation, to minimize recurrent PE after pulmonary endarterectomy. However, if this is not possible, it can also be inserted at the time of operation. If the device is to be placed at operation, radiopaque markers should be placed over the level of the spine corresponding to the location of the renal veins to allow correct positioning. Postoperative venous thrombosis prophylaxis with intermittent pneumatic compression devices is used, and the use of subcutaneous heparin is begun on the evening of surgery. Anticoagulation with warfarin is begun as soon as the pacing wires and mediastinal drainage tubes are removed, with a target international normalized ratio (INR) of 2.5 to 3.

## COMPLICATIONS

Aside from complications that are associated with open heart and major lung surgery (arrhythmias, atelectasis, wound infection, pneumonia, mediastinal bleeding, etc.), there are complications specific to this operation. These include persistent pulmonary hypertension, reperfusion pulmonary response, and neurologic disorders related to deep hypothermia.

**Persistent Pulmonary Hypertension.** The decrease in PVR level usually results in an immediate and sustained restoration of pulmonary artery pressures to normal levels, with a marked increase in cardiac output. In a few patients, an immediately normal pulmonary vascular tone is not achieved, but an additional substantial reduction may occur over the next few days because of the subsequent relaxation of small vessels and the resolution of intraoperative factors such as pulmonary edema. In such patients, it is usual to see a large pulmonary artery pulse pressure, the low diastolic pressure indicating good runoff, yet persistent pulmonary arterial inflexibility still resulting in a high systolic pressure.

There are a few patients in whom the pulmonary artery pressures do not resolve substantially. If the operation has been performed as described in the preceding, using circulatory arrest, and ensuring that all distal disease is removed, this will be the result of type IV disease. We do operate on some patients with severe pulmonary hypertension but equivocal embolic disease. Despite the considerable risk of attempted endarterectomy in these patients, because transplantation is the only other avenue of therapy, there may be a point when it is unlikely that a patient will survive until a donor is found. In our most recent 1000 patients, the majority of perioperative deaths were directly attributable to the problem of inadequate relief of pulmonary artery hypertension. This was a diagnostic rather than an operative technical problem. Attempts at pharmacologic manipulation of high residual PVR levels with sodium nitroprusside, epoprostenol sodium, or inhaled nitric oxide are generally not effective. Because, if the operation has been performed thoroughly, there will be no further resolution, it is not appropriate to use mechanical circulatory support or extracorporeal membrane oxygenation in these patients if they deteriorate subsequently.

**The "Reperfusion Response."** A specific complication that occurs in many patients to some degree is localized pulmonary edema, or the "reperfusion response." Reperfusion response or reperfusion injury is defined as a radiologic opacity seen in the lungs within 72 hours of pulmonary endarterectomy. This unfortunately loose definition may therefore encompass many other causes, such as fluid overload and infection.

True reperfusion injury that directly adversely impacts the clinical course of the patient now occurs in approximately 10% of patients. In its most dramatic form, it occurs soon after operation (within a few hours) and is associated with profound desaturation. Edema-like fluid, sometimes with a bloody tinge, is suctioned from the endotracheal tube.<sup>95</sup> Frank blood from the endotracheal tube, however, signifies a mechanical violation of the blood airway barrier that has occurred at operation and generally stems from a technical error, though we have seen some cases where significant blood in the airway was the result of a technically good operation, but reperfusion of a known infarcted area of the lung with subsequent cavity formation. This complication should be managed, if possible, by identification of the affected area by bronchoscopy and balloon occlusion of the affected lobe until coagulation can be normalized.

One common cause of reperfusion pulmonary edema is persistent high pulmonary artery pressures after operation when a thorough endarterectomy has been performed in certain areas, but there remains a large part of the pulmonary vascular bed affected by type IV change. In this situation all pulmonary artery flow is directed toward the endarterectomized areas. However, the reperfusion phenomenon is often encountered in patients after a seemingly technically perfect operation with complete resolution of high pulmonary artery pressures. In these cases the response may be one of reactive hyperemia, after the revascularization of segments of the pulmonary arterial bed that have long experienced no flow. Other contributing factors may include perioperative pulmonary ischemia and conditions associated with high permeability lung injury in the area of the now denuded endothelium. Fortunately, the incidence of this complication is much less common now in our series, probably as a result of the more complete and expeditious removal of the endarterectomy specimen that has come with the large experience over the last decade.

**Management of the "Reperfusion Response".** Early measures should be taken to minimize the development of pulmonary edema by diuresis, maintenance of hematocrit levels, and the early use of peak end-expiratory pressure. Once the capillary leak has been established, however, treatment is supportive because reperfusion pulmonary edema will eventually resolve if satisfactory hemodynamics and oxygenation can be maintained. Careful management of ventilation and fluid balance is required. The hematocrit is kept high (32-36%), and the patient undergoes aggressive diuresis, even if this requires ultrafiltration. The patient's ventilatory status may be dramatically position sensitive. The fraction

of inspired oxygen (FIO<sub>2</sub>) level is kept as low as is compatible with an oxygen saturation of 90%. A careful titration of positive end-expiratory pressure is carried out, with a progressive transition from volume to pressure-limited inverse ratio ventilation and the acceptance of moderate hypercapnia.<sup>95</sup> The use of steroids is discouraged because they are generally ineffective and may lead to infection. Infrequently, inhaled nitric oxide at 20 to 40 parts per million can improve the gas exchange. On occasion we have used extracorporeal perfusion support (extracorporeal membrane oxygenator or extracorporeal carbon dioxide removal) until ventilation can be resumed satisfactorily, usually after 7 to 10 days. However, the use of this support is limited to patients who have benefited from hemodynamic improvement, but are suffering from significant reperfusion response. Extracorporeal devices should not be used if there is no evidence or hope of subsequent hemodynamic improvement, because it will not play a role in improving irreversible pulmonary pressures and carries mortality close to 100%.

**Delirium.** Early in the pulmonary endarterectomy experience (before 1990), there was a substantial incidence of postoperative delirium. A study of 28 patients who underwent pulmonary endarterectomy showed that 77% experienced the development of this complication.<sup>96,97</sup> Delirium appeared to be related to an accumulated duration of circulatory arrest time of more than 55 minutes; the incidence fell to 11% with significantly shorter periods of arrest time.<sup>96-98</sup> With the more expeditious operation that has come with our increased experience, postoperative confusion is now encountered no more commonly than with ordinary open heart surgery.

## RESULTS

More than 3500 pulmonary thromboendarterectomy have been performed at UCSD Medical Center since 1970. Almost all of these cases have been completed since 1990, when the surgical procedure was modified as described earlier in this chapter. The mean patient age in our group is 54 years, with a range of 3 to 85 years. There is a very slight male predominance. In nearly one-third of the cases, at least one additional cardiac procedure was performed at the time of operation. Most commonly, the adjunct procedure was closure of a persistent foramen ovale or atrial septal defect (26%) or coronary artery bypass grafting (8%).<sup>87</sup>

**Hemodynamic Results.** A reduction in pulmonary pressures and resistance to normal levels and a corresponding improvement in pulmonary blood flow and cardiac output are generally immediate and sustained.<sup>98,99</sup> In general, these changes can be assumed to be permanent. Whereas before the operation, more than 95% of the patients are in NYHA functional class III or IV; at 1 year after the operation, 95% of patients remain in NYHA functional class I or II.<sup>99,100</sup> In addition, echocardiographic studies have demonstrated that, with the elimination of chronic pressure overload, right ventricular geometry rapidly reverts toward normal. Right atrial

and right ventricular enlargement regresses. Tricuspid valve function returns to normal within a few days as a result of restoration of tricuspid annular geometry after the remodeling of the right ventricle, and tricuspid repair is not therefore part of the operation.

**Operative Morbidity.** Severe reperfusion injury was the single most frequent complication in the UCSD series, occurring in 10% of patients. Some of these patients did not survive, and other patients required prolonged mechanical ventilatory support. A few patients were salvaged only by the use of extracorporeal support and blood carbon dioxide removal. Neurologic complications from circulatory arrest appear to have been eliminated, probably as a result of the shorter circulatory arrest periods now experienced, and perioperative confusion and stroke are now no more frequent than with conventional open heart surgery. Early postoperative hemorrhage required re-exploration in 2.5% of patients, and less than half of patients required intraoperative or postoperative blood transfusion. Despite the prolonged operation, wound infections are relatively infrequent. Only 1.8% experienced the development of sternal wound complications, including sterile dehiscence or mediastinitis.

**Deaths.** In our experience, the overall mortality rate (30 days or in-hospital if the hospital course is prolonged) is 6% for the entire patient group, which encompasses a time span of over 35 years. The mortality rate was 9.4% in 1989 and has been less than 5% for more than 3000 patients who have undergone the operation since 1990. In our most recent experience over the last 5 years, the mortality rate has been less than 2%. With our increasing experience and many referrals, we continue to accept some patients who, in retrospect, were unsuitable candidates for the procedure (type IV disease). We also accept patients in whom we know that the entire degree of pulmonary hypertension cannot be explained by the occlusive disease detected by angiography but feel that they will be benefited by operation, albeit at higher risk. Primary causes of death are operation on patients in whom thromboembolic disease was not the cause of the pulmonary hypertension (50%) and the rare case of reperfusion pulmonary edema that progresses to a respiratory distress syndrome of long-standing, which is not reversible (25%).

## LATE FOLLOW-UP

A survey of the surviving patients who underwent pulmonary endarterectomy surgery at UCSD between 1970 and 1995 formally evaluated the long-term outcome.<sup>100</sup> Questionnaires were mailed to 420 patients who were more than 1 year after operation. Responses were obtained from 308 patients. Survival, functional status, quality of life, and the subsequent use of medical help were assessed. Survival after pulmonary thromboendarterectomy was 75% at 6 years or more. Ninety-three percent of the patients were found to be in NYHA class I or II, compared with about 95% of the patients being in NYHA class III or IV preoperatively. Of the working

population, 62% of patients who were unemployed before operation returned to work. Patients who had undergone pulmonary endarterectomy scored several quality-of-life components just slightly lower than normal individuals, but significantly higher than the patients before endarterectomy. Only 10% of patients used oxygen, and in response to the question, "How do you feel about the quality of your life since your surgery?" Seventy-seven percent replied much improved, and twenty percent replied improved. These data appear to confirm that pulmonary endarterectomy offers substantial improvement in survival, function, and quality of life, with minimal later health-care requirements.<sup>100</sup>

# **SURGERY FOR CARDIAC ARRHYTHMIAS**

*This page intentionally left blank*

# Interventional Therapy for Atrial and Ventricular Arrhythmias

Jason S. Chinitz • Robert E. Eckart • Laurence M. Epstein

Interventional therapies for the treatment of heart rhythm disorders have rapidly evolved over the past three decades, and continue to go through significant evolution. Though management options for cardiac arrhythmias were previously limited to pharmacologic therapy, the transformation and adaptation of surgical procedures to less invasive catheter-based approaches have led to a new paradigm in arrhythmia management. A fundamental understanding of diagnostic and therapeutic strategies for treating heart rhythm disorders is critical to surgical specialties exposed to these rhythm disorders.

The recording of intracardiac signals through electrodes, and subsequent stimulation of the cardiac tissue, allowed for the concept of ablation. In 1967, Durrer and associates described reproducible initiation and termination of tachycardia in a patient with atrioventricular re-entrant tachycardia (AVRT) using a bypass tract.<sup>1</sup> In 1969, the His bundle was first reproducibly recorded using a transvenous electrode catheter.<sup>2</sup> The continued advancements allowing localization of intracardiac signals led to the study of a variety of tachyarrhythmias.

The concept emerged that critical regions of cardiac tissue were necessary for the initiation and propagation of tachyarrhythmias, and that if these regions could be interrupted, the tachyarrhythmia could be cured. Once catheter-based mapping strategies were developed to localize arrhythmogenic foci, surgical excision was contemplated. In 1968, a description of such a surgical procedure for the elimination of an accessory pathway (AP) was first published.<sup>3</sup> This heralded an era of nonpharmacologic treatment of tachyarrhythmias.

## ABLATION ACCESS

### Surgical Ablation

A variety of arrhythmogenic foci and circuits were successfully mapped and ablated using surgical techniques in the 1970s.

Resection of an atrial focus felt to be responsible for an atrial tachycardia was reported in 1973.<sup>4</sup> Identification of reentry circuits within the atrioventricular (AV) node allowed surgical dissection to treat AV nodal re-entrant tachycardia (AVNRT) without causing complete heart block.<sup>5</sup> Although surgical ablation was therapeutic for a variety of tachyarrhythmias, the morbidity and mortality associated with thoracotomy and open-heart surgery limited its widespread application. Because most supraventricular tachycardias (SVTs) are not life-threatening, the risk of the procedure limited its routine adoption. Surgical ablation was therefore limited to highly symptomatic patients refractory to medical therapy.

### Catheter Ablation

In order to minimize the morbidity associated with surgical ablation, a method of using a transvenous catheter for the delivery of energy directly to cardiac tissue was sought. In 1981, Scheinman and colleagues reported the first catheter-based ablation procedure, describing the ablation of the His bundle in dogs.<sup>6</sup> This same group performed the first closed-chest ablation procedure in a human; in a patient with atrial fibrillation (AF) and rate control refractory to medical therapy, a transvenous catheter was advanced to the His bundle region. Using a standard external direct-current (DC) defibrillator, they attached one of the defibrillator pads to the intracardiac catheter and used the second defibrillator pad as a cutaneous grounding pad. A series of DC shocks was delivered between the two pads and complete heart block, and thereby rate control, was achieved.<sup>7</sup>

This closed-chest catheter-based procedure was quickly adopted to treat a variety of SVTs dependent on the AV node.<sup>8</sup> As experience was gained and dedicated ablation catheters were developed, energy could be more precisely directed to allow ablation of APs, atrial tachycardia, single limb of AVNRT, and ventricular tachycardia (VT).

Although DC shock ablation allowed for the initiation of catheter-based ablation, it had various limitations. Because

energy delivery was not titratable, such treatment had variable outcomes and complications, including massive damage to surrounding myocardium.<sup>6,7,9</sup> Because DC energy was delivered from the intracardiac electrode toward a cutaneous site, general anesthesia was required.

The introduction of radiofrequency (RF) energy as an ablative energy source heralded a new era in the catheter-based treatment of arrhythmias. RF energy had been used for decades by surgeons for surgical cutting and cautery and had a long history of safety and efficacy. Animal studies using RF energy for the treatment of arrhythmia were first described in 1987.<sup>10</sup> Intracardiac RF energy produces controlled lesions at the catheter tip using resistive heating.<sup>11,12</sup> RF now remains the primary energy source for catheter-based ablation, though alternative energy sources such as microwave, laser, high-intensity focused ultrasound, and cryothermal energy continue to be developed as a means to optimize patient safety and clinical outcomes.<sup>13</sup>

## BIOPHYSICS OF ABLATION

Ablation using RF as an energy source involves the delivery of sinusoidal alternating current between the catheter tip at the endocardial surface and a large grounding pad on the skin. The current has a frequency of 350 to 700 kHz. The principal method of tissue injury with RF delivery is thermal. As the RF energy passes through the tissue at the distal electrode of the ablation catheter, resistive heating occurs at the catheter tip, and deeper tissue heating occurs through passive heat conduction, producing coagulation necrosis, and a discrete homogenous lesion. To achieve irreversible tissue injury, a tissue temperature of 50 to 58°C is required. Lesion size is proportional to the tissue temperature, size of the ablation electrode, contact force between the catheter and tissue, and duration of RF delivery.<sup>14</sup> If subendocardial tissue temperature exceeds 100°C, steam may form within the tissue, resulting in a rapid expansion and crater formation and an audible “pop” during ablation. Much like DC shocks, such “steam pops” can cause unpredictable injury (eg, to surrounding normal conduction tissue) as well as local tissue rupture. Contemporary RF ablation catheters have a thermistor or thermocouple that allows for automatic adjustment of the power output to achieve a preset temperature at the electrode tip-tissue interface.

With endocardial ablation, the lesions produced are limited such that some intramural and epicardial foci and arrhythmia circuits may not be reachable with standard ablation. One method to increase lesion size and depth uses the principle of limiting coagulum development by increasing the electrode-tissue interface by increasing tip size.<sup>15,16</sup> A limitation of larger catheter tips is that the larger surface area makes it difficult to regulate power delivery and achieve even temperatures.

Cooling the ablation catheter tip with saline irrigation, either within the catheter or external to the catheter, can also prevent coagulum formation at the tissue interface. This prevents a rise in impedance and allows for more energy

delivery deep into the tissue.<sup>17,18</sup> Irrigated RF catheters bathe the catheter tip internally using recirculating saline or externally through a porous electrode tip. These catheters continue to use RF as an energy source, with maximization of power delivery resulting in deeper lesions with a greater volume than with standard RF.<sup>19</sup> Cooled epicardial RF ablation probes have been US Food and Drug Administration (FDA) approved, and transfers established catheter-based technology to a surgical approach for epicardial ablation of cardiac arrhythmias, used primarily in conjunction with other open cardiac surgical procedures.<sup>20,21</sup>

Because of concern about the irreversible nature of RF delivery, alternative energy sources have been developed that allow for a transient tissue injury before placement of permanent lesions. Cryoablation uses cryothermal energy delivered via a dedicated cryoablation catheter to produce gradual cooling of cardiac tissue to create local tissue damage. Hypothermia has been the preferred method of delivering linear lesions in surgical ablation. This technique uses pressurized nitrogen or nitrogen oxide flow through a catheter tip nozzle. As the gas expands beyond the obstruction, there is a temperature drop to as much as -90°C. The major advantage of cryothermal energy delivery relative to RF is its ability to deliver both transient and permanent injury to the tissue; the initial cooling phase (“Cryomapping”) allows one to assess not only the impact of cryoablation on pathologic tissue (eg, anteroseptal APs, the slow limb of a dual AV node), but also the impact of potential lesion placement on nearby structures such as surrounding normal conduction tissue.<sup>22</sup> If the Cryomapping phase yields desirable results, then the temperature is lowered even further to a “freezing” stage. The ability to deliver reversible injury and catheter stabilization has made cryoablation increasingly popular in those cases in which the pathologic lesion is in close proximity to the AV node, and in younger patients in whom avoiding the need for pacemaker implantation is the highest priority.<sup>23</sup>

A second potential disadvantage to RF as an energy source is the risk of extracardiac tissue injury. For example, ablation of AF is becoming the most commonly performed electrophysiologic procedure, and is based on elimination or isolation of triggers for AF, which occur most commonly within the pulmonary veins (PVs). During catheter-based pulmonary vein isolation (PVI), ablation within the left atrium carries risks of collateral damage to surrounding structures, resulting in potentially highly morbid complications such as PV stenosis, atriopharyngeal fistulas, and phrenic nerve paralysis.<sup>24,25</sup> As the esophagus runs adjacent to the posterior wall of the left atrium, this structure is highly vulnerable during ablation of AF. Though the rate of clinical atriopharyngeal fistulas after ablation of AF is very low (around 0.04%),<sup>26</sup> the rate of intraoperative atriopharyngeal perforation was as high as 1.3% in one open-chest series of patients undergoing linear lesions between PV ostia, to include the posterior wall overlaying the esophagus.<sup>27</sup> Current ablation strategies include methods to monitor for esophageal heating, such as continuous monitoring of esophageal temperature with an adjustable esophageal temperature probe.

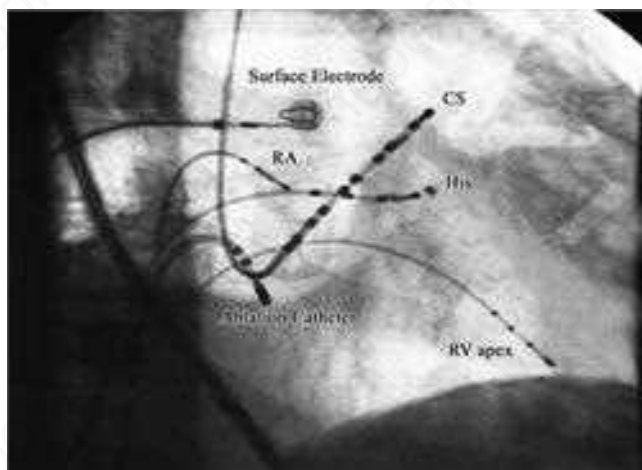

## ELECTROPHYSIOLOGY STUDY PROCEDURAL PROTOCOL

### Diagnostic Electrophysiology Study

Diagnostic localization of tachyarrhythmias involves positioning catheters in strategic locations within the heart to obtain intracardiac recordings from various cardiac chambers as well as from the His bundle. Venous access is typically obtained in the bilateral femoral veins using the Seldinger technique. Catheters of 4 to 6 French in size are passed under fluoroscopic guidance into the right atrium and right ventricle, as well as positioned just across the tricuspid valve (TV) on the septum to obtain His bundle recordings. To obtain recordings of the left atrium and left ventricle (LV), a catheter is guided into the coronary sinus (CS), which passes posteriorly behind the mitral annulus and drains into the right atrium (Fig. 53-1).

### Anticoagulation and Electrophysiology Studies

Direct recordings of the left heart are sometimes necessary and accomplished either by transeptal cannulation through the intra-atrial septum from the right atrium, or via a retrograde approach across the aortic valve into the LV, using catheters percutaneously placed into the femoral artery. Catheter and sheath placement within the left heart, however, imposes a risk of thrombus formation on the intracardiac catheter and

**FIGURE 53-1** Radiograph in the right anterior oblique projection showing catheters positioned for a standard diagnostic electrophysiology procedure. Three nonsteerable diagnostic catheters are introduced from the inferior vena cava into the right heart. Two 4-French catheters with four electrodes are positioned in the region of the right atrial appendage (RA) and right ventricular apex (RV apex). A 5-French catheter with six electrodes is positioned across the tricuspid annulus to obtain a His bundle recording (His). A nonsteerable 6-French catheter is introduced via the right internal jugular vein into the coronary sinus (CS) to obtain left atrial and ventricular recordings. Finally, a deflectable 7-French ablation catheter is positioned in the region of the low right atrium.

at the site of ablation, with the resultant risk of stroke and thromboembolism. Animal models have determined that mural thrombus is evident in up to 50% of cases immediately after RF ablation.<sup>10,28</sup> In addition to the risk of mural thrombus at the site of ablation, there are mounting evidence of a systemic prothrombotic condition after RF ablation.<sup>29,30</sup> Therefore, during left-sided ablation, anticoagulation with intravenous heparin is typically administered throughout the procedure, and substantially reduces the thromboembolic risk. During ablation of AF, with the majority of the procedure performed within the left atrium, heparin is administered to achieve and maintain a target activated clotting time of 300 to > 400 seconds throughout the procedure.<sup>31</sup> Many patients undergoing ablation, particularly for AF, are on chronic systemic anticoagulation. Historically anticoagulation with warfarin was held prior to the procedure, and the patient was bridged with heparin in the periprocedural period. This strategy has now been recognized to be associated with a high incidence of bleeding complications, and now ablations are routinely performed in patients on uninterrupted therapeutic anticoagulation. In the event of procedure-related bleeding complications such as cardiac tamponade, anticoagulation can be reversed with protamine, fresh frozen plasma, and/or prothrombin complex concentrate (PCC). While most experience has been with continuous warfarin, evidence is emerging that ablations can also be safely performed in the setting of anticoagulation with the novel oral thrombin inhibitor or Factor Xa inhibitors, though clinical experience is limited and options for reversal of anticoagulation, when necessary, are still in development.<sup>31</sup>

Once diagnostic catheters are positioned in preparation of an electrophysiologic study, programmed electrical stimulation is performed to induce and study the tachyarrhythmia. Sometimes modulation of the autonomic nervous system is required to induce tachyarrhythmias with the infusion of atropine, isoproterenol, or epinephrine.<sup>32</sup> Once an optimal site for ablation is determined, a steerable ablation catheter is positioned at the target site, and energy is delivered.

At the end of the procedure, all catheters and sheaths are removed and manual pressure is applied to the access sites to achieve hemostasis. If the patient was heparinized for the procedure, sheath removal is delayed until anticoagulation reverses, either when the activated clotting time is less than 200 to 250 seconds, or after administration of protamine. The patient is placed on bed rest for 4 or more hours. Routine follow-up studies are not warranted unless required to assess for a complication. As mentioned, because of the risk of thromboembolic events, patients are frequently sent home on aspirin, thienopyridines, low-molecular-weight heparin, warfarin, or a combination of risk-appropriate antithrombotic therapies depending on the type and extent of ablation performed.

### Complications Associated with Electrophysiology Studies

In referring patients for catheter ablation, it is important to weigh the risks and benefits of the procedure for the individual

patient. Most tachyarrhythmias, although causing a variety of symptoms, are generally hemodynamically well tolerated and are not life-threatening. Thus awareness of the potential complications of catheter ablation is necessary before referring a patient. Complications can be divided into those involving vascular access, catheter manipulation within the heart, and ablation.

Access-related complications include pain, adverse drug reaction from anesthesia and sedation, infection, thrombophlebitis, bleeding at the site of access, hematoma, arteriovenous fistula, and pseudoaneurysm formation. Arterial damage or dissection may also result. Systemic or pulmonary thromboembolism can occur, most seriously resulting in transient ischemic attack or stroke. It is felt that performance of complex ablations while on systemic anticoagulation and with externally irrigated tipped catheters may reduce the risk of mural thrombus and thereby periprocedural embolic events. However, there may be an increased risk of access complications in a patient with therapeutic anticoagulation.<sup>33,34</sup>

Complications associated with placement of intracardiac catheters can be more life threatening. These include perforation of a cardiac chamber or the CS, resulting in hemopericardium, cardiac tamponade, and potentially coronary artery injury. Programmed electrical stimulation can result in the induction of hemodynamically unstable tachyarrhythmias such as VT or fibrillation. Catheter manipulation can also result in usually transient but sometimes permanent damage to valvular apparatus or the conduction of the right or left bundle branches owing to mechanical trauma.

RF delivery to cardiac tissue is associated with risk of collateral damage to intracardiac and extracardiac structures. Inadvertent ablation of the normal conduction system may result in complete heart block requiring permanent pacing. Perforation of a cardiac chamber or vascular structure can also occur with catheter manipulation or RF delivery; small perforations can often be adequately controlled with percutaneous pericardiocentesis and reversal of anticoagulation if present, however, if cardiac bleeding does not stop with these conservative measures an urgent open surgical approach is needed. Collateral damage to coronary circulation can result in myocardial infarction, heart failure, or cardiogenic shock. Phrenic nerve paralysis can occur due to ablation in proximity to the right or left phrenic nerves, which course along the pericardium. Ablation near the PVs within the left atrium can result in venous stenosis and pulmonary hypertension. Ablation in the posterior wall of the left atrium, as is routinely performed during ablation of AF, can result in damage to the esophagus, including esophageal ulcer formation and the potentially fatal complication of atrial-esophageal fistula.<sup>35</sup> Given these risks, a center undertaking these procedures must be prepared to urgently treat these potential complication. All operators performing electrophysiologic studies should be trained in pericardiocentesis, and certain procedures associated with higher risks of perforation should only be performed at centers with available cardiac surgeons in the event of severe complications.<sup>36</sup>

An 8-year prospective study published in 1996 of 3966 procedures found an overall complication rate of 3.1% for

ablative and 1.1% for diagnostic procedures, with complications more likely to occur in elderly patients and those with systemic disease.<sup>37</sup> A more recent series evaluating ablations performed in patients across a series of age ranges identified a rate of procedural complications of 1.3%, with no significant differences between patients under 70 years of age relative to septagenarians or octogenarians.<sup>38</sup> Various studies have shown very low mortality rates directly attributable to the electrophysiology study.

## DIAGNOSTIC ELECTROPHYSIOLOGY TECHNIQUES

A variety of techniques have been developed to elucidate the origin and mechanism of tachyarrhythmia propagation. Some of these techniques involve pacing in sinus rhythm, whereas others are performed during the tachyarrhythmia. Diagnostic studies typically involve programmed electrical stimulation with pacing at particular intervals to initiate a tachyarrhythmia, assess its response to pacing maneuvers, or terminate it.<sup>39</sup>

Activation mapping is used to localize the origin of various tachycardias. It involves positioning a mapping catheter in various intracardiac locations during the tachyarrhythmia, to identify a site where activation is earliest, and precedes any other intracardiac activation or corresponding surface P wave or QRS. The earliest site of activation during a focal tachycardia must by definition be the source of the tachycardia.<sup>40,41</sup> This technique is most useful for localizing focal atrial tachycardias, stable VT, and APs.

Entrainment mapping is used for localization of re-entrant circuits, and is often used in conjunction with activation mapping to identify targets for ablation. In entrainment mapping, pacing is performed from intracardiac sites during tachycardia and slightly faster, to penetrate the arrhythmia circuit and entrain the tachycardia when pacing from sites within the re-entrant circuit, the time from the last paced stimulus to the first return signal on the pacing electrode (called the "post-pacing interval") should equal the tachycardia cycle length. Since you are pacing from within the circuit, one cycle results in the "return" signal which is the same of the tachycardia cycle length. Pacing from sites more remote from the circuit will produce a post-pacing interval greater than the tachycardia cycle length. Because pacing is not within the circuit, the time to the "return" signal is the sum of one revolution around the circuit (the tachycardia cycle length) plus the time it takes to get to the circuit and back from the circuit. The difference between the post-pacing interval and the tachycardia cycle length can be used to determine whether sites are within the arrhythmia circuit and therefore guide ablation. This strategy is particularly useful for mapping atrial flutter, re-entrant atrial tachycardia, and scar-related VT.<sup>42</sup>

Pace mapping is another method used to localize the origin of a tachycardia, with particular usefulness in mapping VT or ventricular ectopy.<sup>43</sup> In this method, pacing is performed during sinus rhythm at various intracardiac locations, and the paced QRS morphology is compared to the

QRS morphology during tachycardia; the disparity in QRS morphologies can be assessed and the catheter repositioned until a match is obtained. At the site of tachycardia origin or myocardial exit, pacing is likely to produce a QRS morphology identical to that observed during tachycardia since the remainder of the heart is being activated in a similar manner.<sup>44</sup>

Mapping may also be performed based on anatomical landmarks. For example, ablation of the slow AV nodal pathway for the treatment of AVNRT is performed by ablating well-defined targets identified by fluoroscopy with or without the assistance of an electroanatomic mapping system. In common right atrial flutter, in which conduction across the cavotricuspid isthmus (CTI) is necessary to sustain the arrhythmia, anatomical landmarks are used for ablation to create a line of block between the tricuspid annulus and the inferior vena cava (IVC).<sup>45</sup>

In various clinical situations, a combination of these mapping techniques may be used to localize an appropriate target for ablation.

## Advanced Mapping Techniques

The success of ablation is dependent on precise localization of arrhythmogenic foci and critical parts of arrhythmogenic circuits. Advanced mapping techniques have been developed as adjuncts to conventional mapping methods to improve the efficacy and safety of catheter ablation. The systems described below are useful to improve the rapidity and precision of mapping arrhythmias, while decreasing the need for fluoroscopy.

The CARTO electroanatomical mapping system (Biosense-Webster, Diamond Bar, CA) uses a magnetic field and emitted currents to localize a mapping catheter in three-dimensional space. Various locator pads placed beneath the patient's chest generate ultra-low-intensity magnetic fields in the form of spheres that decay in strength. A sensor in the catheter tip measures the relative strength and hence the distance from each of the pads, triangulating the temporal-spatial location of the catheter. For activation mapping, electrodes at the catheter tip record local electrograms, and the local activation times acquired from various mapping points are reconstructed on a three-dimensional map relative to a reference catheter, and presented on the map in a color-coded fashion. By acquiring multiple mapping points during tachycardia, the sequence of arrhythmia propagation can be reconstructed. Voltage maps can also be obtained to delineate regions of scar and diseased myocardium.<sup>46</sup>

Another commonly used nonfluoroscopic three-dimensional electroanatomic mapping system is the EnSite system (Ensite NavX and EnSite Velocity, St. Jude Medical, St. Paul, MN), which consists of surface electrode patches applied to several places on the patient's body. To create a three-dimensional model of the chamber of interest in the heart, an electrical signal is transmitted between the patches, and the signal is sensed by the catheters within the heart; as the catheter is moved within the chamber, information from the intracardiac catheters including location, activation timing, and local electrogram amplitude is relayed to the computer

system that generates the three-dimensional model. Cardiac electrical activity, including activation and voltage maps, can be superimposed on the anatomic model. The EnSite Velocity System can display the real-time position of conventional electrophysiology catheters, and can provide visualization and navigation of up to 128 electrodes on a combination of catheters.<sup>47</sup>

Intracardiac ultrasound catheters have had substantial benefits in improving the safety and efficacy of ablation, by providing real-time visualization of intracardiac structures. Radial array intravascular ultrasound (IVUS) (9 MHz Ultra ICE, Boston-Scientific, Natick, MA) may be positioned within the atria, allowing visualization of the interatrial septum, thereby enhancing the safety of transseptal punctures. Phased array intracardiac echocardiography (ICE) has extended the principles of IVUS for electrophysiologic use.<sup>48</sup> Newer ICE catheters are steerable and have Doppler capability (Acuson, AcuNav, Mountain View, CA). In addition to guiding transseptal punctures, ICE catheters allow the accurate targeting of anatomical sites such as PV ostia and papillary muscles.<sup>49</sup> They are also useful for imaging diagnostic and ablation catheter positions and visualization of tissue contact for optimal ablation. Additional benefit to ICE is integration with electroanatomical mapping systems to allow for non-contact real-time reconstruction of cardiac structures (CartoSound, Biosense-Webster, Diamond Bar, CA) (Fig. 53-2).

## CLINICAL APPLICATIONS

Using the techniques described in the preceding sections, most focal and re-entrant tachyarrhythmias can be mapped and targeted for catheter-based ablation.

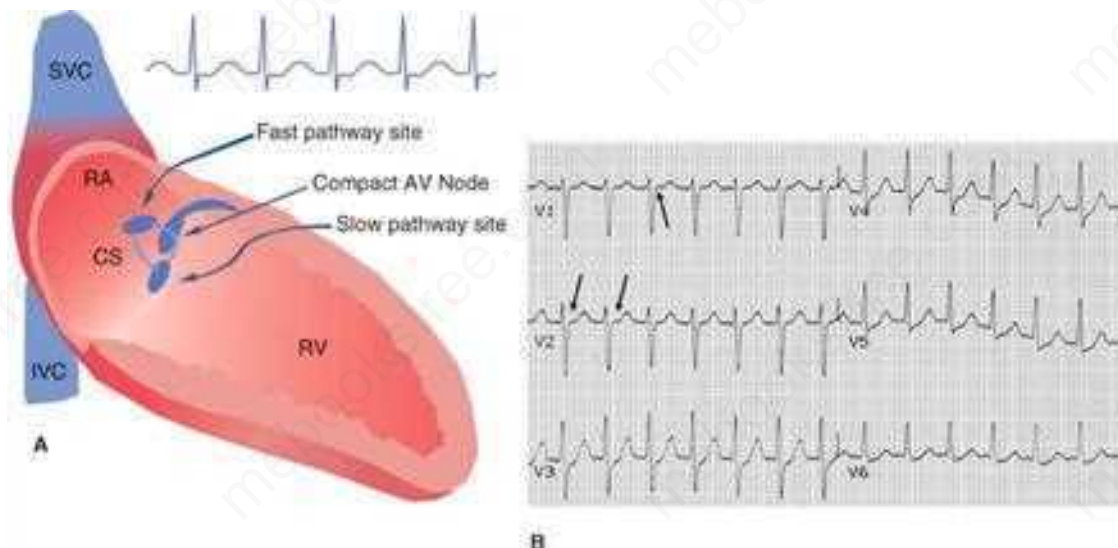

### Atrioventricular Nodal Re-entrant Tachycardia

AVNRT is the most common form of SVT identified during electrophysiologic studies. This tachycardia can present at any age, although most patients who present for medical attention are in their forties and the majority are females.<sup>50,51</sup> Advances in catheter ablation of this tachycardia has made it a first-line therapy for those symptomatic patients not wishing to take long-term medications.<sup>52</sup>

AVNRT has a re-entrant mechanism using two distinct electrical pathways within the AV nodal tissue. The common pathways are known as "slow" and "fast" based on their relative conduction properties. The anatomical location of these pathways is variable but generally located within the triangle of Koch in the septal right atrium, which is bounded by the tricuspid annulus and the tendon of Todaro with the CS at the base. The apex of the triangle is the His bundle at the membranous septum where it passes through the central fibrous body. The anterior third of the triangle contains the compact AV node and the fast pathway, and the inferior and posterior portion, near the CS ostium, is the typical location for the slow pathway (Fig. 53-3).<sup>53</sup>

**FIGURE 53-2** Integration of live intracardiac echocardiography (A) into the creation of a three-dimensional electroanatomic map of the left ventricle using the CARTO mapping system (CartoSound, Biosense-Webster, Diamond Bar, CA). (B) A voltage map of the left ventricle is shown in the RAO view, superimposed over the corresponding echocardiographic image.

**FIGURE 53-3** (A) Diagrammatic representation of typical atrioventricular nodal re-entrant tachycardia. Surface ECG shows narrow complex tachycardia with no clear P waves. The re-entrant circuit (blue arrows) consists of the posterior slow pathway region acting as the antegrade limb, and the anterior fast pathway region acting as the retrograde limb. The slow pathway target site is located between the coronary sinus os (CS) and the tricuspid valve annulus (TV). IVC = inferior vena cava; RA = right atrium; RV = right ventricle; SVC = superior vena cava. (B) Surface ECG showing precordial leads in AVNRT. This demonstrates that the retrograde P waves are barely discernible in some leads. In  $V_1$ , it forms a pseudo  $r'$  wave (arrow). P waves are also visible in the terminal portions of QRS complexes in  $V_2$  and  $V_3$  but not in the lateral leads.

In the typical form of AVNRT, antegrade conduction from the atrium to the ventricle occurs over the slow AV nodal pathway, and the retrograde conduction through the AV node occurs over the fast pathway. Because conduction in the retrograde direction is fast, the atria and ventricle are depolarized almost simultaneously. Thus the electrocardiographic feature of this tachycardia is P waves that are inscribed within the QRS and thus not seen or barely discernible at the termination of the QRS complex.<sup>54</sup> The arrhythmia is usually triggered by an atrial premature complex (APC). The refractory period of the fast pathway is longer than that of the slow. Under the right conditions, the premature impulse blocks in the fast pathway and proceeds antegrade down the slow pathway, resulting in marked PR prolongation (a “jump”). Since nothing came down the fast pathway the impulse can turn around and conduct retrograde up the fast pathway resulting in an atrial echo beat. If the slow pathway has recovered the tachycardia can continue.<sup>55</sup> In fewer than 10% of cases, the circuit is reversed. In *atypical* AVNRT, antegrade conduction occurs over the fast pathway and retrograde conduction occurs over the slow pathway. Thus the ECG of this tachycardia shows inverted P waves in the inferior leads denoting retrograde activation of the atria with a longer RP segment owing to slower retrograde conduction.<sup>56</sup> Less commonly other AV nodal circuits may be present such as “slow-slow” AVNRT, using antegrade conduction down one slow pathway, and retrograde conduction utilizing another “slow pathway,” with different functional and anatomic properties. These alternate AV nodal pathways occasionally have leftward extensions creating eccentric retrograde atrial activation patterns.<sup>55</sup>

Slow pathway ablation has a high degree of success for elimination of AVNRT, with a recurrence rate in the range of 2 to 7%. Complete AV block can occur as a complication of attempted slow pathway ablation in less than 1% (range 0 to 3%) of cases.<sup>57</sup> The North American Society of Pacing and Electrophysiology (NASPE) self-reported surveys on 4249 patients who underwent slow pathway ablations had success rates of greater than 96% and complication rates of less than 1%.<sup>58,59</sup>

## Atrioventricular Re-entrant Tachycardia

About 30% of SVTs are caused by AVRT. This is a re-entrant tachycardia using the AV node and an AP. These APs are muscular bundles or remnants of conductive tissue from embryonic development that span the normally electrically inert tricuspid and mitral valve annulus and provide an independent path of conduction between the atria and the ventricles outside of the AV node. AVRT is part of the Wolff-Parkinson-White (WPW) syndrome of ventricular pre-excitation and symptomatic arrhythmias. The most common APs connect the atrium to the ventricular myocardium, but other APs may connect the atria or AV node to the His-Purkinje system. APs can conduct in the antegrade direction, retrograde direction, or both. In sinus rhythm, in patients with antegrade conduction over the AP there is preexcitation of the ventricles.

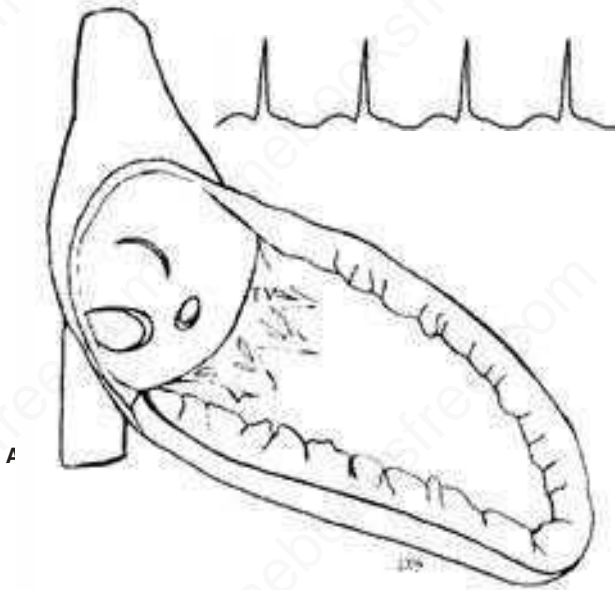

Ventricular activation is a result of “fusion” between activation over the AP and over the AV node. The degree of preexcitation is determined by the conduction velocity through the AV node and the time the sinus impulse takes to get to the AP. Preexcitation is manifested on the surface electrocardiogram by a short PR segment and slurring of the onset of the QRS, known as the delta wave. This slurring is due to slower “muscle to muscle” conduction in the ventricle from site of AP insertion. Absence of these findings does not exclude an AP. This may be due to a “latent AP” where there is antegrade conduction but the majority of the ventricle is being activated by the normal conduction system. This is most often seen in young patients with rapid AV nodal conduction and a far left lateral AP. In addition, up to 30% of AP conduct in the retrograde direction only (“concealed pathways”).<sup>60</sup>

The term “WPW syndrome” is the combination of ventricular preexcitation on the surface ECG and symptomatic palpitations. However, it is often used to refer to any patient with an AP and SVT. Patients with WPW typically present with palpitation caused by rapid heart rate. This may be the result of AVRT or any supraventricular arrhythmia, including AF, with resulting rapid AV conduction via the AP. Associated symptoms may be mild such as palpitation and shortness of breath, or as severe as syncope and sudden death.<sup>61,62</sup> Sudden death is a very rare complication of rapidly conducting APs, and may be caused by ventricular fibrillation resulting from the extremely rapid ventricular activation over the AP during AF.

Indications for ablation of APs include patients with symptomatic AVRT or those with atrial tachyarrhythmias with rapid ventricular conduction who fail or do not wish to undergo medical therapy.<sup>62</sup> Relative indications for ablations include asymptomatic patients with “high risk” APs that are capable of rapid conduction thus posing a small risk of sudden death as the initial presentation of AF. Similarly, patients in high-risk professions, those with family history of sudden death, or those mentally distraught over their condition may be candidates for ablation.<sup>63</sup>

In the typical or orthodromic form of AVRT, antegrade conduction from the atrium to the ventricle occurs over the AV node and retrograde conduction occurs over the AP. In this form of AVRT, the P wave in the tachycardia follows the preceding QRS complex, resulting in a “short RP” tachycardia but often a longer RP segment on the surface ECG than seen in AVNRT (Fig. 53-4). In the rare antidromic form of AVRT, antegrade conduction occurs over the AP with retrograde conduction over the AV node, or more commonly a second AP. This results in eccentric depolarization of the ventricle, producing a wide complex tachycardia with retrograde P waves that can be easily mistaken for VT with one-to-one ventriculoatrial conduction.

An unusual form of AVRT utilizes a slowly conducting or decremental AP. Since conduction in both limbs, antegrade AV node and retrograde AP, is slow the tachycardia can be very stable and almost incessant. These tachycardias were misnamed the “permanent form of reciprocating junctional

**FIGURE 53-4** (A) Diagrammatic representation of atrioventricular re-entrant tachycardia. This macro re-entrant circuit (*gray arrows*) uses the AV node and an accessory pathway (AP), in this case a right lateral pathway. In orthodromic AVRT, antegrade conduction occurs over the AV node and retrograde conduction occurs over the AP. Because of the conduction delay from the His-Purkinje system through the ventricular myocardium to reach the AP, retrograde P waves are discernible after the QRS complexes (*arrow*). In antedromic AVRT, the re-entrant circuit is reversed and surface ECG shows P waves that closely precede the QRS complexes. CS = coronary sinus; IVC = inferior vena cava; RA = right atrium; RV = right ventricle; SVC = superior vena cava; TV = tricuspid valve. (B) Intracardiac recording of atrioventricular re-entrant tachycardia with termination of eccentric conduction over the accessory pathway during RF ablation. The tracing at 50-mm-per-second speed shows four surface leads (VI, II, I, and aVF) and intracardiac recording from catheters: ablation (ABL); His distal, mid, and proximal; as well as right ventricular apex (RVA). The first three beats of the tracing show evidence of eccentric conduction over an accessory pathway: short PR segment and delta wave. With onset of RF energy (RF On) from the ablation catheter positioned in the region of shortest AV conduction, conduction becomes normal within two beats, with normalization of the PR segment and loss of the delta wave.

tachycardia” or PJRT. They tend to be relatively slow (100 to 140 BPM) and can be mistaken for sinus tachycardia. On the surface ECG this is a “long RP” tachycardia with a short PR interval and inverted P waves in the inferior leads. It is important to recognize this entity as the incessant elevated heart rate can lead to a tachycardia-related cardiomyopathy. These pathways are almost always posteroseptal in location and ablation results in normalization of ejection fraction in most cases.<sup>64</sup>

Additional unusual APs are those that conduct slowly in the antegrade direction, connect into the specialized conduction system, and support preexcited tachycardias with a wide QRS. These are known as Mahiem pathways in which there is a slowly conducting antegrade AP connecting from the atrium to a fascicle (atriofascicular pathway) or from the AV node to a fascicle (nodofascicular pathway).

The 1998 NASPE prospective catheter ablation registry reported on 654 patients with a 94% success rate.<sup>59</sup> Success rates are lower (in the range of 84-88%) for septal and right free wall pathways.<sup>65-67</sup> Mortality rates are less than 1% and nonfatal complications occur in about 4%.<sup>59</sup> The major challenges of AP ablation are the location of APs near the normal conduction system and those that are epicardial in location. Ablation of pathways that are anteroseptal and midseptal in location carry a higher risk of causing complete heart block due to ablation near the compact AV node or His bundle. In these cases, alternate ablative energy sources such as cryoablation may offer a potentially safer alternative due to its ability to deliver reversible injury, permitting of the resulting effects, prior to irreversible lesion formation.<sup>22,68,69</sup> However, the vast majority of these pathways can be safely ablated with standard RF energy.

## Atrial Tachycardia

Atrial tachycardias depend wholly on atrial tissue for initiation and maintenance of the tachycardia. Ectopic atrial tachycardia, sinoatrial nodal re-entrant tachycardia, inappropriate sinus tachycardia, atrial flutter, and AF can all be considered atrial tachycardias. Multifocal atrial tachycardia is caused by multiple foci of abnormal automaticity or triggered activity and is not amenable to curative catheter ablation.<sup>70</sup>

Focal atrial tachycardias, a less common type of SVT, form about 10% of all SVTs referred for electrophysiologic studies.<sup>63</sup> These arrhythmias are more common in patients with structural heart disease. Indications for ablation include failure or intolerance of medical therapy. Rarely, incessant tachycardias can lead to cardiomyopathy. With control of heart rate or restoration of sinus rhythm, myocardial dysfunction can be reversed, although there may be a delayed risk of sudden death that necessitates use of a defibrillator.<sup>71-73</sup>

Surface ECG features of focal atrial tachycardia include abnormal P wave morphology or axis that are typically close to the following QRS complexes (long RP tachycardia). Mapping and ablation of atrial tachycardias can be more difficult than ablation of other SVTs, as they can originate from anywhere in the right or left atrium, or within the interatrial

septum and venous/arterial structures. Fortunately, there are specific anatomical regions that have a high incidence of foci and serve as primary targets, including the crista terminalis, atrial appendages, CS ostium, valve annuli, and pulmonary vein ostia.<sup>74</sup> Focal atrial tachycardia is frequently amenable to catheter ablation by targeting the site of origin of the arrhythmia, typically by identifying the earliest site of atrial activation using activation mapping. However, ablation success rates for AT are lower than that for other SVTs; the wide range of possible locations of AT origin require that the arrhythmia be present or readily inducible at the time of mapping, so that it can be localized for successful ablation. Success rates for ablation of focal AT have been reported to be 86% on average, with a recurrence rate of 8%. Complications from ablation include cardiac perforation, phrenic nerve damage, AV block, and sinus node dysfunction, with a combined incidence of 1 to 2% in experienced centers.<sup>63</sup>

Sinoatrial nodal reentry tachycardias occur infrequently and experience with catheter ablation of these tachycardias is more limited, however possible. As the name suggests the tachycardia is due to reentry in the tissue in and around the sinus node. The P wave morphology is identical to sinus rhythm but the tachycardia can start and stop suddenly, unlike sinus.<sup>75</sup>

Inappropriate sinus tachycardia is not a well-defined disorder. It appears to result from a combination of autonomic dysfunction (when part of the postural orthostatic tachycardic syndrome, POTS) and perhaps some other endocrine and psychiatric component. While catheter ablation has been utilized as a “last resort” it is challenging because of the variability and diffuse location of sinoatrial tissue, as well as its multifactorial causes not treated by ablation.<sup>76</sup> Catheter ablation may be complicated by sinoatrial node dysfunction and persistent junctional escape rhythm, necessitating implantation of a pacemaker. Even if the resting heart rate is reduced with nodal modification, symptoms may continue with episodes of tachycardia. Catheter ablation is therefore generally avoided, in favor of a multidisciplinary approach, including cardiovascular, endocrinologic, and psychiatric evaluation and pharmacologic management.<sup>77</sup>

## Atrial Flutter

Atrial flutter is a type of atrial tachycardia that uses a macro-reentrant circuit contained within the atria. A variety of natural and surgical barriers to conduction can create a re-entrant circuit within the atria. “Typical” or “isthmus dependent” atrial flutter involves a right atrial circuit, with an obligate limb in the isthmus of tissue between the IVC and the TV annulus, known as the cavotricuspid isthmus (CTI). The flutter circuit is bound anteriorly by the TV annulus, and posteriorly by the superior vena cava, crista terminalis, IVC, eustachian ridge, and CS (Fig. 53-5).<sup>78</sup>

In the most common form of typical, isthmus-dependent atrial flutter, the circuit transverses the right atrium in a counterclockwise manner in the frontal plane. Because the anatomy of the right atrium is elongated in a caudad-cephalad direction, a typical atrial flutter spends large portions of circuit

**FIGURE 53-5** Diagrammatic representation of typical or counterclockwise right atrial flutter. Surface ECG shows large inverted P waves in the inferior leads. Lead III above shows 2:1 AV conduction with “sawtooth” flutter waves. The re-entrant circuit is confined to the right atrium by the tricuspid valve annulus (TV) and barriers to conduction within the right atrium. These include the superior vena cava (SVC), crista terminalis (CT), inferior vena cava (IVC), eustachian ridge (ER), and coronary sinus (CS). The isthmus between the IVC and TV is the preferred target for ablation.

activation going superior along the interatrial septum; therefore, on the surface ECG in leads II, III, and a VF, the P waves (called “flutter waves”) are negative and have a sawtooth appearance. In  $V_1$ , the flutter waves are usually upright and in  $V_6$  they are inverted. Clockwise isthmus-dependent flutter uses the same circuit but in a reversed direction, and the ECG also shows a reversed pattern with upright flutter waves in the inferior leads, and flutter waves that are negative in  $V_1$  and upright in  $V_6$ . This surface ECG morphology is suggestive of the circuit but needs intracardiac confirmation.<sup>79</sup>

Catheter ablation for typical atrial flutter involves ablation in the CTI, by transecting the flutter circuit between the IVC and TV annulus. Long-term success rates for eradication of CTI-dependent atrial flutter have been reported to be approximately 87 to 95%.<sup>80</sup> Given high success rates and relatively infrequent complications, ablation has become the first line of therapy for recurrent typical atrial flutter. Despite successful treatment of flutter, up to one half of patients may develop de novo AF after flutter ablation during long-term follow-up, mandating careful monitoring for recurrent arrhythmias prior to cessation of anticoagulation even after successful ablation.<sup>81,82</sup>

Although the isthmus-dependent right atrial circuit described in the preceding is the most common type of flutter, a variety of other macro re-entrant circuits in the right and left atria are also possible, and are termed “atypical atrial flutters”. These are more common in patients with underlying heart disease, or in those having previously undergone atrial ablation or cardiac surgery.<sup>49,83-85</sup> Mapping and ablation

of these arrhythmias are now also routinely performed. However, the success rate is somewhat lower than that for typical isthmus-dependent atrial flutter.

Incisional scars from prior cardiac surgery can be the substrate for re-entrant atrial arrhythmias.<sup>86-88</sup> The most common post-surgical atrial tachycardia is an atypical atrial flutter related to a lateral right atrial incision. Activation mapping typically demonstrates a circuit encircling a region of scar related to the incision. Ablation from the end of the scar to either the superior vena cava or more commonly the IVC is often curative (Fig. 53-6).<sup>89</sup>

Atrial arrhythmias are also common in patients who have undergone prior atrial ablation, particularly after more extensive left atrial ablation performed for persistent AF, or after a surgical Maze procedure (see below). These tachycardias may be a result of macro reentry, micro reentry, or a focal source. Common macro re-entrant circuits in these patients include typical right atrial flutter or atypical flutters encircling the mitral annulus or involving the roof of the left atrium. Re-entrant circuits may result from incomplete lines of block created during the prior intervention, or through alternative pathways such as the musculature surrounding the CS.<sup>90</sup> These tachycardias are often incessant and may be highly symptomatic and difficult to control with antiarrhythmic medications. Catheter ablation is therefore frequently pursued to target these recurrent arrhythmias and restore sinus rhythm. Ablation of these post-ablation arrhythmias are often delayed until 2 or 3 months after the index ablation, once the inflammatory response to the initial ablation has passed and the lesions have completely healed. During electrophysiologic study, the circuit of these arrhythmias can usually be determined using a combination of activation and entrainment mapping.<sup>91</sup> The main principle of ablation involves interrupting these circuits in obligate limbs, such as the left atrial roof or lateral mitral isthmus, by ablating between electrically inert anatomic barriers, such as the mitral annulus and the electrically isolated PV antrum.<sup>92</sup>

## Atrial Fibrillation

Atrial fibrillation is the most common cardiac arrhythmia affecting upwards of 8 million Americans. AF is often highly symptomatic due to irregular and/or rapid ventricular rates and loss of AV synchrony. Patients can also be completely asymptomatic, but are still at risk of stroke, heart failure, and dilated cardiomyopathy due to prolonged periods of tachycardia.<sup>73,93</sup> The primary goal of pharmacologic therapy is prevention of thromboembolism in those at risk using systemic anticoagulation. Pharmacologic therapy for control of AF-related symptoms, however, has limited efficacy, carries risk of proarrhythmia and other systemic toxicities, and has not demonstrated a benefit in the reduction of stroke or mortality in large trials.<sup>94-97</sup> Catheter ablation of AF has consistently shown greater efficacy in maintenance of sinus rhythm than antiarrhythmic drugs and avoids long-term drug-related side effects. Ablation therefore has an expanding role in the restoration of sinus rhythm and control of AF-related symptoms,

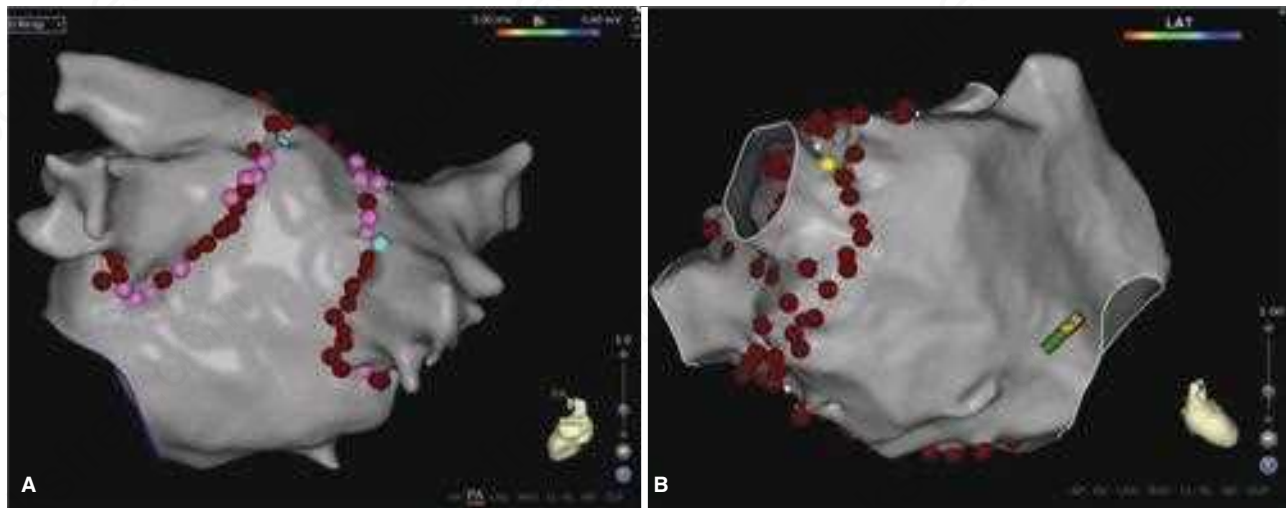

**FIGURE 53-6** Electroanatomic reconstruction of the right atrium in a patient with an atypical atrial flutter following mitral valve surgery. Panel A shows a voltage map, with regions of low voltage (nonpurple regions on map), and electrically nonexcitable tissue (gray dots) representing abnormal or scarred atrial myocardium, likely related to the lateral atriotomy incision site. Panel B shows an activation map during tachycardia, demonstrating a macro re-entrant circuit around the scarred segments in the right atrium. Ablation lesions between electrically inert regions of the right atrium (red dots in panel A) terminated the tachycardia.

particularly after failure or intolerance of at least one antiarrhythmic drug trial. In patients with tachycardia-related cardiomyopathy, ablation is also often considered when medical therapy is inadequate for persistent rate control, or when restoration of sinus rhythm is the priority.<sup>31</sup>

The initial surgical Maze procedure was performed in 1987, and with several modifications aimed to make the procedure more tolerable, the Cox Maze III procedure has shown excellent long-term success rates, with an operative mortality of 2 to 3%.<sup>98,99</sup> This procedure is based on the concept that AF consists of multiple re-entrant circuits within the atria, and that creation of lines of conduction block between nonconducting atrial structures may preclude propagation of arrhythmic circuits and such that AF cannot sustain.<sup>100</sup> It is termed the “MAZE” in addition to creating lines of conduction block there is an attempt to avoid areas of atrial isolation and therefore promote atrial contraction in sinus rhythm. The electrical impulse from the sinus node therefore traverses a “MAZE” as it makes its way to the AV node. This procedure has been limited by the need for open-heart surgery with its mortality, morbidity, and expense, as well as post-op sinus node dysfunction requiring a pacemaker and the creation of new atrial arrhythmias. The surgical experience with the Maze procedure has led to the development of both more minimally invasive surgical approaches and a catheter-based approach.

Attempts at catheter-based left atrial or biatrial lesions for the purpose of replicating the Maze were met with limited success because of the prolonged procedure times, high risk of complications, and limited efficacy.<sup>101</sup> As understanding of the mechanism of AF has evolved, attempts to block propagation of atrial fibrillatory circuits have given way to attempted ablation of the fibrillatory triggers. When the identification of AF triggers arising from the PVs was first described by Haissaguerre et al. in 1998, the discipline of catheter-based ablation of AF emerged into the forefront of clinical electrophysiology. In a series of patients undergoing a left-sided catheter Maze procedure it was discovered that rapidly firing premature atrial contractions arising from the musculature of the PVs were triggering AF. Ablation of these foci eliminated AF in some patients.<sup>102</sup> Catheter-based ablation targeting triggers within the PVs has now gained worldwide acceptance as a therapeutic option for patients with symptomatic AF.

An early approach to PVI involved segmental isolation of each PV by mapping the location of the connecting muscular fibers.<sup>103</sup> This procedure has since evolved to an empiric electrical isolation of the PVs, with complete encircling of the PV antra, typically performed as ipsilateral pairs (Fig. 53-7).<sup>104,105</sup> In patients with paroxysmal AF, antral PVI is often sufficient to prevent recurrent AF. Ablation of additional atrial substrate is often needed to restore sinus rhythm in patients with more persistent forms of AF.<sup>106</sup>

**FIGURE 53-7** Electroanatomic map showing a series of radiofrequency ablation lesions (red and pink dots) encircling the pulmonary vein antra as ipsilateral pairs. Panel A: posterior-anterior view; panel B: right anterior oblique view.

Due to the high prevalence of AF in the general population, along with the increasing success of ablation, catheter ablation for AF has become one of the most commonly performed electrophysiologic procedures. However, methods for optimizing outcomes are still in evolution. Approaches beyond PVI, particularly for patients with persistent AF, continue to be evaluated. While in most patients with paroxysmal AF the arrhythmia is driven by PV triggers, as the arrhythmia becomes more persistent or occurs in more diseased atria, AF becomes maintained by arrhythmogenic atrial substrate. Those with a more permanent form of AF have been demonstrated to have either atrial scarring or structural disease in 65%. This arrhythmogenic substrate may be manifest as regions of electrical block and complex fractionated atrial electrograms (CFAEs) on intracardiac recordings, and may be targeted during catheter ablation.<sup>106</sup>

Whether ablation targeting additional atrial substrate, including CFAE ablation or creating additional lines of ablation to segment the atria (similar to the Maze procedure), improve ablation success is still under investigation. In randomized trials, the addition of targeting of CFAEs to a conventional PV antral isolation has not resulted in increased freedom from recurrent arrhythmia.<sup>107,108</sup> In a study comparing the efficacy of adding linear lesions to PVI alone, additional lines did improve the maintenance of sinus rhythm, although the results were much more apparent in those with persistent AF at baseline.<sup>109</sup> As discussed above, additional lines of ablation also predispose to recurrent atrial tachycardias, which have the potential to conduct rapidly and may be even more symptomatic than was the original arrhythmia. Though PVI alone may be sufficient for most patients with paroxysmal AF, those with persistent arrhythmia often require more extensive ablation to terminate AF and prevent recurrence. In all patients, targeting additional substrate in the pulmonary venous antra appears to have a beneficial role over ostial isolation alone. A recent systematic

review and meta-analysis found a highly significant lower rate of recurrent arrhythmias in patients undergoing wide antral PVI relative to segmental ostial isolation (odds ratio 0.42,  $p < .00001$ ), including a much lower AF recurrence rate (odds ratio 0.33), despite a trend towards greater incidence of left atrial tachycardia occurrence in the wide antral circumferential ablation group.<sup>110</sup> In addition, ostial ablation increases the risk of PV stenosis, which is largely avoided by wide circumferential ablation.

Due to the evolving nature of AF ablation and range of techniques and experience, as well as nonuniform methods of follow-up and postoperative surveillance, accurate data regarding the efficacy and long-term outcomes of the procedure are limited. Furthermore, results are also dependent on individual patient factors, particularly the pattern of preexisting AF (universally worse outcomes in patients with persistent AF), patient comorbidities, and left atrial size. There is now strong evidence that ablation improves maintenance of sinus rhythm greater than antiarrhythmic medications. One randomized multicenter comparison of ablation versus antiarrhythmic drugs in patients with paroxysmal AF who failed at least one medication found freedom from documented symptomatic recurrence in 66% of patients treated with ablation compared to 16% of patients treated with medications at 9 months (hazard ratio 0.30,  $p < .001$ ), as well as greater improvement in symptom severity score and quality of life in the ablation group.<sup>111</sup> Another meta-analysis comparing ablation to medical management in patients with paroxysmal AF found that at 1 year, ablation was associated with a 16-fold rate of freedom from recurrent AF (odds ratio, 15.78; 95% CI, 10.07-24.73) and with decreased hospitalization for cardiovascular causes (rate ratio, 0.15; 95% CI, 0.10-0.23).<sup>112</sup>

One-year outcomes after AF ablation, particularly in well-selected patients with paroxysmal arrhythmia, have demonstrated impressive results; the A4 trial showed at 1 year, 23%

of those randomized to antiarrhythmic drug therapy, and 89% of those randomized to ablation had no recurrence of AF.<sup>113</sup> A large international survey assessing global outcomes from AF, including over 20,000 ablations performed between 2003 and 2006, found that a median of 70% of patients became asymptomatic without antiarrhythmic drugs, and another 10% became asymptomatic in the presence of previously ineffective antiarrhythmic drugs over an average of 18 months of follow-up. Success rates were significantly greater for patients with paroxysmal AF (75% without antiarrhythmic drugs) than in patients with persistent or long-standing AF (63-65% without antiarrhythmic drugs).<sup>26</sup> A second ablation procedure is often required to achieve the quoted freedom from arrhythmia in up to 30% of patients, either from recurrent AF or due to post-ablation atrial tachycardias.<sup>26</sup> Most patients with arrhythmia recurrence demonstrate recovered electrical conduction into the PVs at the time of redo procedures, demonstrating the difficulty achieving durable transmural ablation lesions. Furthermore, since arrhythmias can recur asymptotically and sporadically, it is likely that the published rates of ablation success are an underestimation of the actual rate of AF recurrence.

As AF has been associated with increased mortality in various populations, it is possible that ablation will have a positive effect on mortality, though this has not yet been proven. Trials to assess the late success and long-term outcomes of AF ablation with regard to mortality, stroke risk, and heart failure, such as the CABANA trial, are ongoing.<sup>31</sup>

Encouraging results for AF ablation, however, must be tempered by the rare but significant risks involved. In the worldwide survey of AF, major complications occurred in 4.5% of procedures, including cardiac tamponade, PV stenosis, diaphragmatic paralysis, thromboembolism, atriopharyngeal fistula, pneumothorax or hemothorax, vascular complications, valve damage, and congestive heart failure; procedure-related death occurred in 0.15%.<sup>26</sup> Interestingly, the rate of major adverse effects from antiarrhythmic drug treatment (including life-threatening arrhythmias and disabling drug intolerance) has been higher than ablation-related complications in various comparisons.<sup>111,114</sup>

Increasing acknowledgement of the risks associated with RF ablation have led to interest in alternate approaches to PVI, with the intent of improving the permanency of lesion formation and avoiding collateral damage to extracardiac structures. One such approach may be through the use of energy-delivering balloons, which can be placed within the orifice of a PV with the goal of creating circumferential lesions around the vein ostia. Most notably, the Cryoballoon (Arctic Frost, Medtronic CryoCath, Montreal, Quebec, Canada) using cryothermal energy from a balloon-tipped catheter has been used with success for treatment of paroxysmal AF.<sup>115</sup> Though the Cryoballoon provides a relatively simple alternative to point-by-point RF ablation delivery and may be associated with a lower rate of cardiac perforation, with increasing experience with this tool various complications have been reported including atriopharyngeal fistulas, and a higher rate of phrenic nerve palsy.<sup>116</sup> Initial enthusiasm for an

endocardial deflectable catheter-based high-intensity focused ultrasound balloon (ProRhythm, Ronkonkoma, NY), allowing for the development of transmural linear lesions without direct tissue contact was dampened by low clinical success, and significant morbidity and mortality.<sup>117,118</sup> Using endoscopic visualization, laser balloon ablation (CardioFocus, Marlborough, MA) has also demonstrated promising initial results.<sup>119</sup>

In elderly patients or those with severe comorbidities in whom standard treatment modalities cannot be achieved or are contraindicated, permanent rate control may be achieved through AV junction ablation and permanent pacemaker implantation, eliminating the need for aggressive pharmacologic treatment. The “Ablate and Pace” strategy is highly effective, relatively simple to perform, has been shown to improve quality of life in highly symptomatic patients, and may improve cardiac symptoms and decrease healthcare utilization when pharmacologic therapy is limited by hypotension or intolerable side effects.<sup>120</sup> Cessation of previously needed rate control and antiarrhythmic medications, often used in high-doses, after this procedure also generally results in immediate symptomatic improvement. This strategy is potentially problematic for many patients though, as it mandates continued anticoagulation, creates pacemaker dependence and tolerates permanent AV dyssynchrony. Patients dependent on the atrial contribution to diastole, such as those with diastolic dysfunction, may not symptomatically improve with this strategy. An additional limitation of this strategy is that right ventricular pacing promotes interventricular dyssynchrony, and may result in worsened LV function. The PAVE trial found that biventricular pacing after AV node ablation can result in better performance status (31 vs 24% above baseline in the 6-min walk test) and LV function (LV ejection fraction 46 vs 41%) at 6 months compared to right ventricular pacing.<sup>121</sup> This improvement with cardiac resynchronization may be even more pronounced in patients with preexisting systolic dysfunction. In a retrospective study comparing PV antral isolation versus AV node ablation and pacemaker implantation, the ablate and pace strategy was associated with a shorter procedure time with fewer complications, although there was higher rate of heart failure and continued, albeit asymptomatic, AF.<sup>122</sup>

A more complex technique known as AV node modification attempts to ablate certain inputs to the AV node thus slowing the ventricular rate without requiring concomitant pacemaker implantation.<sup>123</sup> This procedure has not been widely implemented because of the risk of inadvertent complete AV block, and a tendency for the ventricular rate to rise again in the post-ablation period.

## Ventricular Tachycardia

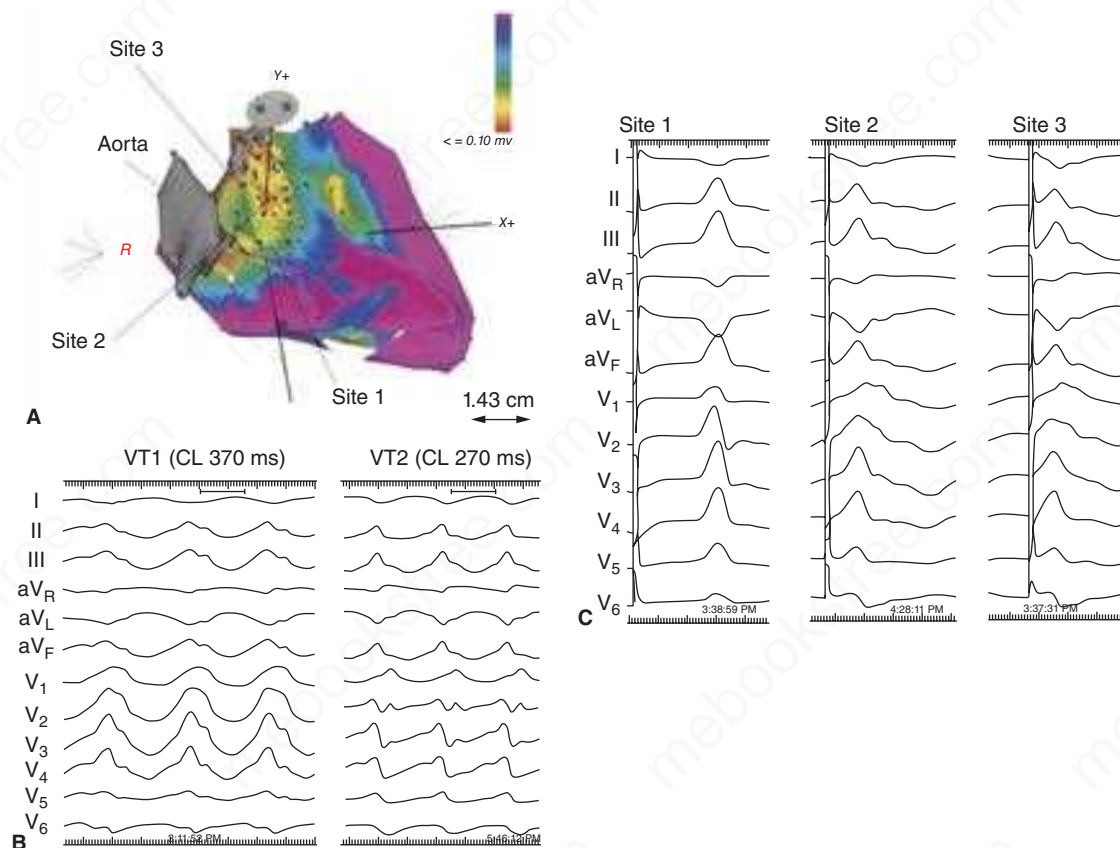

Catheter ablation also has an important role in the treatment and prevention of VT. Greater than 90% of life-threatening ventricular arrhythmias originate in myocardium with structural abnormalities, most commonly ischemic heart disease. In these cases, regions of scarred myocardium create channels

of viable tissue that support re-entrant circuits; these circuits may be mapped and targeted with ablation. Patients with nonischemic cardiomyopathy generally also have scar-related circuits related to myocardial fibrosis, however, these scars are often multifocal and located in the epicardium or midmyocardium, complicating endocardial ablation. Initial experience with surgical endocardial resection and direct surgical ablation to eliminate VT led to advancements in catheter-based ablation techniques. In patients with extensive structural abnormalities, multiple VT circuits are often present, and thus even after successful VT ablation primary therapy remains implantable cardiac defibrillators (ICDs) for prevention of sudden death. However, VT ablation is an important adjunct to reduce the arrhythmia burden and ICD shocks. According to the 2006 ACC/AHA/ESC guidelines on management of ventricular arrhythmias, VT ablation has a class I indication as an adjunctive therapy in patients with an ICD who have received multiple shocks for sustained VT that is not manageable by device reprogramming of drug therapy.<sup>124</sup>

Ablation for VT can be performed during ongoing VT, using activation and entrainment mapping to localize the

critical isthmus supporting the re-entrant circuit, or by identifying arrhythmogenic substrate during sinus rhythm. In “substrate mapping,” intracardiac electrodes are used to identify regions with abnormal myocardial substrate that represent areas of slow conduction within the region of scar that may support VT. Determination of scarred myocardium requires the use of an electroanatomic mapping system, in which the amplitude of electrograms recorded at various sites are recorded, and area with low amplitude electrograms are represented as regions of scar on a color-coded three-dimensional map. Pace-mapping allows identification of VT exit or isthmus sites by matching the QRS morphology produced by pacing during sinus rhythm to the VT morphology; pacing can also identify areas with delayed conduction that may occur when pacing from within a protected channel, such as within the VT isthmus. Ablation is performed generally within the scar at sites thought to be critical for supporting re-entrant circuits (Fig. 53-8).<sup>125</sup>

In experienced centers, epicardial mapping and ablation is also commonly performed when the VT substrate cannot be eradicated by endocardial ablation. Access to the pericardium is achieved via pericardial puncture from a subxiphoid

**FIGURE 53-8** (A) Endocardial voltage map of the left ventricle created using a three-dimensional electroanatomic mapping system. An extensive region of low voltage representing scarred myocardium is present in the left ventricular outflow tract region. (B) Two morphologies of ventricular tachycardia were induced. (C) Pace mapping from different sites within the scar are shown. A good pace map for VT1 is observed with pacing at sites 2 and 3. A long delay between the pacing stimulus and the QRS occurs with pacing from site 1, demonstrating slow conduction away from the pacing site. A series of radiofrequency ablation lesions (red dots in panel A) across this region abolished both VT morphologies. (Reproduced with permission from Soejima K1, Stevenson WG, Sapp JL, et al: Endocardial and epicardial radiofrequency ablation of ventricular tachycardia associated with dilated cardiomyopathy: the importance of low-voltage scars, *J Am Coll Cardiol*. 2004 May 19;43(10):1834-1842.)

approach, and is often not possible in patients who have had prior cardiac surgery, particularly prior coronary artery bypass surgeries.<sup>126</sup> Epicardial ablation is more likely to be required in patients with nonischemic cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy, and in patients who have failed initial attempts at endocardial ablation.

In large trials, success of VT ablation in patients with structural heart disease is promising, but recurrences are common. Acute procedural success is usually defined as noninducibility of any VT after ablation, while partial short-term success is defined as ablation of the clinical VT only. The Multicenter ThermoCool Ventricular Tachycardia Ablation trial evaluated 231 patients with recurrent monomorphic VT, including 69% of patients with hemodynamically poorly tolerated VT, and a median of three VTs per patient; ablation acutely abolished all inducible VTs in 49% of patients, while at 6 months 53% of patients were VT-free.<sup>127</sup> Furthermore, ablation success is dependent on the underlying myocardial substrate and patient population. A recent prospective evaluation reported a VT-free survival at 1 year of 57% for patients with ischemic cardiomyopathy, and 40.5% for patients with nonischemic cardiomyopathy, despite complete acute procedural success achieved in 77% of patients with ischemic cardiomyopathy, and 67% of patients with nonischemic cardiomyopathy.<sup>128</sup> While VT is not completely abolished in all patients, the frequency of VT recurrences and associated ICD shocks may be dramatically reduced, resulting in a substantial improvement in an individual's quality of life, even when VT is not completely eradicated. In the ThermoCool VT Ablation trial, among patients with at least 6 months of follow-up, VT episodes were reduced from a median of 11.5 episodes preablation, to a median of 0 postablation, and the frequency of VT was reduced by  $\geq 75\%$  in two-thirds of patients.<sup>127</sup> Complications from VT ablation include stroke, cardiac tamponade, valve damage, heart failure, AV block, vascular complications, and death. Procedure-related deaths have been reported in up to 3%, and most commonly occurs as a result of progressive ventricular arrhythmias and cardiac arrest after failed ablation. In the ThermoCool study, death occurred in the electrophysiology laboratory in 4 of 231 patients. Nonfatal complications have been reported in approximately 7%.<sup>127,129-131</sup>

Bundle branch reentry VT is another type of VT that may occur in patients with dilated cardiomyopathy and His-Purkinje system disease. In bundle branch reentry, a macro re-entrant circuit using the conduction system occurs, most commonly with propagation antegrade down the right bundle branch and retrograde up the left bundle branch, resulting in a wide complex tachycardia with a left bundle branch block pattern. Patients typically present with palpitation, syncope, or sudden death. Treatment involves ablation of the right bundle branch to interrupt the re-entrant circuit. Long-term success is good for prevention of recurrent bundle branch reentry, however, as these patients generally have extensive ventricular structural abnormalities, other VTs may develop, and ICDs are still required even after successful ablation. In addition to other established risks of ablation, ablation within the specialized conduction system poses a risk of ablation-related heart block.<sup>132,133</sup>

Other cardiac disorders associated with sustained monomorphic VT include right ventricular dysplasia,<sup>134</sup> infiltrative disorders such as cardiac sarcoidosis<sup>135,136</sup> and hypertrophic cardiomyopathy.<sup>137</sup> Patients with prior ventricular surgery can develop incision-related VT, commonly seen in patients who have undergone repair of congenital cardiac abnormalities such as tetralogy of Fallot,<sup>138</sup> or after corrective valve surgery.<sup>139</sup>

VT that presents in patients without structural heart disease is termed *idiopathic* and represents up to 10% of all VTs that present to tertiary referral centers. In these patients, VT ablation may be curative, and long-term prognosis after ablation is good even without ICDs. Patients may be asymptomatic or present with palpitation, dizziness, or syncope. Patients may present with frequent premature ventricular contractions (PVCs), nonsustained VT, or even sustained VT. In patients with a high PVC burden ( $>20,000$  in 24 h) a myopathy may develop that is treatable by elimination of the ventricular ectopy. Idiopathic outflow tract arrhythmias typically have a left bundle branch QRS morphology with an inferior axis; though classically described as originating in the right ventricular outflow tract, PVCs, or VT may be mapped and successfully ablated anywhere in the base of the heart, including in the regions of the aortic valve cusps or along the mitral annulus. These occur more often in women than in men, and patients typically present in their thirties to fifties.<sup>140</sup> While they may be responsive to medical management with beta blockers or other medications such as flecainide (if there is no underlying cardiomyopathy) they are certainly amenable to ablation. One of the biggest reasons for failure is the lack of target PVCs/tachycardia at the time of ablation.

Other idiopathic VTs may be focal or involve a micro re-entrant circuit, often using branches of the Purkinje system. Fascicular VT most often originates from the left posterior fascicle, producing a right bundle branch VT morphology with rightward, superior axis. These VTs occurs more often in men, and are classically sensitive to verapamil. Success rates for ablation of idiopathic VT are in the range of 70 to 90% with recurrence rates in the range of 15%. Complication rates are consistent with those of other ablative procedures.<sup>27,141</sup>

## Cost-effectiveness

Several studies have shown the cost-effectiveness of catheter ablation compared with medical therapy and surgical ablation. Catheter ablation has lower procedural costs than surgical ablation and reduces the need for further medical care and emergency department visits in comparison to drug therapy. Studies from the United States, Canada, the United Kingdom, and from Australia have shown both cost savings and improvement in quality of life for those undergoing catheter-based ablation compared to medical management.<sup>142-146</sup>

As AF is the most common sustained arrhythmia and is associated with substantial healthcare costs related to hospitalizations and drug costs, the cost-effectiveness of catheter ablation for the treatment of AF has gained particular attention. AF ablation is associated with substantial upfront expenditures but greater efficacy in maintaining sinus

rhythm, and thus likely fewer subsequent cardioversions and hospitalization costs. Initial ablation costs have been estimated at approximately \$15,000, with follow-up costs after ablation ranging from \$200 to \$1300 annually, compared to approximately \$4000 annually for patients treated with antiarrhythmic medications; total costs of the two strategies appear to converge after about 5 years of follow-up.<sup>147</sup> Another analysis suggested that the cost-effectiveness of a rhythm-control strategy with ablation would be most cost-effective in younger patients and patients with at least moderate risk of stroke.<sup>148</sup> One study performed in the United Kingdom demonstrated cost savings for ablation in combination with antiarrhythmic drug therapy compared to drug therapy alone, in large part driven by reduction in health-care utilization rather than the mere cost of the drug itself.<sup>149</sup> Essentially all cost-effectiveness analyses of AF ablation thus far have calculated incremental cost-effectiveness ratios close to the value of \$50,000 per quality-adjusted life year that is typically considered acceptable in the United States.<sup>147</sup> The cost-effectiveness calculations for ablation, however, will continue to be unreliable until the long-term outcomes of ablation with regard to mortality and morbidity are clarified. In addition the value of this procedure will continue to evolve along with the procedure itself. The development of a more reliably successful ablation procedure that only requires a single attempt would dramatically increase cost effectiveness.

## FUTURE DIRECTIONS

Catheter ablation is a relatively young field and has undergone dramatic advances over the past three decades. Technologic developments focused on improving the safety and efficacy of targeted catheter ablation, using minimally invasive methods, have led the way to a revolution in the treatment of arrhythmias. Mapping systems are rapidly evolving to provide more accurate reconstructions of intracardiac geometry and electrical activation. Integration of ICE, MRI, and CT images, fluoroscopy, and cineangiographic sequences into electroanatomic maps can support understanding of complex anatomy, and allow contextual visualization of the movement of intracardiac catheters, while minimizing fluoroscopic exposure to the operator.<sup>150</sup> Noncontact mapping systems are also in development to quickly reproduce cardiac activation sequences without tedious point-by-point electrogram acquisition.<sup>151</sup> For patients with AF, ablation techniques beyond targeting PV triggers are of great interest. Methods of mapping AF-sustaining substrate in the atria, such as electrical rotors, have been developed that use intracardiac catheters to reconstruct three-dimensional maps of AF propagation; early studies suggest that ablation targeting this substrate in addition to conventional triggers improves long-term freedom from arrhythmia.<sup>152</sup> Developing technology and techniques are also focusing on novel methods to more effectively and safely deliver durable ablation lesions. The recent approval of force sensing catheters in the United States has the potential to revolutionize the industry; real-time feedback of force application within the cardiac chamber during mapping and

ablation supports improved ablation delivery, lesion creation, and safety. Multicenter experience using force sensing catheter for ablation of AF have shown promise that this technology will improve outcomes.<sup>153</sup> Integration of careful impedance monitoring into electroanatomic mapping systems provides additional feedback of local heating and lesion application.<sup>154</sup> New techniques are also focusing on novel methods to deliver ablation deep into tissues. Ablation of VT is sometimes limited by inability to reach arrhythmogenic substrate deep within the myocardium, such as within the interventricular septum. A novel needle-tipped ablation catheter, capable of mapping and delivering RF energy from a retractable needle, is undergoing clinical trials, and holds promise to improve ablation of deep intramyocardial substrate not reachable by traditional endocardial ablation.<sup>155</sup>

Remote navigation systems have been developed and are now in use to support catheter ablation of various arrhythmias. Though these tools have not replaced the value of a human operator, but do reduce operator exposure to fluoroscopy and may shorten procedural times.<sup>156-160</sup> The Niobe system (Stereotaxis, Inc., St. Louis, MO) is a remote magnetic navigation system that uses two externally located magnets to create a steerable field that can be used to steer the magnetically active atraumatic catheter tip (Magnetic GentleTouch Catheters, Stereotaxis). The unit can be completely controlled remotely through a small motor, and the entire system can be controlled from a shielded room by joystick and touch-screen monitors using a hands-free robotic catheter control.<sup>161</sup> Another robotic catheter system, Sensei (Hansen Medical, Mountain View, CA) allows catheter manipulation from a control room using a mechanical steering outer sheath through which a conventional catheter is inserted.<sup>162</sup> Clinical results from remote navigation for AF ablation have yet to demonstrate superiority over manual operation and frequently require crossover to manual ablation. In addition the cost of the equipment greatly reduces the cost effectiveness of the procedure.

As the left atrial appendage is the most important source of thrombi in patients with non-valvular AF,<sup>163</sup> percutaneous left atrial appendage occlusion devices have been developed to reduce stroke risk in patients with AF and elevated bleeding risks that preclude systemic anticoagulation. The Watchman device is nearing FDA approval. In the Watchman Left Atrial Appendage System for Embolic Protection in Patients with AF (PROTECT AF) trial, the Watchman occlusion device percutaneously implanted at the ostium of the left atrial appendage compared favorably to warfarin with regard to the composite endpoint of stroke, cardiovascular or unexplained death, or systemic embolism at a mean follow-up of 18 months.<sup>164</sup> With extended follow-up, it appears that most complications associated with the device occur in the early post-procedure period and decline with operator experience. Other methods of left atrial appendage closure, such as epicardial suture ligation have also been used. The lariat device is delivered via subxiphoid epicardial access, and has been used with success in various centers.

The past 40 years have seen the development of intracardiac recording, programmed stimulation, and catheter

ablation. Though rapidly expanding, the field of interventional electrophysiology is still young. Tremendous advances in technology and understanding of arrhythmia mechanisms have resulted in improvement in the care, and in many cases cure, or formerly intractable arrhythmias. Similar advances have allowed these minimally invasive procedures to be performed with impressive safety. Further improvements in the interventional treatment of complex arrhythmias such as AF and VT will come with further understanding of the mechanisms underlying these arrhythmias. Future innovations in catheter design, energy delivery, and imaging techniques will continue to advance the field of electrophysiology.

# Surgery for Atrial Fibrillation

Matthew C. Henn • Spencer J. Melby • Ralph J. Damiano, Jr.

Atrial fibrillation (AF) remains the most common arrhythmia in the world.<sup>1</sup> It is associated with significant morbidity and mortality secondary to its detrimental sequelae: (1) palpitations resulting in patient discomfort and anxiety; (2) loss of atrioventricular (AV) synchrony, which can compromise cardiac hemodynamics, resulting in various degrees of ventricular dysfunction; (3) stasis of blood flow in the left atrium, increasing the risk of thromboembolism and stroke.<sup>2-11</sup>

Medical treatment of AF has had many shortcomings including both the inefficacy of many of the antiarrhythmic drugs and their unwanted side effects. Because of this, interest in nonpharmacologic treatment approaches led to the development of catheter-based and surgical techniques beginning in the 1980s. Initial attempts aimed at providing rate control failed to address the detrimental hemodynamic and thromboembolic sequelae of AF. The early attempts at finding a surgical treatment culminated in the introduction of the Maze procedure in 1987, which became the surgical gold standard for decades.

The following sections describe the historical aspects and the current status of surgery for AF, including the introduction of minimally invasive techniques.

## HISTORICAL ASPECTS

### The Left Atrial Isolation Procedure

The first surgical procedure designed specifically to eliminate AF, the *left atrial isolation*, was described in 1980 in the laboratory of Dr. James Cox at Duke University. This approach confined AF to the left atrium, and restored the remainder of the heart to sinus rhythm (Fig. 54-1).<sup>12</sup> This reestablished a regular ventricular rate without requiring a permanent pacemaker. Isolating the left atrium allowed the right atrium and the right ventricle to contract in synchrony, providing a normal right-sided cardiac output. This effectively restored normal hemodynamics.

However, by confining AF to the left atrium, the left atrial isolation procedure only eliminated two of the three detrimental sequelae of AF: an irregular heartbeat and compromised

cardiac hemodynamics. It did not eliminate the thromboembolic risk because the left atrium usually remained in fibrillation. This procedure never achieved clinical acceptance, and was only performed in a single patient.

### Catheter Ablation of the Atrioventricular Node-His Bundle Complex

In 1982, Scheinman and coworkers introduced *catheter fulguration of the His bundle*, a procedure that controlled the irregular cardiac rhythm associated with AF and other refractory supraventricular arrhythmias.<sup>13</sup> This procedure electrically isolated the fibrillation to the atria. Unfortunately, ablating the bundle of His required permanent ventricular pacemaker implantation to restore a normal ventricular rate.

The shortcoming of this intervention was that it only eliminated the irregular heartbeat. Both atria remained in fibrillation, and the risk of thromboembolism persisted. AV contraction remained desynchronized, compromising cardiac hemodynamics. In addition, patients become pacemaker dependant for the remainder of their lives. Nevertheless, AV node ablation has remained a common treatment for medically refractory AF.

### The Corridor Procedure

In 1985, Guiraudon and associates developed the *corridor procedure* for the treatment of AF.<sup>14</sup> This operation isolated a strip of atrial septum harboring both the sinoatrial (SA) node and the AV node, allowing the SA node to drive both the ventricles. This procedure effectively eliminated the irregular heartbeat associated with AF, but both atria either remained in fibrillation or developed their own asynchronous intrinsic rhythm because they were isolated from the septal “corridor.” Furthermore, the atria were isolated from their respective ventricles, thereby preventing AV synchrony. The corridor procedure was abandoned because it had no effect on the hemodynamic compromise or the risk of thromboembolism associated with AF.

**FIGURE 54-1** Standard left atriotomy, demonstrating incisions to the mitral valve annulus at both the 10 and 2 o'clock positions. The superior and inferior vena cavae are seen with tourniquets, and the pulmonary vein orifices are seen inferiorly. Cryoablation is used to complete the line of conduction block at the valve annuli. (Adapted with permission from Williams JM, Ungerleider RM, Lofland GK, Cox JL: Left atrial isolation: new technique for the treatment of supraventricular arrhythmias, *J Thorac Cardiovasc Surg.* 1980 Sep;80(3):373-380.)

## The Atrial Transection Procedure

In 1985, Dr. James Cox and associates described the first procedure that attempted to terminate rather than simply isolate or confine AF to the atria.<sup>15</sup> Using a canine model, they found that a single long incision around both atria and down into the septum could terminate AF. This *atrial transection procedure* effectively prevented AF or atrial flutter in animals.<sup>16</sup> Although this procedure was not effective clinically and was soon abandoned, it laid the foundation for the development of the Cox-Maze procedure.

## THE COX-MAZE PROCEDURE

The Maze procedure was clinically introduced in 1987 by Dr. Cox after extensive animal investigation.<sup>16-18</sup> The Cox-Maze procedure was originally developed to interrupt any and all macro-reentrant circuits that were felt to cause AF, thereby precluding the ability of the atrium to flutter or fibrillate (Fig. 54-2). Unlike previous procedures, the Cox-Maze procedure successfully restored both AV synchrony and sinus rhythm, thus potentially reducing the risk of thromboembolism and stroke.<sup>19</sup> The operation consisted of creating an array of surgical incisions across both the right and left atria. These incisions were placed so that the SA node could still direct the propagation of the sinus impulse throughout both atria. It allowed for most of the atrial myocardium to be activated, resulting in preservation of atrial transport function in animals and in most patients.<sup>20</sup>

The first iteration of the Maze procedure was modified because of problems with late chronotropic incompetence

**FIGURE 54-2** By creating a myriad of surgical incisions in the atria, the Maze procedure was designed to prevent atrial fibrillation. AVN = atrioventricular node; LAA = left atrial appendage; PVs = pulmonary veins; RAA = right atrial appendage; SAN = sinoatrial node. (Reproduced with permission from Cox JL, Schuessler RB, D'Agostino HJ Jr, et al: The surgical treatment of atrial fibrillation. III. Development of a definitive surgical procedure, *J Thorac Cardiovasc Surg.* 1991 Apr;101(4):569-583.)

and a high incidence of pacemaker implantation. The resulting Maze II procedure, however, was technically difficult to perform, and was soon replaced by the Maze III procedure (Fig. 54-3).<sup>21,22</sup>

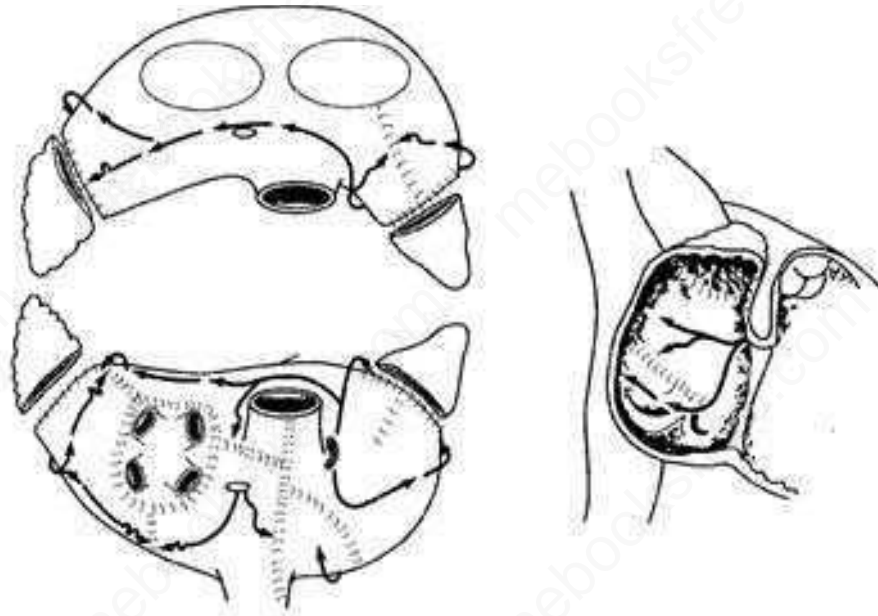

The Cox-Maze III procedure—often referred to as the “cut-and-sew” Maze—became the gold standard for the surgical treatment of AF. In a long-term study of patients who underwent the Cox-Maze III procedure at our institution, 97% of the patients at late follow-up were free of symptomatic AF.<sup>23</sup> These excellent results have been reproduced by other groups.<sup>24-26</sup>

Although the Cox-Maze III procedure was effective in eliminating AF, it was technically difficult and required a lengthy period of aortic cross-clamping. This limited adoption and only a handful of cardiac surgeons still perform the cut-and-sew operation.

Over the last 15 years, the field of AF surgery was revolutionized by the introduction of a variety of ablation devices that have been used to replicate the surgical incisions on the atrium. This has made AF ablation much simpler to perform. These ablation-assisted procedures have greatly expanded the field of AF surgery and have resulted in a much wider adoption.<sup>27</sup> With present ablation technology, surgery can be performed with low morbidity and mortality and often through less invasive approaches.

## SURGICAL ABLATION TECHNOLOGY

The development of surgical ablation technology has transformed a difficult and time-consuming operation that few surgeons were willing to perform into a procedure that is

**FIGURE 54-3** The lesions set of the traditional cut-and-sew Cox-Maze III procedure. (Reproduced with permission from Cox JL, Schuessler RB, D'Agostino HJ Jr, et al: The surgical treatment of atrial fibrillation. III. Development of a definitive surgical procedure, *J Thorac Cardiovasc Surg.* 1991 Apr;101(4):569-583.)

technically easier, shorter, and less invasive. Several ablation technologies exist, each with its relative advantages and disadvantages.

For an ablation technology to successfully replace surgical incisions, it must meet several criteria. First, it must reliably produce bidirectional conduction block across the line of ablation. This is the mechanism by which incisions prevent AF, by either blocking macro-reentrant or micro-reentrant circuits or isolating focal triggers. Our laboratory and others have shown that this requires a transmural lesion, as even small gaps in ablation lines can conduct both sinus and fibrillatory impulses.<sup>28-30</sup> Second, the ablation device must be safe. This requires a precise definition of dose-response curves to limit excessive or inadequate ablation, and potential injury to surrounding vital cardiac structures, such as the coronary sinus, coronary arteries, and valvular structures. Third, the ablation device should make AF surgery simpler and require less time to perform. This requires the device to create lesions rapidly, be simple to use, and have adequate length and flexibility. The following sections will briefly summarize the two current ablation technologies in clinical use: cryoablation and radiofrequency (RF) ablation.

## Cryoablation

Cryoablation technology is unique in that it destroys myocardial tissue by freezing rather than heating. It has the benefit of preserving the myocardial fibrous skeleton and collagen structure and is thus one of the safest energy sources available. These devices work by pumping a refrigerant to the electrode tip where it undergoes transformation from a liquid to a gas phase, and in so doing absorbs heat energy from the tissue in

contact with the tip. The formation of intracellular and extracellular ice crystals disrupts the cell membrane and causes cell death. There is also evidence that the induction of apoptosis plays a role in late lesion expansion. Lesion size depends on the temperature of the probe and thermal conductivity and temperature of the tissue.<sup>31</sup>

There are currently two commercially available sources of cryothermal energy that are being used in cardiac surgery. The older technology, based on nitrous oxide, is manufactured by AtriCure (Cincinnati, OH). More recently, devices using argon have been developed, and are currently distributed by Medtronic (Minneapolis, MN). At 1 atmosphere of pressure, nitrous oxide is capable of cooling tissue to  $-89.5^{\circ}\text{C}$ , whereas argon has a minimum temperature of  $-185.7^{\circ}\text{C}$ . The nitrous oxide technology has a well-defined efficacy and safety profile and is generally excellent except around the coronary arteries.<sup>32,33</sup> Experimental and clinical studies have shown intimal hyperplasia and coronary stenosis after cryoablation.<sup>33-35</sup> The potential disadvantage of cryoablation, however, is its relatively long time required to create lesions (1-3 minutes). There is also difficulty in creating lesions on the beating heart because of the "heat sink" of the circulating blood volume.<sup>36</sup> Furthermore, if blood is frozen during epicardial ablation on the beating heart, it may coagulate, creating a potential thromboembolic risk.

## Radiofrequency Energy

RF energy has been used for cardiac ablation for many years in the electrophysiology laboratory, and was one of the first energy sources to be applied in the operating room.<sup>37</sup> Resistive RF energy can be delivered by either unipolar or bipolar

electrodes, and the electrodes can be either dry or irrigated. With unipolar RF devices, the energy is dispersed between the electrode tip and an indifferent electrode, usually the grounding pad applied to the patient. In bipolar RF devices, alternating current is passed between two closely approximated electrodes. The lesion size depends on electrode-tissue contact area, the interface temperature, the current and voltage (power), and the duration of delivery. The depth of the lesion can be limited by char formation, epicardial fat, myocardial and endocavity blood flow, and tissue thickness.

There have been numerous unipolar RF devices developed for ablation. These include both dry and irrigated devices and devices that incorporate suction. Although dry unipolar RF has been shown to create transmural lesions on the arrested heart in animals with sufficiently long ablation times, it has not been consistently successful in humans. After 2-minute endocardial ablations during mitral valve surgery, only 20% of the *in vivo* lesions were transmural.<sup>38</sup> Epicardial ablation on the beating heart has been even more problematic. Animal studies have consistently shown that unipolar RF is incapable of creating epicardial transmural lesions on the beating heart.<sup>39,40</sup> Epicardial RF ablation in humans resulted in only 10% of the lesions being transmural.<sup>41</sup> This deficiency of unipolar RF ablation has been felt to be caused by the heat sink of the circulating blood.<sup>42</sup> This has led industry to examine adding both irrigation and suction to improve lesion formation. Although these additions have improved depth of penetration, there has been no unipolar RF device that has been shown by independent laboratories to be capable of creating reliable transmural lesions on the beating heart.

To overcome this problem, bipolar RF clamps were developed. With bipolar RF, the electrodes are embedded in the jaws of a clamp to focus the delivery of energy. By shielding the electrodes from the circulating blood pool, this improves and shortens lesion formation and limits collateral injury. Bipolar ablation has been shown to be capable of creating transmural lesions on the beating heart both in animals and humans with short ablation times.<sup>43-45</sup> Two companies (AtriCure, West Chester, OH and Medtronic, Minneapolis, MN) currently market bipolar RF devices.

Another advantage of bipolar RF energy over unipolar RF is its safety profile. A number of clinical complications of unipolar RF devices have been reported, including coronary artery injuries, cerebrovascular accidents, and esophageal perforation leading to atrioesophageal fistula.<sup>46-49</sup> Bipolar RF technology has virtually eliminated this collateral damage; there have been no injuries described with these devices despite extensive clinical use. The Cobra Fusion™ (AtriCure, West Chester, OH) is a new device that combines bipolar and unipolar RF into a single suction-assisted device. Early experimental results have shown consistency in creating transmural epicardial lesions on the beating heart.<sup>50</sup>

Other types of devices utilizing microwave, laser, and ultrasound energy have been used clinically, but limitations of each technology have led to limited use and withdrawal of these devices from the market.<sup>42,51-55</sup>

In summary, ablation technology has made significant progress over the past decade and has allowed for a broader application of surgical ablation. As new devices and techniques are developed, continued research investigating their effects on atrial hemodynamics, function, and electrophysiology is imperative.

## SURGICAL TECHNIQUES

There are three categories of procedures that presently are performed to surgically treat AF: the Cox-Maze procedure, left atrial lesion sets, and pulmonary vein isolation (PVI). Each of these approaches is described in the following sections.

### The Cox-Maze IV Procedure

The original “cut-and-sew” Cox-Maze III procedure is rarely performed today. At most centers, the surgical incisions have been replaced with lines of ablation using a variety of energy sources. At our institution, bipolar RF energy and cryoablation has been used successfully to replace most of the surgical incisions of the Cox-Maze III procedure. Our current RF ablation-assisted procedure, termed the Cox-Maze IV, incorporates the lesions of the Cox-Maze III (Fig. 54-4).<sup>56</sup> Our clinical results have shown that this modified procedure has significantly shortened operative time while maintaining the high success rate of the original Cox-Maze III procedure.<sup>57,58</sup>

The Cox-Maze IV procedure is performed on cardiopulmonary bypass with central or femoral cannulation. The operation can be done either through a median sternotomy or a less invasive (4-5 cm) right minithoracotomy. The right and left pulmonary veins (PVs) are bluntly dissected. If the patient is in AF, amiodarone is administered and the patient is electrically cardioverted. Pacing thresholds are obtained from each PV. Using a bipolar RF ablation device, the PVs are individually isolated by ablating a cuff of atrial tissue surrounding the right and left PVs. Proof of electrical isolation is confirmed after ablation by demonstrating exit block from each PV.

The right atrial lesion set is performed on the beating heart. A bipolar RF clamp is used to create most of the lesions (Fig. 54-5). A unipolar device, either cryoablation or RF energy, is used to complete the ablation lines endocardially down to the tricuspid annulus because of the difficulty of clamping in this area.

The remaining left-sided lesion set (Fig. 54-6) is performed on the arrested heart. First, the left atrial appendage is amputated and an ablation is performed through the amputated left atrial appendage into one of the left PVs. A standard left atriotomy is performed and extended inferiorly around the right inferior PV and superiorly onto the dome of the left atrium. Connecting lesions are made with the bipolar RF device into the left superior and inferior PVs and a final ablation is performed down toward the mitral annulus. Our group has shown that isolating the entire posterior left atrium with ablation lines into both left PVs resulted in a

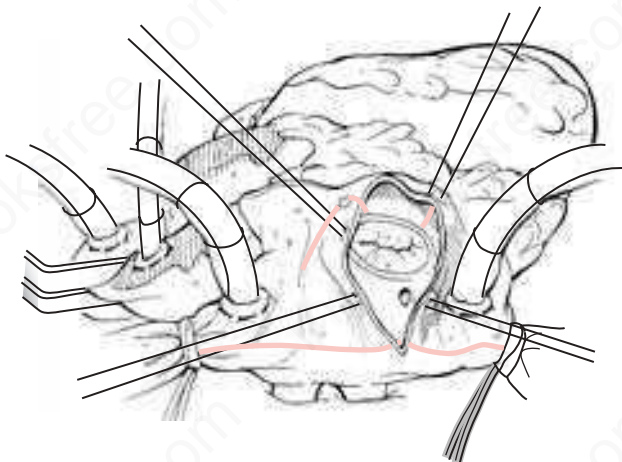

**FIGURE 54-4** The Cox-Maze IV lesion sets. IVC = inferior vena cava; SVC = superior vena cava. (Reproduced with permission from Cox JL, Schuessler RB, D'Agostino HJ Jr, et al: The surgical treatment of atrial fibrillation. III. Development of a definitive surgical procedure, *J Thorac Cardiovasc Surg.* 1991 Apr;101(4):569-583.)

better drug-free freedom from AF at 6 and 12 months than a single connecting lesion.<sup>59</sup> Unipolar cryoablation is used to connect the lesion to the mitral annulus and complete the left atrial isthmus line.

### Left Atrial Procedures

Over the past decade, there have been a number of new surgical procedures introduced in attempt to cure AF. The results have been variable and have had a wide range of success rates.<sup>55,60-67</sup> Various ablation technologies have been used to create a large number of different lesion patterns. All of

these procedures have generally involved some subset of the left atrial lesion set of the Cox-Maze procedure. Results have been dependent on the technology used, the lesion set, and the patient population. From a technical standpoint, all of the approaches have attempted to isolate the PVs. The importance of the rest of the left atrial Cox-Maze lesion set has also been generally established. However, Gillinov et al. published

**FIGURE 54-5** Illustration of the right atrial lesion set. White lines indicate bipolar RF ablation. Cryoablation is used to complete the ablation line at the tricuspid valve annulus.

**FIGURE 54-6** Illustration of the left atrial lesion set. White lines indicate RF bipolar ablation. Cryoablation is used to complete the ablation line at the mitral valve annulus.

a large series demonstrating that the omission of the left atrial isthmus lesion resulted in a significantly higher incidence of recurrent AF in patients with permanent AF.<sup>68</sup> To complete this lesion, it is mandatory to also ablate the coronary sinus in line with the endocardial lesion. In addition, our clinical results have shown that it is critically important to isolate the entire posterior left atrium and it is not enough just to isolate the PVs.<sup>59</sup>

## Pulmonary Vein Isolation

PVI is an attractive therapeutic strategy because the procedure can be done without cardiopulmonary bypass and with minimally invasive techniques, using either a thoracoscopic approach or small incisions. It can also be easily and quickly added to other cardiac surgery procedures (eg, coronary bypass graft or a valve procedure). Based on the original report of Hassaiguere, it has been well documented that the triggers for paroxysmal AF originate from the PVs in the majority of cases.<sup>69</sup> However, it is important to remember that up to 30% of triggers may originate outside the PVs.<sup>70</sup> In an attempt to increase efficacy, some investigators have added ablation of the ganglionic plexi (GP).<sup>71-73</sup>

The PVs can be isolated separately or as a box (Fig. 54-7). The most common approach for treatment of lone AF uses an endoscopic, port-based approach to minimize incision size and pain for the patient. At our center, bipolar RF clamps are favored to isolate the PVs, but unipolar RF, cryoablation, and HIFU devices have also been used.<sup>53,74,75</sup> Accumulating data suggest that a box isolation of the entire posterior left atrium is the more effective strategy.<sup>59,76</sup>

Patient preparation begins with double-lumen endotracheal intubation. A transesophageal echocardiogram is performed to confirm the absence of thrombus in the left atrial appendage. If a thrombus is found, the procedure is either aborted or converted to an open procedure, in which the risk of systemic thromboembolism from left atrial clot can be minimized. External defibrillator pads are placed on the patient and the patient is positioned with the right side turned upward 45 to 60° and the right arm positioned above the head to expose the right axilla.

**FIGURE 54-7** Diagram illustrating the methods to isolate the pulmonary veins, either separately (A), with a connecting lesion (B), or as a box isolation of the entire posterior left atrium (C).

An initial port for the thoracoscopic camera is placed at the sixth intercostal space. Under thoracoscopic vision, a small working port can then be placed in either the third or fourth intercostal space at the midaxillary line depending on surgeon preference and patient anatomy. The right phrenic nerve is identified to avoid injury to this structure. An incision is made in the pericardium, anterior and parallel to the phrenic nerve, to expose the heart from the superior vena cava to the diaphragm. Through this pericardiotomy, the space above and below the right PVs is dissected to allow enough room for insertion of a specialized thoracoscopic dissector. This includes opening into the oblique sinus and dissecting the space between the right superior PV and the right pulmonary artery. The dissector and a guiding sheath is introduced through a second port, either lateral or medial to the scope port, and guided into the space between the right superior PV and right pulmonary artery. After the dissector is carefully removed from the chest, the sheath remains in place as a guide for the insertion of the bipolar RF clamp. At this point, the patient is cardioverted into sinus rhythm so that pacing thresholds can be obtained. As with a Cox-Maze IV procedure, it is critical to document pacing thresholds from the PVs before isolation. Some surgeons also use the opportunity provided by surgical exposure to test and ablate ganglionated plexi but there are no data to support this and it is not performed at our institution.

The sheath is attached to the lower jaw of a bipolar RF clamp. The clamp is introduced into the chest, and the left atrium surrounding the PVs is clamped and ablated. After confirmation of exit block by pacing, the instruments are removed from the right chest and the right chest ports are closed.

The approach to the left chest is similar to the right. The patient is repositioned such that the left chest is elevated 45 to 60° and the left arm is held up to expose the left axilla. A port for the thoracoscopic camera is placed in the sixth intercostal space, slightly more posterior than on the right side. With thoracoscopic visualization, a left-sided working port is created in the third or fourth intercostal space. The left phrenic nerve is identified, and the pericardium is opened posterior to the course of the nerve. The ligament of Marshall is identified and divided. The dissector is then introduced through a second port, also in the sixth intercostal space. This port site is placed to allow for a straight-line introduction of the dissector around the PVs. The guiding sheath is used to position the RF clamp around the left PVs, and they are isolated. Again, conduction block is confirmed with pacing.

The procedure is not complete until the left atrial appendage has been addressed. Historically, this has been done by stapling across the base of the left atrial appendage with an endoscopic stapler. This requires careful surgical technique and attention because it can result in tears and bleeding.<sup>77</sup> Clip devices have been designed to address this difficulty, and they are used exclusively at our center because of their improved efficacy and safety when compared to staplers.<sup>78,79</sup> After ablation of the left PVs and exclusion of the left atrial appendage, the left side of the pericardium is closed.

## SURGICAL RESULTS

### The Cox-Maze Procedure

The Cox-Maze III procedure has had excellent long-term results. In our series at Washington University, 97% of 198 consecutive patients who underwent the procedure with a mean follow-up of 5.4 years were free from symptomatic AF. There was no difference in the cure rates between patients undergoing a stand-alone Cox-Maze procedure and those undergoing concomitant procedures.<sup>23</sup> Similar results have been obtained from other institutions around the world with the traditional “cut-and-sew” method.<sup>24,26,80</sup>

Our results from patients who underwent the Cox-Maze IV procedure have been encouraging as well. In a prospective, single-center trial from our institution, 91% of patients at the 6-month follow-up were free from AF.<sup>43,58</sup> The Cox-Maze IV procedure has significantly shortened the mean cross-clamp times for a lone Cox-Maze from  $93 \pm 34$  minutes for the Cox-Maze III to  $47 \pm 26$  minutes for the Cox-Maze IV ( $p < .001$ ), and from  $122 \pm 37$  minutes for a concomitant Cox-Maze III procedure to  $92 \pm 37$  minutes ( $p < .005$ ) in those undergoing the Cox-Maze IV procedure concomitantly with another cardiac operation.<sup>43</sup> A propensity analysis performed by our group has shown that there was no significant difference in the freedom from AF at 3, 6, or 12 months between the Cox-Maze III and IV groups.<sup>58</sup> A more recent prospective study in 100 consecutive patients who underwent the Cox-Maze IV procedure demonstrated postoperative freedom from AF at 93, 90, and 90% at 6, 12, and 24 months, respectively.<sup>81</sup> We also recently reported over two decades of experience at our institution with both the Cox-Maze III and Cox-Maze IV procedures. Freedom from AF was 93% and freedom from AF and AADs was 82% at a mean follow-up time of 3.6 years, while freedom from symptomatic AF was 85% at 10 years.<sup>82</sup>

The Cox-Maze IV procedure worked as well in patients with paroxysmal as for long-standing persistent AF. The 6-month freedom from AF was 91% in the paroxysmal group compared with 88% in the persistent group ( $p = .53$ ). The drug-free success rate was also similar.<sup>83</sup> Our present series consists of 532 consecutive patients undergoing a Cox-Maze IV between January 2002 and September 2014. All patients have been followed with ECGs or prolonged monitoring. Our 12-month freedom from AF was 92%, with 82% of patients also off all antiarrhythmic drugs, while our 5-year freedom from AF was 77%, with 64% of patients also off all antiarrhythmic drugs (unpublished data).

The Cox-Maze procedure has also been very successful in reducing the incidence of stroke. In patients undergoing the Cox-Maze procedure, the preoperative incidence of neurological events has been high due to inherent risk in patients with AF. In a report from our institution, 57 out of 389 patients (14%) had experienced a neurological event before surgery. Despite this, there were only six neurological events during long-term follow-up (mean,  $6.6 \pm 5.0$  years) in this cohort. The long-term stroke rate after the Cox-Maze procedure has been 0.2% per year despite the fact that the great majority of patients were able to discontinue anticoagulation.<sup>84</sup>

The Cox-Maze procedure is being increasingly used as a concomitant procedure.<sup>27</sup> Previous studies from our institution and others have documented high rates of restoration of sinus rhythm without increasing morbidity following concomitant procedures including coronary artery bypass, mitral valve surgery, and tricuspid valve surgery.<sup>85-91</sup> Surgical ablation should be considered in all patients with AF undergoing concomitant cardiac procedures, and a biatrial Cox-Maze IV lesion set is recommended in most cases. A recent study from Dr. Ad and his colleagues have shown that adding a Cox-Maze procedure to either aortic valve replacement or coronary artery bypass grafting did not increase operative morbidity or mortality.<sup>92</sup>

In an effort to decrease operative morbidity, a minimally invasive Cox-Maze IV lesion set has been introduced through a right minithoracotomy.<sup>93,94</sup> In both the stand-alone Cox-Maze IV and concomitant population, this approach has been shown to be equally effective at restoring sinus rhythm while significantly decreasing major complications, operative mortality, intensive care unit length of stay, and hospital length of stay when compared to sternotomy approach.<sup>95</sup>

### Left Atrial Lesion Sets

A number of centers around the world have suggested performing ablation confined to the left atrium only to cure AF. This concept is supported by the fact that the majority of paroxysmal AF appears to originate around the PVs and the posterior left atrium. A left atrial lesion set typically involves PVI with a lesion to the mitral annulus as well as removal of the left atrial appendage. One advantage of avoiding right atrial lesions is a potentially lower rate of postoperative pacemaker implantation.<sup>96</sup> Many ablation technologies have been used to create these lesion sets with varied degrees of success.<sup>48,60-67</sup>

There have been no randomized trials of biatrial versus left atrial ablation only in the surgical population. Because of this, the importance of the right atrial lesions of the traditional Cox-Maze procedure is difficult to precisely determine. A meta-analysis of the published literature by Barnett and Ad revealed that a biatrial lesion set resulted in a significantly higher late freedom from AF when compared with a left atrial lesion set alone (87 vs 73%,  $p = .05$ ).<sup>97</sup> This is not surprising considering the results of intraoperative mapping of patients with AF. Both our group and others have shown that AF can originate from the right atrium in 10 to 30% of cases.<sup>97-100</sup>

Of the specific left atrial lesions of the Cox-Maze procedure, it is difficult to determine the precise importance of each ablation line. All surgeons agree on the importance of isolating the PVs. As stated previously, work from Gillinov et al has shown the importance of the left atrial isthmus in a retrospective study.<sup>68</sup> Moreover, omitting the lesion to the mitral annulus leaves the patient at risk for the development of late left atrial flutter. In a rare randomized trial, Gaita and coauthors examined PVI alone versus two alternate lesion sets that both included ablation of the left atrial isthmus. In this study, normal sinus rhythm at 2-year follow-up was only seen in 20% in the PVI group versus 57% in the other groups ( $p < .006$ ).<sup>65</sup>

Finally, our group has shown that isolating the entire posterior left atrium significantly improved our drug-free freedom from AF at 6 months (54 vs 79%,  $p = .011$ ) in a retrospective analysis of our results.<sup>59</sup> Thus, it is our opinion that most of the left atrial Cox-Maze lesion set is needed to ensure a high success rate.

### Pulmonary Vein Isolation

The results of PVI alone have been variable and have been dependent on patient selection and the energy source utilized. In the first report of surgical PVI, Wolf and colleagues reported that 91% of patients undergoing a video-assisted bilateral PVI and left atrial appendage exclusion were free from AF at three months follow-up.<sup>101</sup> However, this was a small study with very limited follow-up. Edgerton et al reported on 57 patients undergoing PVI with GP ablation with more thorough follow-up and found 82% of their patients with paroxysmal AF to be free from AF at 6 months, with 74% off antiarrhythmic drugs.<sup>102</sup>

Subsequent studies have shown encouraging results in patients with paroxysmal AF. In a study involving 21 patients with paroxysmal AF undergoing PVI with GP ablation, McClelland et al reported 88% freedom from AF at 1 year without antiarrhythmic drugs.<sup>72</sup> A larger, single-center trial recently reported a 65% single-procedure success at 1 year in a series of 45 patients undergoing PVI with GP ablation, including patients with persistent and paroxysmal AF.<sup>103</sup> A multicenter trial reported 87% normal sinus rhythm rate in a more diverse patient population, including some patients with long-standing persistent AF; however, those patients with long-standing persistent AF only had a 71% incidence of normal sinus rhythm.<sup>104</sup> The FAST trial, a more recent multicenter randomized trial, compared 63 patients who received linear antral PVI by way of catheter ablation and 61 patients who received bipolar RF PVI and ganglionated plexi ablation. Most patients in both groups had paroxysmal AF. At 1 year, freedom from left atrial arrhythmias >30 seconds evaluated by a 7-day Holter without antiarrhythmic drugs was 66% for surgical ablation versus 37% for catheter ablation ( $p = .002$ ).<sup>105</sup>

In patients with long-standing or persistent AF, the results have been worse. In a study from Edgerton and his group, only 35% of patients were free from AF and antiarrhythmic drugs at 6 months follow-up.<sup>106</sup> Long-term data for PVI with ganglion plexus ablation are equally disappointing. One group reported 139 patients with up to 5 years of follow-up: freedom from AF and antiarrhythmic drugs was 52, 28, and 29% for paroxysmal, persistent, and long-standing persistent AF.<sup>107</sup> With concomitant procedures, the success rate of PVI is also low. Of 23 patients undergoing mitral valve surgery or coronary revascularization with concomitant PVI, only half of patients were free from AF at a follow-up of  $57 \pm 37$  months.<sup>108</sup> In the setting of mitral valve disease, Tada and colleagues report only 17% freedom from AF and antiarrhythmic drugs in their series of 66 patients undergoing PVI.<sup>109</sup> In patients undergoing aortic valve replacement and

PVI, freedom from AF and antiarrhythmic drugs was only 50% at two years at our institution.<sup>110</sup>

### INDICATIONS FOR SURGICAL ABLATION

The indications for surgery have been defined in a recent consensus statement.<sup>111</sup> These presently include (1) All symptomatic patients with documented atrial fibrillation undergoing other cardiac surgical procedures; (2) selected asymptomatic patients with atrial fibrillation undergoing cardiac surgery in which the ablation can be performed with minimal risk in experienced centers; and (3) stand-alone atrial fibrillation ablation should be considered for symptomatic patients with atrial fibrillation who either prefer a surgical approach, have failed one or more attempts at catheter ablation, or are not candidates for catheter ablation.

There is still controversy regarding the referral of patients for surgery with medically refractory, symptomatic AF in lieu of catheter ablation. In these instances, clinical decisions should be made based on the individual institution's experience with catheter and surgical ablation, the relative outcomes and risks of each in the individual patient, and patient preference. Programs involved in the surgical treatment of AF should develop a team approach to these patients, including both electrophysiologists and surgeons, to ensure appropriate selection of patients.

There are relative indications for surgery that were not included in the consensus statement. The first is a contraindication to long-term anticoagulation in patients with persistent AF and a high risk for stroke (CHADS score  $\geq 2$ ). Up to one-third of patients with AF screened for participation in clinical trials of warfarin were deemed ineligible for chronic anticoagulation, mainly because of a high perceived risk for bleeding complications.<sup>112-114</sup> In one study, the annual rate of intracranial hemorrhage in anticoagulated patients with AF was 0.9% per year, and the overall major bleeding complication rate was 2.3% per year.<sup>114</sup> The stroke rate following the Cox-Maze procedure off anticoagulation has been remarkably low, even in high-risk patients. At our institution, only 5 of 450 patients had a stroke after a mean follow-up of  $6.9 \pm 5.1$  years. There was no difference in stroke rate in those patients with CHADS scores above or below 2.<sup>115</sup> This low risk of stroke after the Cox-Maze procedure has been noted in other series.<sup>19,116,117</sup> The decrease in stroke risk is likely due to the high cure rate, as well as the obliteration of the left atrial appendage. Surgical treatment for AF with amputation of the left atrial appendage also should be considered in patients with chronic AF who have suffered a cerebrovascular accident despite adequate anticoagulation, as these patients are at high risk for repeat neurologic events.

### HYBRID ABLATIONS

Although the Cox-Maze procedure achieves high rates of success and recent technological advances have made it easier to perform through less invasive incisions, it still requires

cardiopulmonary bypass. Several groups have started performing epicardial ablations with the aid of suction based RF and cryoablation probes, which can be placed through thoracoscopic ports. However, these probes do not achieve the same degree of transmural ablation achieved with bipolar probes.<sup>118</sup> This led to the idea of combining both endocardial ablation via transcatheter techniques and epicardial ablation via surgical techniques in a “hybrid” approach.

Though specific lesion sets and approaches vary greatly from institution to institution, early results are promising.<sup>119,120</sup> In one study, 78 consecutive patients underwent thoracoscopic hybrid ablation and 74% were free of AF off antiarrhythmic drugs without further ablations at 24 months follow-up.<sup>121</sup> Another group utilized a similar lesion set via a pericardioscopic hybrid approach in 101 consecutive patients, and demonstrated a freedom from AF in 66% at one year.<sup>122</sup> However, with increasing data on these newer procedures, important safety concerns including high rates of conversion to sternotomy and reoperation for bleeding have been reported.<sup>123</sup>

Though new minimally invasive and hybrid techniques have yet to be standardized, they hold promise and require continued clinical investigation to determine their precise role.

## FUTURE DIRECTIONS IN AF SURGERY

The ideal surgical procedure for AF would be a minimally invasive operation that does not require cardiopulmonary bypass. Such a procedure should preserve normal atrial physiology, have minimal morbidity, and have a high success rate. Achieving this goal will require progress in understanding the mechanism of AF in individual patients, and tailoring of treatment approaches. The surgical approach may need to be redesigned based on a better understanding of the mechanisms and the effects of surgical ablation on atrial electrophysiology.

It is now known that there are multiple different possible mechanisms of AF. Multipoint mapping is necessary to describe this complex arrhythmia.<sup>98,100,101,124,125</sup> Epicardial activation sequence mapping has been the traditional gold standard for mapping of AF, but is both invasive and time consuming, limiting its clinical use.<sup>18</sup> A newer non-invasive technique, electrocardiographic imaging (ECGI), offers a potentially useful way to describe the atrial activation sequence and determine mechanistic information from conscious patients.<sup>126</sup> The technique uses body surface potentials, measured by surface electrodes, and anatomical data obtained through computed tomographic scanning to indirectly calculate the surface potentials on the surface of the heart. This technique has been shown to work well for normal sinus rhythm and atrial flutter as well as ventricular arrhythmias.<sup>127-130</sup> This modality has also been tested in a variety of patient populations including patients with heart failure undergoing biventricular pacing therapy or heart transplant,<sup>131</sup> patients with different substrates of AF,<sup>132</sup> and patients undergoing open-heart surgery.<sup>133</sup> In one particular study, 26 patients with AF underwent ECGI. AF complexity (including number of wavelets, focal sites, and rotor activity)

increased with longer clinical history of AF, although the degree of complexity of nonparoxysmal AF varied widely. This highlights the coexistence of a variety of mechanisms and variable complexity among patients, which could be targeted by patient-specific ablation approaches.<sup>132</sup> Currently our group is testing the technique in patients with AF and mitral valve disease, with a goal of further identifying the mechanisms of AF in this population.

The information acquired from ECGI can be analyzed to determine activation sequence and frequency maps for individual patients noninvasively. Using these data, a strategy for designing patient-specific optimal lesion sets is being developed, taking into account the patient's atrial geometry, conduction velocity, and refractory period.<sup>132,134</sup> Previous work has demonstrated that a critical mass is necessary to maintain AF, and initial lesions could be determined by a calculation of the critical area needed to maintain AF in the individual patient.<sup>135</sup> This could be done using mechanistic information derived from activation data and anatomical data from a CT scan. It will also allow identification of focal sources that can then be either isolated or ablated in the electrophysiologic laboratory or operating room.

In instances in which a specific mechanism of AF cannot be defined, the goal will be to create a lesion pattern that will make the atria unable to fibrillate. Failures of the Cox-Maze III and IV procedures have been seen in patients with increasing left atrial size or long-standing AF.<sup>116,135,136</sup> A study performed by our laboratory on a canine model found that the probability of maintaining AF is correlated with increasing atrial tissue areas, widths, and weights, as well as the length of the effective refractory period and the conduction velocity of the tissue.<sup>134</sup> All of these data can be acquired noninvasively through magnetic resonance imaging scans and ECGI. Using these data may allow surgeons to design custom operations for each patient based on the mechanism of their arrhythmia and their specific atrial anatomy or electrophysiology.

Finally, the limitations of present ablation devices have impeded the development of a truly minimally invasive procedure. Unfortunately, the creation of reliable transmural lines of ablation on the beating heart has been difficult. This has been because of the heat sink of the circulating endocardial blood pool.<sup>42</sup> Future advances may be anticipated with devices that overcome this limitation, but the introduction of hybrid procedures in which surgeons and electrophysiologists work together to complete lines of block with avoiding cardiopulmonary bypass may also circumvent this issue and have shown early promise.

In conclusion, the development of ablation technologies has dramatically changed the field of AF surgery. The replacement of the surgical incisions with linear lines of ablation has transformed a complex, technically demanding procedure into one accessible to the majority of surgeons. More importantly, these new ablation technologies have introduced minimally invasive surgery for AF, prompting efforts to develop simpler procedures that can be performed epicardially on the beating heart. However, surgeons must remember that the

Cox-Maze procedure has excellent efficacy in these patients and can be performed using a small thoracotomy with low morbidity.<sup>95</sup> It is imperative for surgeons trying new procedures to carefully follow their results and publish them in peer-reviewed journals. For surgeons performing AF ablation, it is mandatory to adhere to the recently published guidelines for follow-up of patients and for determining success or failure after these procedures.<sup>111</sup> As we learn more about the mechanisms of AF and develop improved preoperative diagnostic technologies capable of precisely identifying mechanisms, it may become possible to tailor specific lesion sets and ablation modalities to individual patients, making the surgical treatment of AF more effective and available to an even larger population of patients.

# Surgical Implantation of Pacemakers and Automatic Defibrillators

Henry M. Spotnitz • Michelle D. Spotnitz

Pacemaker and defibrillator management is the subject of comprehensive reviews.<sup>1-8</sup> The efficacy and cost-effectiveness of pacemakers are widely accepted, but the appropriate role for ICD insertion<sup>7</sup> and biventricular pacing<sup>5</sup> in older patients is still in evolution. Pacemaker and ICD technology are now applicable across the entire span of human age. Pacing for heart failure and ICD prophylaxis against lethal arrhythmias are recent frontiers. Electrophysiologists dominate these areas, reflecting decreased interest by thoracic surgeons and cardiology referral patterns. However, thoracic surgeons must maintain skills as implanters in order to serve as consultants or surgeons for complex or complicated cases. This chapter reviews practical information related to pacemaker and ICD insertion and management.

A permanent pacemaker or ICD consists of leads and a generator.<sup>2</sup> The generator consists of a battery, a telemetry antenna, and integrated circuits. ICDs also include capacitors that store energy for high-output shocks. The power source is generally lithium iodide, but rechargeable and nuclear batteries have been used. The integrated circuits include programmable microprocessors, oscillators, amplifiers, and sensing circuits.<sup>2</sup> The integrated circuits employ complementary metal-oxide semiconductor (CMOS) technology, which is subject to damage by ionizing radiation. Current pacemakers and ICDs monitor and report the status of internal components, external connections, programmed settings, recent activity, and notable arrhythmias. Unfortunately, each programmer controls only the devices of its manufacturer.<sup>4</sup> Pacing systems compatible with magnetic resonance imaging (MRI)<sup>2</sup> and wireless ICDs and pacemakers are now available, and wireless telemetry is available for remote follow-up.<sup>4</sup>

## PACEMAKERS FOR CONTROL OF BRADYCARDIA

### History

Early cardiac surgery was complicated by lethal iatrogenic heart block. Transthoracic pacing with Zoll cutaneous electrodes provided an early solution. Percutaneous

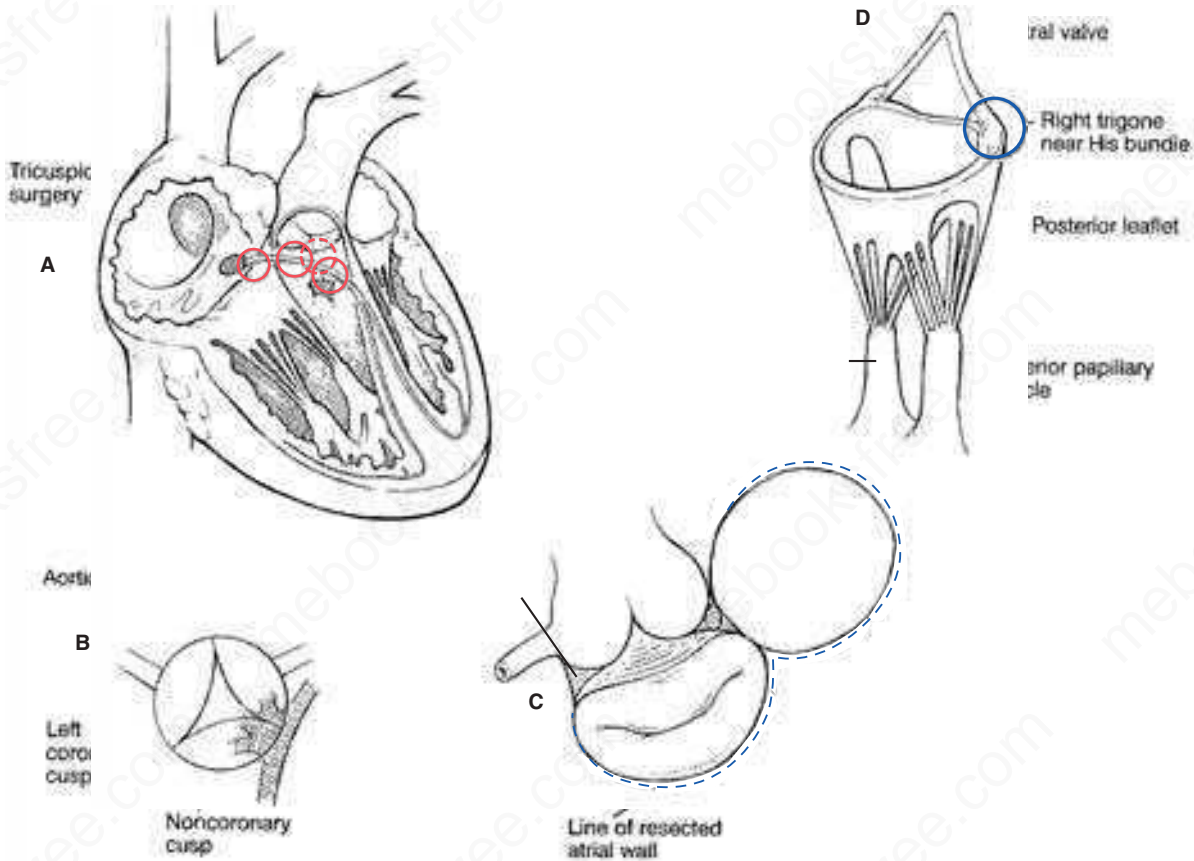

endocardial pacing (1959) and “permanent” pacemakers using epicardial electrodes (1960) followed.<sup>9</sup> Ensuing advances in bioengineering and technology have dramatically improved the quality of life for recipients. Persistent problems include lead durability, inflammatory responses to pacemaker materials, infection, device size, programmer compatibility, battery life, periodic battery replacement, and expense. *Cardiac resynchronization therapy* (CRT) for heart failure has made coronary sinus (CS) lead insertion an important technical skill.

### Anatomy of Surgical Heart Block

The conduction system is vulnerable to injury during heart surgery. Complete heart block can result from suture placement during aortic, mitral, or tricuspid valve surgery, septal defect closure, or from myotomy for idiopathic hypertrophic subaortic stenosis. These lesions are mapped in Fig. 55-1. Infarction/abscess of the conduction system, inadequate myocardial protection, or trauma from retraction can also result in surgical heart block.

### International Pacemaker Code

A three-letter code describes the principal pacemaker functions (Table 55-1).<sup>10</sup> The first letter is the chamber paced, the second the chamber sensed, and the third the algorithm integrating pacing and sensing functions. Fixed-rate ventricular and atrial pacemakers are VOO and AOO, respectively. Demand (rate-inhibited) pacers for the same chambers are VVI and AAI. VDD pacemakers pace only the ventricle but sense both atrium and ventricle. DVI indicates atrial and ventricular pacing, but only ventricular sensing. DDD is the most flexible of current designs. The suffix R after the three-letter code indicates rate responsiveness. Pacemakers capable of biventricular pacing or CRT are referred to as *CRT-P*. Biventricular pacemaker-defibrillators are called *CRT-D*.<sup>8</sup>

**FIGURE 55-1** Anatomy of iatrogenic complete heart block. (A) His bundle and cardiac structures. Sites of injury are circled. (B) His bundle in the ventricular septum, below the noncoronary-right coronary aortic commissure. (C, D) During mitral surgery, the His bundle is on the ventricular septum anteromedial to the posterior commissure and right fibrous trigone. VSD = ventricular septal defect.

### Cellular Electrophysiology

Cell membrane depolarization and repolarization provide automaticity of the cardiac chambers and conduction system. The outside of the resting myocardial cell is positive, and the interior is negative. Unipolar pacing threshold is lowest when the negative terminal (cathode) of a pacemaker

is connected to the heart and the positive terminal (anode) is connected to ground. Electrogram amplitude is unaffected by polarity.<sup>2</sup>

### Rhythm Disorders

#### INDICATIONS FOR PACEMAKER INSERTION

Pacemaker insertion guidelines (Table 55-2) are periodically updated. In 2008, an American College of Cardiology/American Heart Association/North American Society for Pacing and Electrophysiology (ACC/AHA/NASPE) task force revised recommendations for pacemaker and ICD insertion, further updated in 2013.<sup>11</sup> Any practitioner who implants arrhythmia control devices should be familiar with these guidelines. Documentation is required for billing and can be an important medical-legal issue.

Indication categories are “accepted (Class I),” “controversial (Class II),” or “not warranted (Class III).” Evidence from large randomized clinical trials is designated level A, from less stringent trials or registries, level B, and from consensus, level C. Profound sinus bradycardia or symptomatic second- or

**TABLE 55-1: International Pacemaker Code**

I Chamber paced	II Chamber sensed	III Pacing algorithm
A	A	T
V	V	I
D	D	D
O	O	O
S	S	—

A, atrium; D, dual (both triggered and inhibited); I, inhibited; O, none; S, single; T, triggered; V, ventricle.

**TABLE 55-2: Medicare Guidelines for Cardiac Pacemaker Implantation (pre-2002)**

**Accepted, in symptomatic patients with chronic conditions**

- Atrioventricular block
  - Complete (third-degree)
  - Incomplete (second-degree)
    - Mobitz I
    - Mobitz II
  - Incomplete with 2:1 or 3:1 block
- Sinus node dysfunction (symptomatic)
  - Sinus bradycardia, sinoatrial block, sinus arrest
  - Bradycardia-tachycardia syndrome

**Controversial**

- In symptomatic patients
  - Bifascicular/trifascicular intraventricular block
  - Hypersensitive carotid sinus syndrome
- In asymptomatic patients
  - Third-degree block
  - Mobitz II
  - Mobitz II atrioventricular block following myocardial infarction
  - Congenital atrioventricular block
  - Sinus bradycardia < 40 bpm with long-term necessary drug therapy
  - Overdrive pacing for ventricular tachycardia

**Not warranted**

- Syncope of undetermined cause
- In asymptomatic patients
  - Sinus bradycardia, sinoatrial block, or sinus arrest
  - Bundle-branch blocks
  - Mobitz I

Data from Epstein AE, DiMarco JP, Ellenbogen KA, et al: ACC/AHA/HRS 2008 Guidelines for Device-Based Therapy of Cardiac Rhythm Abnormalities: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the ACC/AHA/NASPE 2002 Guideline Update for Implantation of Cardiac Pacemakers and Antiarrhythmia Devices): developed in collaboration with the American Association for Thoracic Surgery and Society of Thoracic Surgeons, *Circulation*. 2008 May 27;117(21):e350-e408.

third-degree heart block indicates pacemaker insertion. Sinus bradycardia justifies pacemaker insertion if simultaneous symptoms are documented by Holter or other means. Pacemakers may be appropriate for bradycardia less than 40 bpm if long-term drug therapy is necessary for supraventricular arrhythmias, ventricular tachycardia (VT), hypertension, or angina. Although new indications for arrhythmia control devices may be supported by clinical research, certification of advances by the Food and Drug Administration, insurance carriers, and regulatory agencies is often slow. Electrophysiology (EP) studies help define proper treatment.<sup>3,11</sup>

**ATRIOVENTRICULAR BLOCK**

First-degree block is prolongation of the P-R interval beyond 200 ms. First-degree block at a low atrial rate may

progress to Wenckebach as the atrial rate increases. Second-degree block is incomplete dissociation of the atrial and ventricular rates, either with increasing P-R intervals and dropped beats (Wenckebach and Mobitz I, usually atrioventricular (AV) nodal block), or frequently dropped beats without progression of the P-R interval (Mobitz II, usually in the His-Purkinje system).<sup>3</sup> Third-degree block is complete AV dissociation, the atrial rate usually exceeding the ventricular rate. Left and right bundle-branch blocks and left anterior and posterior hemiblocks are partial conduction system blocks detected by electrocardiogram (ECG). Etiologies of AV block include ischemic injury, idiopathic fibrosis, cardiomyopathy, iatrogenic injury, AV node ablation, Lyme disease, abscess in bacterial endocarditis, and congenital lesions related to maternal lupus erythematosus and other autoimmune diseases.<sup>3</sup>

**SINUS NODE DYSFUNCTION**

Sinus node dysfunction is an intrinsic disease that can be accentuated by drugs required for ancillary conditions. The role for pacing depends on symptoms. Sinus node dysfunction is caused by coronary artery disease, cardiomyopathy, and reflex abnormalities.<sup>3</sup>

Reflex problems include carotid sinus hypersensitivity, vasovagal syncope, and oddities including micturition-induced and deglutition syncope. Cardioinhibitory (asystole >3 seconds) and vasodepressor (marked fall in blood pressure despite adequate heart rate) components of reflex-mediated syncope are recognized. Medical therapy is favored for vasodepressor syncope. Tilt table testing provides objective data.<sup>3,12,13</sup> Decisions on pacemaker insertion are based on symptoms and the duration of asystole. Pacemaker insertion is recommended for asystolic intervals greater than 3 seconds. Dual-chamber pacing (DDD or VDD) is favored for these patients, because AV synchrony increases stroke volume and decreases symptoms.<sup>3,14</sup>

**Features of Permanent Pacing**

**DUAL-CHAMBER PACING AND ATRIOVENTRICULAR SYNCHRONY**

In the normal heart, stroke volume is increased 5 to 15% by AV synchrony versus asynchrony.<sup>8,14</sup> Left ventricular hypertrophy, decreased diastolic compliance, and heart failure increase the quantitative importance of AV synchrony.<sup>8,14</sup> Pacing of the right ventricular apex disrupts the normal sequence of activation because depolarization spreads more slowly over the ventricular myocardium than through the conduction system.<sup>8,14</sup>

Recent experience emphasizes clinical relevance of the sequence of activation. Right ventricular outflow tract pacing may improve stroke volume versus apical pacing because of favorable effects on the activation sequence.<sup>15</sup> Disruption of activation sequence by DDD pacing reduces the ventricular-aortic gradient in some patients with idiopathic

hypertrophic subaortic stenosis.<sup>16,17</sup> Biventricular (right ventricle [RV] apex and CS) pacing in patients with advanced cardiomyopathy and an intraventricular conduction defect improves left ventricular function by restoring simultaneous contraction of the septum and free wall, also known as cardiac resynchronization therapy (CRT).<sup>5,18</sup> Single-site, epicardial left ventricular pacing may provide similar benefits.<sup>18</sup> For temporary pacing in postoperative heart block, biventricular pacing is superior to right ventricular pacing<sup>18</sup> and may be useful for left ventricular dysfunction after cardiac surgery. Clinical trials suggest that biventricular pacing is superior to standard pacing for heart block.<sup>8</sup>

### DUAL-CHAMBER PACING ALGORITHM

DDD pacemaker programming includes a lower rate, an upper rate, and AV delay. When the intrinsic atrial rate is between the upper and lower rate limits, the pacemaker tracks the atrium to maintain a 1:1 response between the right atrium and right ventricle. If the atrial rate falls to or below the lower rate limit, the atrium is paced at the lower rate limit. If the atrial rate exceeds the upper rate limit, the ventricle is paced at the upper rate limit with loss of AV synchrony, resembling a Wenckebach effect. If the patient develops atrial fibrillation, mode switching converts the pacing algorithm to VVI or VVI(R) at the lower rate limit.

Programmable AV delay defines the interval allowed between atrial and ventricular depolarization. Timing starts with the atrial electrogram or pacing stimulus and continues until the AV delay elapses. If no ventricular depolarization is detected during the delay, the ventricle is paced. *Atrial latency*, a varying delay between the atrial pacing artifact and the P wave, requires different AV delays for atrial sensing versus pacing.<sup>4</sup>

### RATE RESPONSE TO INCREASED METABOLIC DEMAND

During high metabolic demand, cardiac output is augmented by increased ventricular contractility, venous return, and heart rate. In patients with heart block and a normal sinus exercise response, dual-chamber pacing maintains both AV synchrony and a physiologic rate response.<sup>8</sup> However, sinus node incompetence (no atrial rate increase with exercise) or single-chamber ventricular (VVI) pacemakers require alternate mechanisms for rate response. The letter R after the three-letter pacemaker code indicates rate responsive capability. If a sensor detects increased metabolic demand, the lower rate of the pacemaker increases within a programmable range. Body vibration or respiratory rate<sup>8,19,20</sup> is commonly employed to estimate demand. Other indicators are body temperature, venous oxygen saturation, QT interval, right ventricular systolic pressure, and right ventricular stroke volume. All such indicators can aberrantly increase heart rate, for example, during a bumpy car ride. Patients with sedentary life styles do not benefit from rate-responsive pacing. Adverse results of fast heart rates can include angina or infarction in patients with coronary disease.

### CHOICE OF PACING TECHNIQUE

Dual-chamber pacing has become the standard of care, except in chronic atrial fibrillation. Sinus rhythm appears to be better maintained by atrial than ventricular pacing, and paroxysmal atrial fibrillation, previously problematic for DDD pacemakers, is now well handled by mode switching. Advantages of dual-chamber pacing in reflex-mediated syncope with cardioinhibitory features have also been reported. Dual-chamber pacing may not be warranted in elderly patients, except when pacemaker syndrome, hypertension, or congestive heart failure is present. VVI or VVIR pacing is appropriate for patients with bradycardia and chronic atrial fibrillation. AAIR is useful for cardiac allograft recipients with sinus arrest or sinus bradycardia. Biventricular pacing using an endocardial CS lead is recommended for symptomatic heart failure.<sup>8</sup>

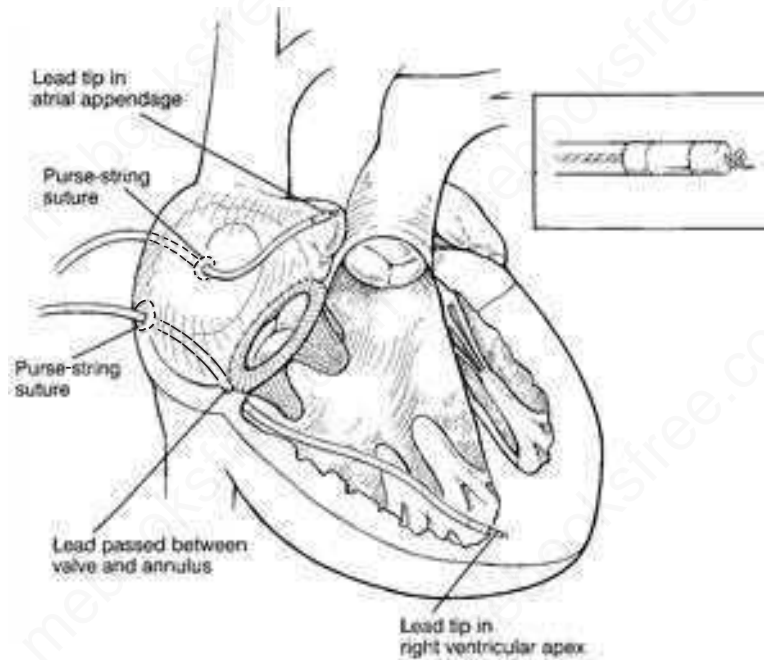

## Pacemaker Technology

### EPICARDIAL VERSUS ENDOCARDIAL LEADS

Epicardial leads are generally inferior to endocardial leads in electrical characteristics and are prone to conductor fractures.<sup>2</sup> Steroid-eluting tips and small contact surfaces have improved epicardial leads. Epicardial pacing is more difficult at reoperative cardiac surgery, where epicardial fibrosis elevates pacing thresholds. Infected epicardial leads must be removed by thoracotomy. The epicardial approach is preferred in patients with congenital septal defects, single ventricle physiology, mechanical tricuspid valves, or venous thrombosis/occlusion.<sup>21</sup> During thoracotomy, insertion of endocardial leads through an atrial pursestring is a useful option.<sup>22</sup> Epicardial left ventricular pacing by the minimal access approach is increasing in importance, driven by a 5 to 10% technical failure rate for CS lead insertion. Approaches to DDD pacing during open-heart surgery are illustrated in Fig. 55-2. Fixed-screw, positive fixation leads are introduced via atrial pursestrings and fixed into position by axial rotation. When a tricuspid prosthesis or ring is to be inserted, a ventricular lead can be passed between the sutures securing the ring or the valve.

### UNIPOLAR VERSUS BIPOLAR

Bipolar leads incorporate two insulated conductors. In unipolar systems, the patient's body is the second (anodal) conductor; a single conductor in the lead carries the negative current to the heart. Bipolar leads reduce electrical noise (oversensing) and adventitious pacing of the diaphragm or chest wall. These advantages are offset by increased engineering complexity. Bipolar leads historically were prone to breakdown of insulation or conductor fracture. This would compromise sensing, pacing, or both (Fig. 55-3). Recent bipolar leads are much improved and similar in dimensions and handling to unipolar leads (Figs. 55-4 and 55-5).<sup>2</sup> Technical failures of some new technology pacemaker and ICD leads emphasize the importance of advanced lead extraction.<sup>6</sup>

**FIGURE 55-2** Endocardial pacing from epicardial approach. Atrial pursestrings provide access; leads are advanced and screwed into position guided by manual palpation. The ventricular lead is passed between the valve prosthesis and the annulus. The inset shows the tip of the endocardial screw-in lead. The coronary sinus os is also accessible.

**FIGURE 55-3** Telemetry from a patient with third-degree block, poor escape rhythm, a bipolar VVI pacemaker, and dizzy spells. Programming to VOO mode eliminated the pauses. The patient was discharged after lead replacement. This illustrates a life-threatening effect of oversensing. This older model pacemaker was not capable of monitoring electrograms to confirm the diagnosis.

**FIGURE 55-4** Positive fixation lead in x-rays demonstrating effects of growth on an intracardiac lead loop from age 1 (*left*) to age 5 (*center*) to age 14 (*right*) years.

**FIGURE 55-5** (A) Bipolar tined ventricular pacing lead with steroid-eluting tip. (B) Similar to (A), with J shape for atrial pacing. (C) Bisping bipolar ventricular pacing lead with retractable, screw-in tip. (D) Bipolar (*left*) and unipolar (*right*) pacing leads with fixed-screw tips. A soluble tip coating dissolves in blood and reduces snagging during insertion. These leads can be used in the atrium or ventricle. The unipolar lead was used by the author for atrial and ventricular pacing. (E) Single-pass lead for VDD pacing. (F) Current leads demonstrating progress in reduction of bipolar lead diameter. (G) Fixed-screw bipolar 7-French lead with steroid-eluting white collar at lead tip. ## LEAD FIXATION

We prefer endocardial positive fixation leads, particularly in chambers with sparse trabeculation. A small wire spiral or screw holds these leads in place (Fig. 55-5G). In designs with fixed, extended screws, a soluble coating over the tip promotes venous passage. In retractable screw designs (Bisping), extension/retraction is accomplished by rotation of the pin at the lead tip. Axial clockwise rotation of screw-in leads during fixation provides tactile feedback on the firmness and security of attachment. Lead impedance provides feedback on the adequacy of tip extension and fixation.

Tined leads use miniature anchors to secure the lead tip within myocardial trabeculae (Fig. 55-5A). Tines require larger introducers than screw-in leads and are not secure in smooth-walled or dilated chambers. Nevertheless, some physicians prefer these leads.<sup>2</sup>

## Temporary Pacing

Acute bradycardia can be treated with transthoracic pacing, temporary endocardial pacing, or chronotropic drugs, including atropine, dobutamine, or isoproterenol. Right ventricular

perforation has become less prevalent with current temporary endocardial leads but must be borne in mind if hypotension develops acutely after removal of temporary wires.

Bradycardia after cardiac surgery is commonly treated with pacing via temporary atrial and ventricular epicardial wires. Problems include unfavorable evolution of right atrial (RA) or right ventricular thresholds and RA sensing. Atrial undersensing and pacemaker competition can precipitate atrial fibrillation or atrial flutter. If atrial sensing is not adequate, overdriving the atrium faster than the intrinsic rate can ameliorate competition. Reversing polarity or inserting a cutaneous ground wire under local anesthesia can improve pacing threshold. The output of the temporary pacemaker in volts or milliamps should be at least twice the threshold and should be measured daily. Ventricular undersensing in critically ill patients can result in pacing during the vulnerable period, which can precipitate VT or fibrillation.

### CARDIAC OUTPUT AND PACING RATE

For patients with hemodynamic compromise following cardiac surgery, optimization of pacing rate and AV delay can affect hemodynamics by compensating for valve leaks or fixed stroke volume. Mean arterial pressure reflects cardiac output if systemic resistance is constant. Rate and timing adjustments over intervals of less than 20 seconds minimize reflex effects. Settings producing the highest sustained mean arterial pressure should also maximize cardiac output.

## Pacemaker Insertion

### ENVIRONMENT AND ANESTHESIA

Pacemaker and ICD surgery are now predominantly performed in EP laboratories. Whether in the operating room or EP laboratory, properly functioning equipment is essential. Infection control is critical<sup>23</sup>; operating room standards for air quality should be enforced. Problems calling for presence of an anesthesiologist include angina, transient cerebral ischemia, patient disorientation, lidocaine toxicity, dementia, myocardial ischemia, heart failure, anxiety, or VT. If English is not the patient's first language, a translator is helpful. Vancomycin reactions (red man syndrome), pacing-induced ventricular fibrillation (VF), air embolism, and Stokes-Adams attacks are rare emergencies that are less problematic if considered in advance. Intraoperative death can occur because of hemorrhage, pericardial tamponade, VF, heart failure, myocardial infarction, and other causes.

### MONITORING

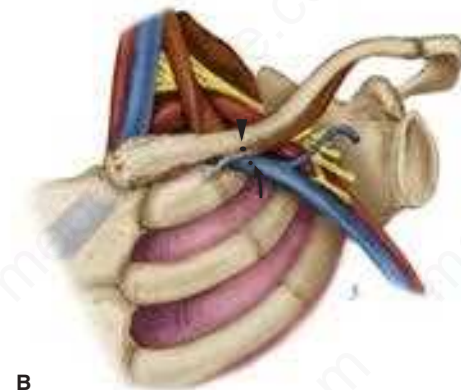

R-wave detection by an ECG monitor is inadequate for pacemaker insertion, because pacing artifacts may trigger the monitor but fail to capture. Thus, subthreshold pacing can elicit regular beeping from the monitor in an asystolic patient. Oxygen saturation monitors are optimal and beep only during blood flow. Pulse oximeters should not be placed on the same extremity as the blood pressure cuff. When monitors are unreliable, palpation by an anesthesiologist or nurse

of the temporal, facial, or radial artery pulse can detect asystole before the patient becomes symptomatic.

### VENOUS ACCESS STRATEGY

Choices include which side to be employed and whether to use cutdown or percutaneous venipuncture. Approaches to the cephalic, subclavian, axillary, external jugular, and internal jugular system are useful.<sup>6</sup> Anatomical considerations<sup>24</sup> may reduce the frequency of subclavian crush (Fig. 55-6). Deep vein punctures are associated with an apparently unavoidable but low incidence of pneumothorax, hemothorax, and major venous injury. Contrast injection from an IV on the side of the implant can confirm patency and location of the target vein. Ultrasonic vessel locators may further reduce the frequency of injury.

Venous access is problematic in superior vena cava syndrome or subclavian/innominate vein obstruction/thrombosis (eg, with chronic dialysis, mediastinal tracheostomy, or multiple

**FIGURE 55-6** Landmarks for subclavian vein puncture. Potential complications include subclavian crush injury. (Reproduced with permission from Magney JE, Flynn DM, Parsons JA, et al: Anatomical mechanisms explaining damage to pacemaker leads, defibrillator leads, and failure of central venous catheters adjacent to the sternoclavicular joint, *Pacing Clin Electrophysiol*. 1993 Mar;16(3 Pt 1):445-457.)

**FIGURE 55-7** X-ray of a patient with very poor escape rhythm, bilateral venous obstruction, and severe exit block. A new pacing system was inserted through the right atrial appendage via right parasternal mediastinotomy. Older pacemaker programmed to backup mode and scheduled for later removal.

pacemaker leads). Access from below or transhepatically is possible,<sup>6</sup> but potential for bleeding, venous thrombosis, and pulmonary embolism are concerns. Right parasternal mediastinotomy with exposure of the right atrium and a Seldinger approach with small introducers and atrial pursestring sutures are useful in difficult cases<sup>22</sup> (Fig. 55-7). Lead extraction may permit reinsertion of leads via the extraction cannula.<sup>6</sup>

### ANTIBIOTIC PROPHYLAXIS

Antibiotic prophylaxis is indicated for insertion of a prosthetic device.<sup>6,23</sup> We have used 1 g of intravenous cefazolin, but the current recommendation is 2 g. We also irrigate the operative field with a solution of 1 g of cefazolin in a liter of warm saline. Patients with prosthetic valves or a penicillin or cefazolin allergy receive vancomycin (500–1000 mg) and gentamicin (1 mg/kg). Doses are adjusted for renal function.

### PACING SYSTEMS ANALYZER

Pacing thresholds and electrogram amplitudes are measured with a pacing systems analyzer. Electrogram characteristics and slew rate can be assessed, and electrogram telemetry is available from most current pacemakers. Analyzers must be serviced and tested periodically, including batteries. Any discrepancies between measurements by the analyzer and the pacemaker should be noted and related functions of the analyzer rechecked.

A skilled operator is needed to run the analyzer and record the results. If placed in a sterile bag, the analyzer can be operated by the surgeon. Manufacturer's representatives, an increasing intraoperative presence, are skilled in operation of these analyzers.

### CABLES

The cables connecting the analyzer to the leads are the patient's lifeline. Even with excellent quality control, cables with open or reversed connections may be delivered to the surgical field. Errors can also occur in connecting the cables to the analyzer. Routine testing of the cables and the integrity of their connections is recommended. After passing the cables from the operating table, pacing is initiated from the analyzer at 5-V output. The connectors are then briefly touched to the subcutaneous tissue, with caution to minimize inhibition of the permanent pacemaker. Current measured in the analyzer should rise to 300 to 1000 ohms. If impedance is more than 5000 ohms, the circuit is faulty. The operation should not proceed until the problem is corrected, if impedance indicates the analyzer-cable circuit is defective. Connections to the analyzer should also be checked, because inadvertent reversal of polarity can make measured pacing thresholds inappropriately high. Disposable leads with polarized connectors have been delivered to us on occasion with the connectors reversed.

### FLUOROSCOPY

Fluoroscopy is essential for transvenous device implantation, and personnel must be familiar with the equipment. Distracting problems with image orientation, rebooting, timers, brakes, and locks can be avoided by a knowledgeable team. Sudden failure of fluoroscopy at a critical point can occur. If a backup unit is not available, the options include "blind" endocardial lead insertion, epicardial insertion, or postponing the procedure. The use of low-dose and pulsed image options can prevent overheating of the fluoroscope, although image quality may be compromised. Radiation exposure or fluoroscopy time should be monitored and recorded.<sup>6</sup>

### SURGICAL APPROACH

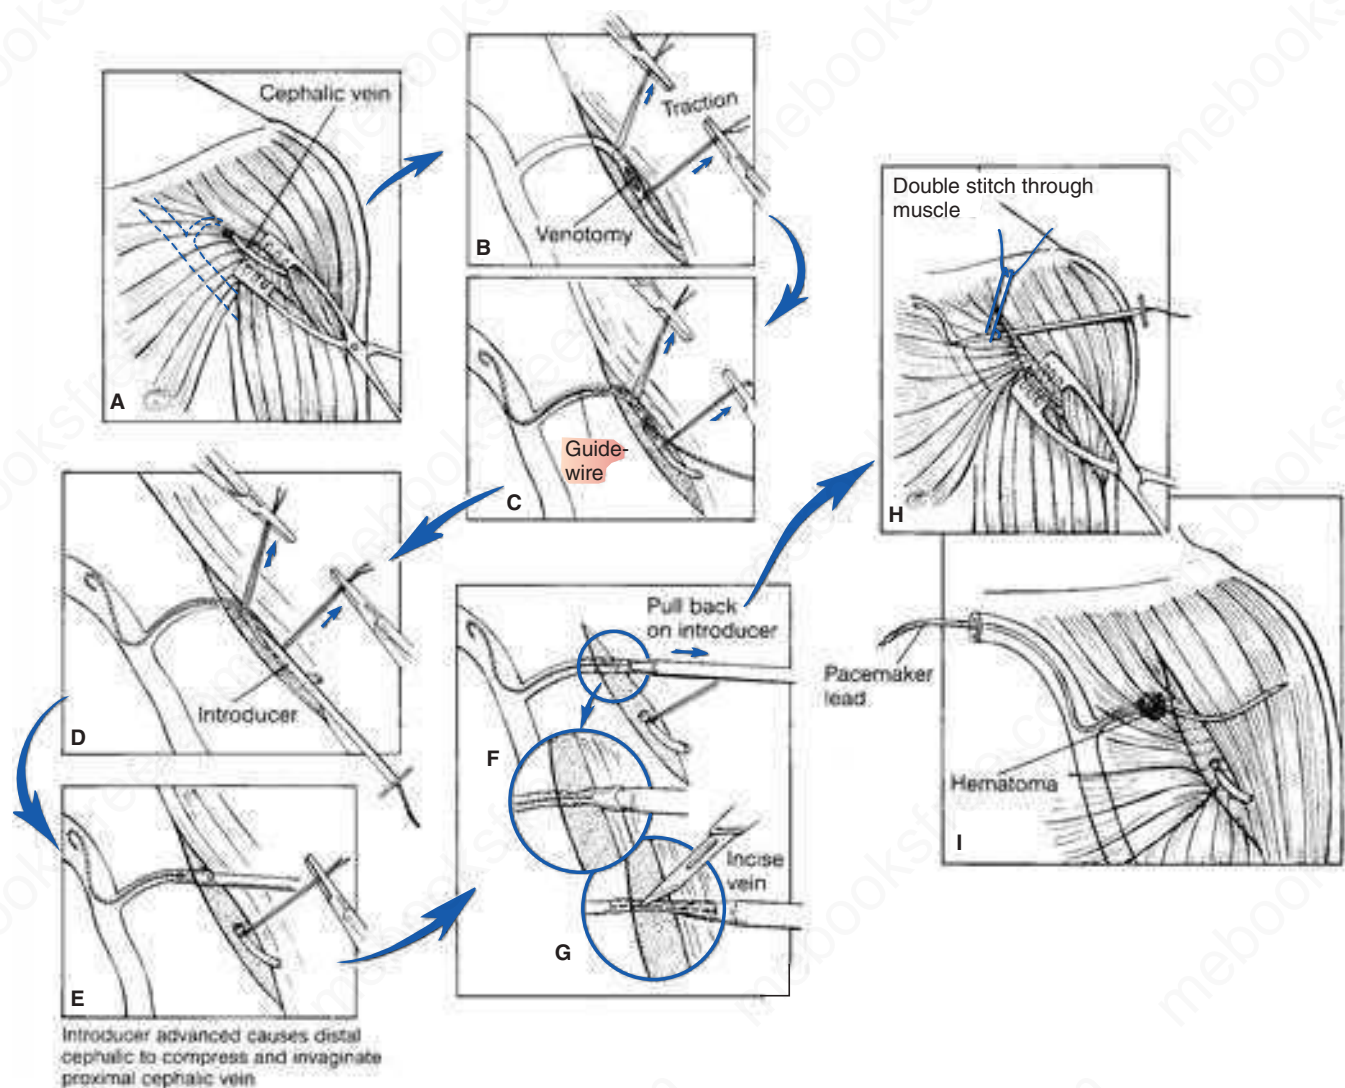

For routine implants, we prefer to approach from the patient's left. The fluoroscope is positioned carefully on the right to allow visualization of the apex, right atrium, and deltopectoral groove. The right arm is extended rightward on an arm board. The drapes are suspended from IV poles. The right-sided pole is caudad to the arm board. Proper positioning exposes the left clavicular region while leaving the patient adequate light and air. After skin preparation, towels aligned with the deltopectoral groove and clavicle define essential landmarks. Conscious sedation with 0.5 mg midazolam and/or 25.0 mcg of fentanyl may be useful. The region of the incision and underlying generator is infiltrated with 1% lidocaine, producing a field block. A 5- to 6-cm horizontal incision is created 4 cm beneath the clavicle, the lateral extent of the incision just reaching the deltopectoral groove. This allows the generator

to be positioned away from the groove and axilla, avoiding interference with motion of the left arm at the shoulder. An alternate incision overlying the deltopectoral groove is preferred for exposure of the cephalic vein in obese patients or elderly patients with atretic veins.

### VENOUS ACCESS

When the deltopectoral groove is exposed, additional anesthetic is infiltrated into the lateral margin of the pectoralis and laterally into the deltoid. The dissection proceeds into the deltopectoral groove, following the lateral edge of the pectoralis, until the cephalic vein or another venous branch

is exposed. Failure to find a vein may mean the incision is too far cephalad or caudad or not lateral enough. The incision can be deepened into the subpectoral fat if necessary. If the vein is too small to pass a pacemaker lead, the curved end of the guidewire for a 7-French introducer is passed centrally. The ability to manually stiffen and extend the curve by manipulation of the tension in the guidewire is an important technical aid in tortuous veins. Hydrophilic guidewires are also useful. The method illustrated in Fig. 55-8 can be used to dilate the vein. A no. 18 Angiocath is advanced over the guidewire, and the vein is slit longitudinally, exposing larger segments more proximally. This step can be repeated until a 7 French introducer will enter the vein. If the introducer

will not advance without invaginating the vein, pulling the introducer back exposes the impaled vein, which can again be longitudinally incised to allow the introducer to advance. If dual-chamber pacing is planned, a guidewire should be reinserted before the introducer is stripped away. These steps provide venous access for the duration of the procedure.<sup>25,26</sup> A pursestring suture in the muscle controls bleeding and stabilizes the lead(s).<sup>27</sup> Ultrasonic localizers may be useful at this stage, with appropriate sterile precautions. If a guidewire will not pass centrally, a no. 18 Angiocath can be advanced for angiography with iodinated contrast. Venography reduces the risk of hemo/pneumothorax during needle puncture.

### RIGHT VENTRICULAR LEAD INSERTION

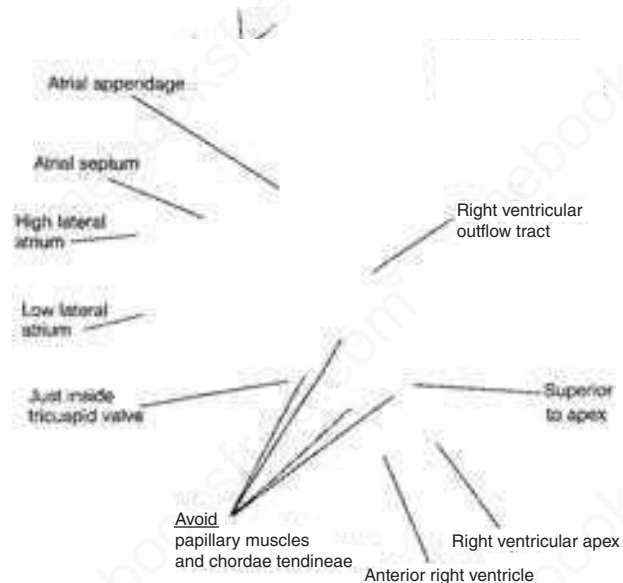

From the patient's left, a gentle spiral in the distal 10 cm of the stylet will guide the lead toward the tricuspid valve, right ventricle, and pulmonary artery. Advancing the lead into the pulmonary artery outside the cardiac silhouette confirms that the lead is not in the CS. For fixed-screw positive fixation leads, withdrawing the stylet 3 to 5 cm minimizes the risk of apical perforation while the lead tip is screwed into the myocardium with axial clockwise rotation. Reverse torque developing as the lead is rotated indicates the tip is in healthy myocardium and is an index of the security of fixation. We fix these leads with three consecutive 360-degree clockwise rotations of the lead shaft, and then the torque is released. This fixation sequence is repeated if necessary, until the lead is secure, with substantial reverse torque after the first 360-degree rotation. No more than three complete axial rotations are employed in any sequence. A potential problem with screw-in leads is ventricular perforation. The lead tip should be imaged during fixation looking for extra-anatomical passage along the edge of the cardiac silhouette and around the apex, tracking cephalad. If this happens, the lead should be withdrawn and repositioned. An echocardiogram should be obtained and the patient monitored for tamponade.

When the lead tip has been properly positioned, the stylet is withdrawn and thresholds are tested. Patient hyperventilation and coughing confirms fixation. The ventricular pacing threshold should be less than 0.7 V, with R-wave amplitude more than 5 mV, and impedance 400 to 1000 ohms, depending on lead design. There should be no diaphragmatic pacing at an output of 10 V.

If the lead is dislodged by hyperventilation and coughing, or thresholds are not adequate, the lead should be repositioned. A positive fixation lead can be unscrewed by counterclockwise axial rotation until it floats free. Positive fixation leads can be secured almost anywhere along the margins of the right ventricular silhouette (Fig. 55-9), including the right ventricular outflow tract (Fig. 55-10).<sup>28</sup> In difficult cases, we have relocated leads as many as 15 times. The geographic center of the right ventricular silhouette is not a desirable location, as it can lead to entanglement of the lead in the chordae tendineae (see Fig. 55-9).

### CORONARY SINUS LEAD INSERTION

Left ventricular pacing via the CS is a valued skill since the MIRACLE trial and subsequent studies indicated that CRT

**FIGURE 55-9** Useful sites for transvenous atrial and ventricular pacing using fixed-screw leads. Avoid the geographic center of the right ventricle (RV), where fixing the lead can entrap it in the chordae tendineae.

reduces symptoms of heart failure and mortality of dilated cardiomyopathy.<sup>5</sup> Electrophysiologists are familiar with CS entry for arrhythmia mapping; steerable mapping catheters and biplane fluoroscopy are important tools. However, the technical failure rate of CS lead insertion is 5 to 10%.<sup>5,29</sup> The CS orifice is usually a posterior structure near the caudal aspect of the tricuspid valve (Fig. 55-11). Locating the os in heart failure patients may be difficult, because the CS can be angulated and distorted as a result of cardiac enlargement. Transesophageal echocardiography and venography may help locate the os. CRT candidates may be prone to ventricular arrhythmias, and

**FIGURE 55-10** Screw-in lead in the right ventricular outflow tract of a patient with complete heart block after tricuspid valve replacement for Ebstein anomaly.

**FIGURE 55-11** (A) Biventricular, CRT-P pacemaker with endocardial leads in the right atrium, right ventricle, and lateral branch of the coronary sinus (left ventricle). This patient was relieved of dobutamine dependence by addition of the left ventricular lead. (B) Lateral x-ray of the same patient. Note posterior course of the coronary sinus.

rapid defibrillation capability is desirable. Even experienced operators may require hours to insert a CS lead with present methods, although technology for both endocardial and epicardial left ventricular lead placement is improving. Over-the-wire lead designs are the most successful.

We prefer to insert the CS lead first via the cephalic approach, RA and right ventricular lead insertion after via subclavian puncture. CS lead insertion involves advancing an angled cannula into the CS, followed by CS venography and lead insertion through the cannula into a lateral CS branch. The CS cannula is then removed and stripped away without dislodging the lead. Positive fixation leads are not available. A large selection of angled CS cannulas, steerable probes, and lead designs testifies to the technical challenge.<sup>2,5</sup> The difficulty of CS lead insertion in heart failure patients should not be underestimated; special training is desirable. Recent availability of multielectrode CS leads is very helpful in preventing phrenic nerve pacing, a complication that can be minimized by high output test pacing.

#### LENGTH ADJUSTMENT

If lead length is “too short,” flattening of the diaphragm during a deep breath can result in lead displacement, if “too long,” a cough can force intracardiac loops that effectively shorten the lead, also potentially causing displacement. Hyperventilation by the patient under fluoroscopy helps adjust length. Vigorous coughing tests the security of lead tip fixation. This valuable feedback is lost if sedation is excessive. Minimizing sedation also promotes early detection of pacemaker syndrome.

#### ATRIAL LEAD INSERTION

For dual-chamber pacing, the atrial lead is introduced last. A J or S stylet shape is best for finding the atrial appendage from the left side. The S shape is also useful for passing a positive fixation

lead to the right margin of the atrium near the junction of the atrium and inferior vena cava (Fig. 55-12). P-wave amplitude is often best in this location. The atrial pacing threshold should be less than 2 V. In the presence of complete heart block, it may

**FIGURE 55-12** DDD pacemaker with atrial lead in low right atrium, advantageous after obliteration of the atrial appendage at heart surgery. This location, which requires positive fixation leads, often provides good P-wave amplitude when other sites fail. Phrenic nerve pacing must be excluded with 10-V pacing at this location.

be difficult to confirm atrial capture from the surface ECG. Pacing the atrium at 150 bpm results in rapid oscillation of the lead tip, which is visible fluoroscopically if mechanical function of the atrium is sufficient. Lead oscillation may thus be used to determine the atrial pacing threshold. This technique should only be used if the high atrial rate is not conducted to the ventricle. In patients with complete heart block, high-output atrial pacing can inhibit whatever temporary VVI pacing is supporting the patient, resulting in asystole.

The P-wave electrogram is the Achilles heel of dual-chamber pacing. If atrial sensing is not satisfactory, a DDD pacemaker will not function properly. The P-wave amplitude should ideally be greater than 2 mV. P-wave amplitude may vary during respiration, and the minimum value, not the maximum, determines the adequacy of sensing. P-wave amplitude is generally reduced during atrial fibrillation versus values in sinus rhythm.

Measurement of P-wave amplitude with unipolar leads can be confusing. Crosstalk or far-field sensing of ventricular depolarization from the atrial lead can occur, so that the

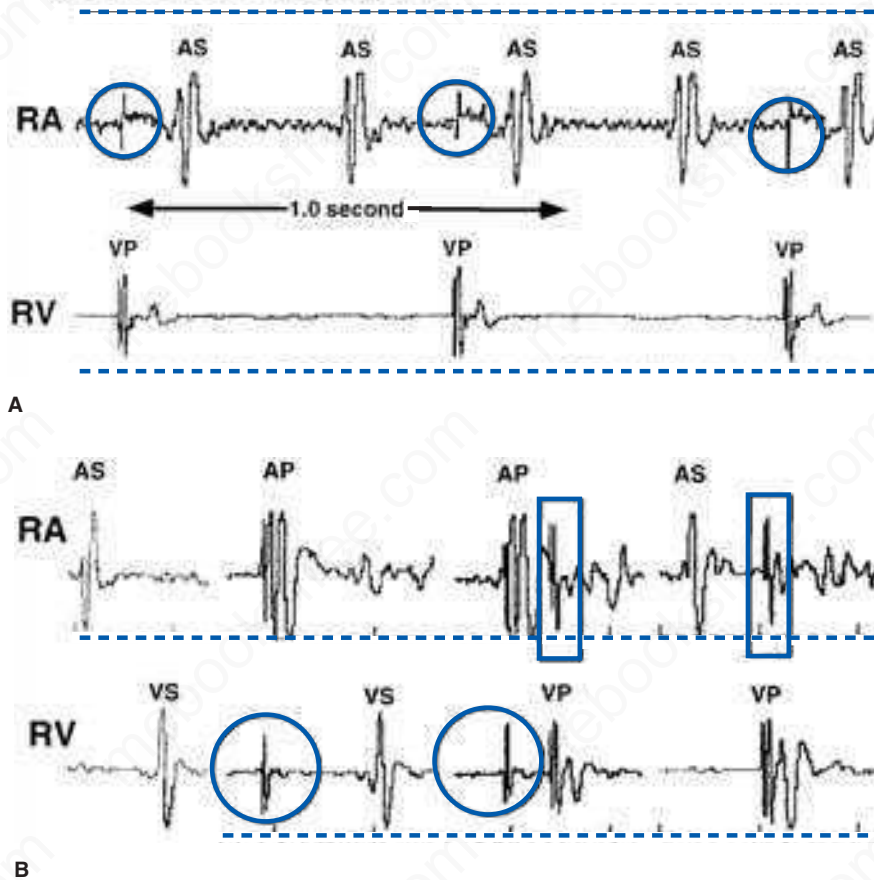

signal measured through a pacemaker analyzer is not the P wave but the QRS complex. Simultaneous measurement and display of atrial and ventricular electrograms as well as the surface ECG can resolve this.

Atrial and ventricular electrogram telemetry provide valuable data. For example, inability to pace the atrium or to record atrial electrograms may indicate low-amplitude atrial fibrillation or supraventricular tachycardia invisible on the surface ECG but detectable in electrograms. Electrogram telemetry can confirm proper DDD pacing (Fig. 55-13).

### GENERATOR LOCATION

We use a watertight, three-layer skin closure for primary implants, three layers in generator replacements. Dermabond can be used for skin closure. Cosmetic appearance is important, and technique is critical to optimize healing. Past injury to the chest wall or surgery/ radiotherapy for breast cancer can present a formidable technical problem. Bipolar systems facilitate optional generator placement behind the

### SVT - DDD pacemaker

**FIGURE 55-13** Right atrial (RA) and right ventricular (RV) electrograms from a unipolar DDD pacemaker during supraventricular tachycardia (SVT). Regular atrial depolarizations appear (AS) at a rate of 160 bpm. The pacemaker paces the ventricle (VP) at 80 bpm, because alternate P waves fall inside the postventricular atrial refractory period and are not detected. The circles illustrate far-field sensing of the RV pacing artifact in the RA lead. The SVT was not detected preoperatively. Once this recording was obtained, overdrive atrial pacing from the pacemaker converted the SVT to normal sinus rhythm, and normal pacemaker function returned.

pectoralis or inside the rectus sheath. Diminutive generators are available, but battery life is reduced. Innovative locations for pacemaker generators include axillary, retromammary, intrathoracic, intra-abdominal, and preperitoneal sites. These approaches are rarely indicated with present generator designs. Temporary endocardial pacing wires are removed under fluoroscopy, watching carefully for displacement of the new permanent leads.

## Length of Stay after Pacemaker Implantation

### AMBULATORY SURGERY

Same-day hospital discharge after pacemaker insertion is reasonable in patients who have an adequate escape rhythm and positive fixation leads. After monitoring and recovery from sedation, patients are ambulated and shown range of motion exercises for the shoulder. A chest x-ray documents lead position and rules out hemothorax, pneumothorax, or increasing heart size.

### PACEMAKER-DEPENDENT PATIENTS

Lead displacement can result from technical error, struggling of demented patients, and other factors. A small percentage of lead displacement is probably unavoidable.<sup>6,30</sup> Patients who might suffer death or injury in the event of pacemaker failure should be observed in the hospital overnight on telemetry. However, lead displacement in our ambulatory patients has not been more frequent than in hospitalized patients. Swan-Ganz catheter removal/insertion, endomyocardial biopsy, or cardiac catheterization can displace pacemaker leads, requiring a backup pacing plan.

## Pacemaker Generator Replacement

### PLANNING

Complications of pacemaker generator replacement include infection, lead damage, connector problems, and asystole during the transition from the old generator to the new. Pacemaker independence at the time of initial pacemaker implant may progress to total pacemaker dependence by the time of generator replacement. Ambulatory surgery is common. As a practical matter, we do not completely reverse warfarin for pacemaker generator replacement unless lead replacement is expected.<sup>31</sup> Patients with leads more than 10 years old should be carefully evaluated for pacemaker dysfunction before the procedure; a Holter monitor should be obtained if lead dysfunction is suspected. Rising pacing threshold may indicate impending lead failure. The possibility of unexpected lead replacement should be discussed with the patient in advance.

### BACKUP PACING

A backup temporary transvenous pacing wire can be inserted for pacemaker generator replacement, but this is rarely necessary. The output of the replacement unit must be higher than

the threshold of the chronically implanted leads. This can be problematic if the expiring generator is an older type with a fixed output of 5.4 V. Lack of programmability prevents preoperative threshold testing, and the 5.4-V output is higher than possible for some current generators. The pacing threshold should be determined with a pacemaker analyzer and the replacement should be programmed to appropriate output. Before disconnecting the old generator, be sure that the pacemaker analyzer, cables, and connections are intact and personnel in the operating room are aware of the cables. Some place the analyzer in a sterile bag on the operative field. With many generators, an Allen wrench placed in the header establishes electrical continuity with the ventricular lead; the pacing threshold can then be established before disconnecting the old generator. The old generator should be kept within reach as a backup in case of trouble with the new generator, the analyzer, or the connectors. Replacement generators must be programmed unipolar or bipolar to match the indwelling lead(s).

### LEAD SIZES

VS-1 or IS-1 are common lead types, both 3.5 mm in diameter. The contacts do not always line up correctly across VS-1 and IS-1 generator ports, even though the connector diameter is the same. It is important to determine in advance whether adapters are needed to bridge incompatibilities. Older 5 and 6 mm leads, increasingly rare, require special adapters or generators.

## Postoperative Care

### WOUND CARE

Patients are instructed to keep implant wounds dry until an office visit 7 to 10 days postoperatively. Any wound drainage at the postoperative visit is cultured, and prophylactic antibiotics are started until culture results are available. We have abandoned aspiration of the rare postoperative hematoma in favor of close observation, unless infection is an issue or spontaneous drainage occurs or appears imminent.

### ANTIBIOTIC PROPHYLAXIS

Routine use of prophylactic antibiotics before dental work and other invasive procedures in pacemaker or ICD recipients is not recommended under AHA/ACC guidelines. We recommend prophylaxis for 3 months after device insertion, allowing time for the pacing leads to become endothelialized.

## Testing and Follow-up

### OFFICE/CLINIC VERSUS TELEPHONE

Pacemakers require periodic testing to confirm sensing and pacing function and battery reserve. Currently these functions are tested at 1- to 3-month intervals. Follow-up can be done by transtelephonic monitoring, wireless telemetry and clinic or office visits.<sup>4</sup> Transtelephonic monitoring alleviates

transportation issues for elderly patients, but may be confusing for new subscribers. In addition to reducing travel and office visits, transtelephonic monitoring can provide 24-hour emergency service, an advantage with apprehensive or incapacitated patients. Techniques for remote management of pacemakers and ICDs are available with some current devices.

### PACEMAKER PROGRAMMING

Trained, experienced personnel can do programming in the office. Manufacturer's representatives can provide valuable help and programmer upgrades. Remote pacemaker/ICD monitoring and programming are under development.

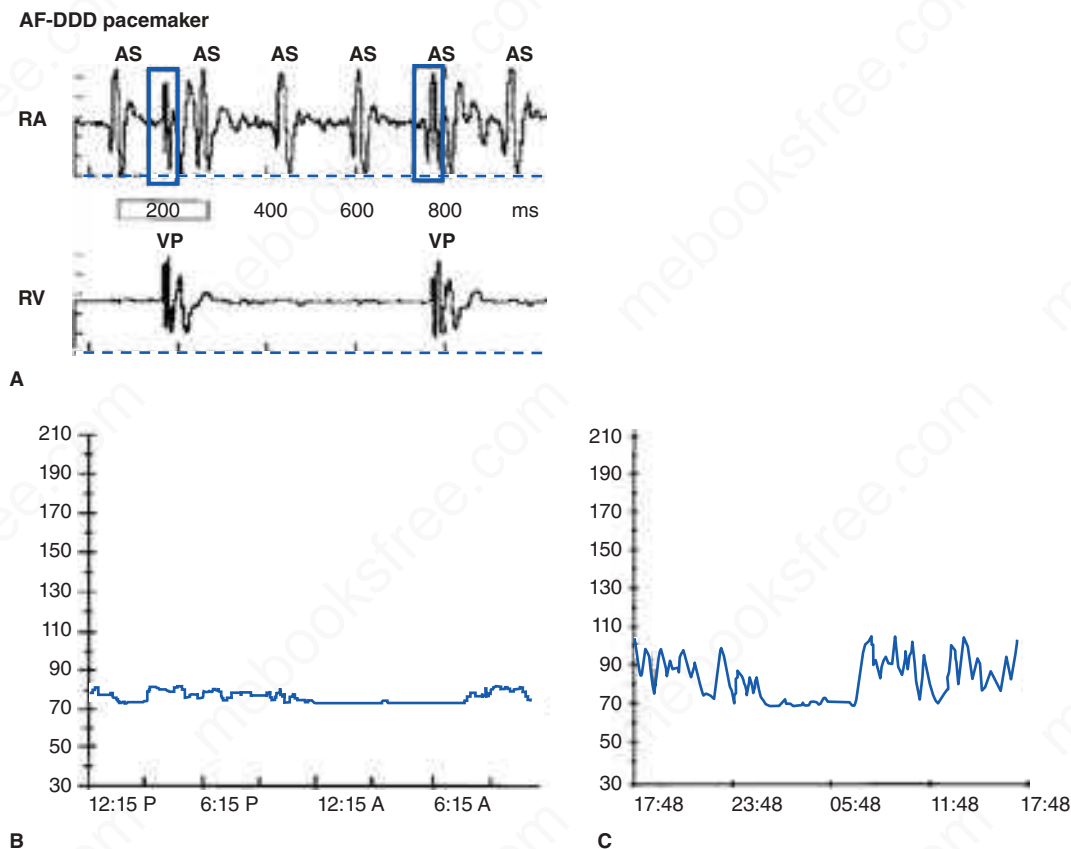

DDD pacemaker programming allows adjustment of electrogram sensitivity as well as pacing stimulus amplitude/pulse width for both the atrium and ventricle. Lower rate, upper rate, AV delay (AVD), and refractory periods for atrial and ventricular sensing are programmable. Rate responsiveness, unipolar/bipolar configuration, and many other options are also adjustable noninvasively.

We program newly inserted pacemaker stimulation amplitude 50% higher than nominal. At a 7- to 10-day

initial office visit, pacing thresholds are retested and amplitude and pulse width are adjusted to nominal levels if pacing thresholds are low. High initial output is less important with steroid-eluting leads. Details of pacemaker programming have been described elsewhere.<sup>4-6,8</sup> Many current pacemakers provide automated threshold adjustment, but this may function inappropriately with unipolar leads.

Most problems detected by monitoring or device interrogation can be corrected by programming. The etiology of symptoms may be elicited from real-time electrograms or stored data. Adjustments can include not only sensitivity or pacing output but also pacing mode and rate for new-onset atrial fibrillation (Fig. 55-14A) or sinus node incompetence related to medication changes (Fig. 55-14B). Reoperation is required for lead displacement or fracture (Fig. 55-15), insulation degradation (Fig. 55-3), very low sensing amplitudes, and exit block (Fig. 55-16).<sup>30</sup>

Pacemaker interrogation should begin with a printout of the initial settings, an invaluable reference after involved programming. Telemetry defines time-related variation in heart rate, percentage of beats sensed and paced, the quality of the electrograms, lead impedance, and battery voltage.

**FIGURE 55-14** (A) Atrial (RA) and ventricular (RV) electrograms from unipolar DDD pacemaker during atrial fibrillation (AF). AF appears as rapid atrial depolarizations (AS). The upper rate limit and postventricular atrial refractory period of the pacemaker determine the rate at which the pacemaker stimulates the ventricle (VP). (B,C) Heart rate over 24 hours from memory of DDD pacemaker. (B) Sinus node incompetence during amiodarone therapy for paroxysmal atrial fibrillation. (C) Rate variation after activation of rate response. Patient reported improved exercise tolerance.

**FIGURE 55-15** Unipolar lead fracture in a 3-year-old child with complete heart block, revealed by x-ray. A replacement lead was inserted and is still functioning normally 18 years later.

Ventricular exit block

Normal AV sequential pacing

**FIGURE 55-16** Right atrial (RA) and right ventricular (RV) unipolar electrograms in right ventricular exit block (*above*). Atrial (AP) and ventricular (VP) pacing are required for sinus arrest and marked first-degree atrioventricular block. Right ventricular capture is restored after RV pacing amplitude is programmed from 3.5 (*above*) to 5.4 V (*below*). Ventricular capture increases the effective heart rate, because the late, conducted ventricular electrograms (VS) in the upper tracing are sensed by the pacemaker and used to begin a new cardiac timing cycle. The circles indicate far-field sensing of the RA pacing artifact in the RV lead.

Pacing amplitude and pulse width are finely tuned for patient complaints, malfunctions on telemetry, or at 1-year follow-up visits. At least 100% safety margin is programmed on the pulse width threshold or amplitude. Parameters are adjusted to optimize patient comfort and battery life. Some pacemakers allow programmed reduction of a lower rate at night, eliminating unnecessary pacing during sleep. Very long AVD can eliminate ventricular pacing in some patients with first-degree block, but a reduction in the upper rate limit to 105 bpm may be necessary to extend AVD to 300 ms. Current pacemakers have a variety of algorithms to prevent excessive pacing in first-degree heart block, including automatic switching between AAI and DDD modes.

## Complications of Pacemaker Insertion

### MORTALITY

Death is a rare complication of pacemaker implantation.<sup>30,33</sup> Lethal problems can include lead displacement, venous or cardiac perforation, air embolism, and VT or fibrillation.<sup>30</sup> A review of 650 pacemaker insertions by the author between January 1984 and April 1993 revealed one perioperative death resulting from heart failure induced by general anesthesia in a child with congenital heart disease (Table 55-3).

### INCIDENCE OF COMPLICATIONS

The incidence of early pacemaker complications in one recent series was 6.7 and 4.9% requiring reoperation.<sup>30</sup> For patients older than 65 years, comparable figures were 6.1 and 4.4%, respectively. Lead displacement, pneumothorax, and cardiac perforation were the most common complications. The incidence of late complications was 7.2%.<sup>30</sup> The incidence of reoperation in the author's review of 480 cases was 4.0% (see Table 55-3).

### LEAD DISPLACEMENT

The incidence of endocardial lead displacement with early lead designs was more than 10%.<sup>32</sup> With tined and positive fixation leads this has fallen to about 2%.<sup>6,30,32,33</sup> The incidence of this complication was 1.5% for atrial and ventricular leads in our review (see Table 55-3). Relevant technical issues have been described. We find that positive fixation leads can be applied in unique anatomical locations with essentially no increase in lead displacement (Table 55-4).

### MYOCARDIAL INFARCTION

Pacemaker insertion may become an adjunct to medical therapy of angina in patients with inoperable coronary artery disease. However, angina, myocardial infarction, or death can result when heart rate increases of 10 bpm or more accompanying surgical implants.

**TABLE 55-3: Results of Pacemaker Implantation, Columbia-Presbyterian Medical Center 1984 to 1993\***

Surgical mortality	1/616 (general anesthesia related)
Mean follow-up	884 ± 675 (SD) days (n = 480 patients, 679 leads)
Morbidity	19 Reoperations (4.0% of 480) 4 Infections (0.8%) 7 Lead displacements (1.5%) 4 Exit block (0.8%) 4 Undersensing (0.8%) 5 Suspected right ventricular perforations 2 Leads abandoned (chordal entrapment) 41 Reprogrammed for dysfunction 0 Hemothorax 0 Pneumothorax 1 Procedure abandoned for thoracotomy (newborn)
Characteristics at generator replacement (n = 40, 75 ± 31 months after implant)	
Pacing threshold	1.3 ± 0.5 V 3.0 ± 1.3 mA
R-wave amplitude	8.9 ± 4.3 mV
Long-term DDD pacing	89% (1109 ± 34 days follow-up)
Causes of DDD failure	8.4% Atrial fibrillation 2.4% Lead dysfunction

### HEMOPNEUMOTHORAX

Hemopneumothorax and pericardial tamponade result from injury to the heart, lungs, arteries, or veins. Errors with the Seldinger technique can cause such injuries. In patients older than 65 years, pneumothorax has been related to subclavian puncture.<sup>33</sup> In our experience with more than 1000 pacemaker insertions by cephalic cutdown, hemopneumothorax did not occur. In contrast, a recent review of 1088 consecutive implants by subclavian puncture revealed a 1.8% incidence of pneumothorax.<sup>33</sup>

### PACEMAKER SYNDROME

Loss of AV synchrony produces symptoms related to reflex effects or contraction of the atria against closed AV valves. The resulting constellation of symptoms is known as *pacemaker syndrome*.<sup>4,8</sup> The symptoms are quite variable, but severely affected patients may refuse pacemaker magnet testing. Symptoms are relieved immediately by conversion from VVI to dual-chamber pacing.

### LEAD ENTRAPMENT

Fixed-screw pacemaker leads can become firmly entangled in chordae tendineae beneath the tricuspid valve. Possible responses include further escalation of force, lead extraction,<sup>6,35-37</sup> or an open procedure. Our experience with this involved three firmly entangled leads in our first 1000 implants of fixed-screw positive fixation leads. The leads were capped and abandoned rather than escalate risk. We now avoid the anatomic center of the right ventricle when implanting these leads. This problem has not recurred subsequent to this experience and presumably is avoidable with Bisping leads.

### INFECTION AND EROSION

Pacemaker infection manifests as frank sepsis, fever with vegetations/inflammation, and/or purulence or drainage at the pacemaker pocket. Indolent generator erosion or cellulitis are alternate presentations. Antibiotic suppression may temporarily abolish signs of infection, but the problem usually recurs weeks or months later.<sup>6,38,39</sup> Negative cultures and erosion may suggest moving the device to a fresh, adjacent site, but this is usually futile. Clinical resolution of recurrent device infection almost always requires removal of all hardware and insertion of a new device in a fresh site, optimally after a device-free interval.<sup>2,38,39</sup> The incidence of erosion, infection, hematoma, and lead displacement early after pacemaker implantation is reduced by operator experience.<sup>6</sup>

### PACEMAKER DYSFUNCTION

Mechanical defects in leads, lead displacement, or connection errors can cause pacemaker dysfunction. Late onset of lead dysfunction usually represents scarring at the lead—myocardial interface, changes in myocardial properties owing to tissue necrosis or drug effects, or a poor choice of lead position.

Insulation erosion can cause oversensing or, in bipolar leads, pacing failure owing to short-circuiting between the two conductors.

### GENERATOR DYSFUNCTION

Electrical component failures are rare. Three pacemaker or ICD generator failures have required urgent device replacement over 10 years at our center. New pacemaker and lead designs may contain flaws that do not become apparent for many years.<sup>2</sup>

### UNDERSENSING

Undersensing is failure to detect atrial or ventricular electrograms corresponding to P waves or R waves. The result is atrial or ventricular pacing that should have been inhibited by the unsensed beat. In a dual-chamber pacemaker, P wave undersensing may also cause failure to pace the ventricle after the P wave. Undersensing is often correctable by increasing generator sensitivity, but this can lead to oversensing. The latitude for reprogramming can be estimated by examining telemetered electrograms<sup>2,4</sup> (Figs. 55-17 and 55-18).

### OVERSENSING

Inappropriate pacemaker inhibition or triggering may result from detection of myopotentials (muscular activity). This is most common in unipolar systems and may be correctable by programming reduced pacemaker sensitivity. External insulation erosion within the pacemaker pocket is a cause of oversensing (Fig. 55-3).

### CROSSTALK AND FAR-FIELD SENSING

A deflection on the ventricular lead immediately after the atrial pacing artifact could be either premature ventricular depolarization (Fig. 55-17) or far-field sensing of an atrial depolarization (Fig. 55-13). Many pacemakers deal with this ambiguity by pacing the ventricle at a short (100 ms) AVD, an algorithm known as *safety pacing*.

Complexities of DDD programming involve blanking and refractory periods used to compensate for crosstalk or prevent retrograde AV conduction from causing pacemaker-mediated tachycardia (see the following). Crosstalk is ameliorated by bipolar lead systems.

### EXIT BLOCK

Exit block is rising pacing threshold due to edema or scarring at the lead tip. Pacing threshold tends to increase over 7 to 14 days after lead insertion and stabilizes at about 6 weeks. This phenomenon is related to inflammation at the lead tip and is ameliorated by steroid-eluting leads.<sup>2</sup> Exit block may be overcome by programming increased amplitude or pulse width, but this shortens battery life. In unipolar systems, pacing of the chest wall and/or diaphragm may result from high generator output.

**FIGURE 55-17** Undersensing of premature depolarizations (VPD) illustrated in the upper panel of electrograms obtained by telemetry from a VVI pacemaker. The amplitude of the electrograms increases, and sensing is corrected after reprogramming to increase sensitivity to P waves from 2.5 mV (*above*) to 1.5 mV (*below*).

### LEAD FRACTURE

Fracture of lead insulation or conductors may be demonstrable by chest x-ray (Fig. 55-15). Lead impedance less than 300 ohms suggest an insulation break, whereas impedance more than 1000 ohms suggests conductor problems, a loose setscrew, or improper connection. High impedance also can indicate incomplete extension of the fixation coil in a Bisping lead. Telemetry may detect impending lead fracture as electrical noise during hyperventilation, coughing, bending, or arm swinging. Oversensing of this type usually mandates lead replacement or repair.

At reoperation, dysfunctional leads can be capped or removed by lead extraction techniques (Figs. 55-19 and 55-20). Lead fracture has been promoted historically by design errors, bipolar construction, certain forms of polyurethane insulation, and epicardial insertion.<sup>1</sup> Technical factors in fracture include ties applied to the lead without an anchoring sleeve, kinking, lead angulation, vigorous exercise programs, and subclavian crush.<sup>6,24</sup>

### SUBCLAVIAN CRUSH

Subclavian crush is probably caused by lead entrapment between the clavicle and first rib, in the costoclavicular ligament.

**FIGURE 55-18** Right atrial (RA) and right ventricular (RV) electrograms from DDD pacemaker during correction of atrial undersensing. Amplitude of the RA electrogram increases after atrial sensitivity is increased from 2.0 mV (*left*) to 0.8 mV (*center*) to 0.5 mV (*right*). The P-wave electrogram (*circled*) is not sensed at 2.0 mV, resulting in unnecessary atrial pacing (AP). Proper sensing is restored and the size of the electrogram increases (AS) as sensitivity is increased. VP indicates ventricular pacing. Rectangles in RA tracing identify far-field sensing of the ventricular pacing artifact.

**FIGURE 55-19** Byrd method of lead extraction using Cook catheters. Drawings illustrate successful removal of a Telectronics Accufix J-lead with a fractured retention wire.

**FIGURE 55-20** Telectronics Accufix atrial J-leads removed for retention wire fracture. Region of fracture appears benign in upper image. Lower image illustrates retention wire extrusion after percutaneous extraction. Extruded wire resembles a safety pin.

Stress during body movement is then thought to cause early lead failure. This pertains primarily to leads implanted by percutaneous puncture of the subclavian vein and seems to be minimized by cephalic cutdown. Techniques to minimize this problem have been described (Fig. 55-6).<sup>6,24</sup>

#### PACEMAKER-MEDIATED TACHYCARDIA

DDD pacemakers can propagate a reentrant arrhythmia, pacemaker-mediated tachycardia. This involves retrograde conduction through the AV node, initially triggered by a premature ventricular depolarization. If the pacemaker senses the retrograde atrial depolarization and paces the ventricle, a cycle is set up that can continue indefinitely at the upper rate limit of the pacemaker. Avoiding high upper rate limits and adjusting the postventricular atrial refractory period so that the pacemaker ignores atrial depolarizations for 300 to 350 ms after the QRS complex can mitigate this problem. Current pacemakers also attempt to break reentrant arrhythmias by periodic interruption of continuous high-rate pacing. Pacemaker telemetry provides notification of high-rate pacing suspicious of pacemaker-mediated tachycardia.<sup>4</sup>

## Innovations and Special Problems

### LEAD REPAIR

Repair can extend the useful life of implanted leads for years. Most repairs are done within the device pocket or in surrounding areas. Fracture or erosion of conductors or insulation can result from normal wear or active life styles. Lead dysfunction can result from vigorous exercise including situps (abdominal insulation erosion), handball (insulation/conductor erosion), and wood chopping (conductor damage).<sup>2</sup>

Repair kits contain silicone glue and silicone tubing or unipolar tip replacements. Possible repairs differ for unipolar and bipolar leads. Unipolar leads consist of a single conductor surrounded by insulation. Insulation breaks can be overlaid with glue and tubing. Conductor fracture can be repaired by splicing a new lead tip onto the functional segment.<sup>41</sup> Bipolar leads contain two conductors with two levels of insulation, one to prevent short-circuiting between the conductors and the other to prevent external current leaks and conductor-generator contact. Representative designs are shown in Figs. 55-19, 55-20, and 55-26d. External insulation repair in such leads is similar to unipolar lead repair. However, internal insulation faults require converting the lead to unipolar function and splicing on a new lead tip. Conductor fracture also can be repaired this way. The repair involves exposing and baring about 10 mm of the conductor to be preserved. The conductor to be excluded is cut back 5 to 10 mm to avoid short-circuiting. A new tip is attached to the bared conductor, using an internal setscrew, silicone glue, and ties. These repairs have been robust in our experience but are not recommended in pacemaker-dependent patients.

Unipolar and bipolar epicardial leads can also be repaired, if the break is accessible. Unipolar lead repair is similar to repair of unipolar endocardial leads. Bipolar epicardial leads generally consist of two unipolar leads connected by a Y to coaxial segments for connection. The simplest repair involves locating the unipolar segment of the good lead and splicing on a new tip. Particularly challenging is a fracture near one of the cardiac electrodes, at a point of metal fatigue. If the broken conductor is not the tip electrode, reprogramming the generator to a unipolar configuration restores function. If the cathode segment is fractured, most generators cannot be programmed to use the anode, and pacing is lost. However, function can be restored by exposing the lead, splicing a new tip on the anode, connecting that lead to generator, and capping the cathode.<sup>41</sup>

When exposing leads within the pocket for repairs, the electrocautery should be set as low as practical, to avoid melting external lead insulation. If cautery contacts a bare conductor, myocardial injury can render the lead useless because of exit block. Also, conduction of cautery to the myocardium can induce VF. Sharp dissection is preferred when close to friction points or angulation that promote conductor exposure.

### PACEMAKER LEAD EXTRACTION

Indications for lead extraction include chronic infection or life-threatening mechanical defects.<sup>6,35-37</sup> Some recommend

that any dysfunctional pacemaker lead should be removed, but there is little objective data to support this. Until recently, extraction of transvenous leads required external traction or thoracotomy/cardiectomy with inflow occlusion or cardiopulmonary bypass. Chronically implanted leads can be densely fibrosed to the right ventricular myocardium, vena cava, innominate vein, or subclavian vein.

Lead extraction was developed by Byrd.<sup>35</sup> A locking stylet is passed inside the central channel to the tip of the lead where it uncoils, allowing traction to be applied to the lead tip. Telescoping Teflon, plastic, or metal sheaths fitting the lead are passed along the lead to mobilize it. When the long sheath reaches the lead tip, counter traction is applied to the myocardium with the sheath while traction is applied to the lead tip with the locking stylet (see Fig. 55-19). Success with this technique has been greater than 90%, with a 3% chance of serious morbidity or death. Laser or radiofrequency energy can also be transmitted through specially constructed sheaths to ablate adhesions.<sup>6,39</sup> Technical details have been described.<sup>6</sup> Extraction of leads more than 10 years old is difficult and tedious. Complete removal of lead tips is inversely related to the age of the lead (Fig. 55-21A).<sup>37</sup>

### ACCUFIX LEAD

An unusual fracture affects the Telectronics Accufix lead, a bipolar, Bisping-type atrial screw-in lead. A J shape near the tip directs the lead to the atrial appendage. A curved retention wire welded to the indifferent ring electrode near the tip and bonded to the lead body with polyurethane maintains the J-shape. Fracture and extrusion of this retention wire (Figs. 55-19 and 55-20) was associated with deaths from cardiac tamponade, related to punctures of the atrium or aorta by fractured wire. More than 45,000 of these leads were implanted, and many have been surgically extracted. Because some morbidity and mortality occurred during extraction of this lead, the manufacturer recommended conservative management. Recently, conservative management has also been recommended for a fracture tendency in the Sprint Fidelis ICD lead.<sup>6</sup>

### ATRIAL FIBRILLATION AND MODE SWITCHING

Sinoatrial node dysfunction can involve both sinus bradycardia and paroxysmal atrial fibrillation. Early DDD pacemakers responded to atrial fibrillation by pacing at the upper rate limit. Initially DDD pacing was avoided in atrial fibrillation for this reason. The current view that atrial pacing decreases the frequency of paroxysmal atrial fibrillation, and mode switching allows DDD pacing to be used despite a history of paroxysmal atrial fibrillation. Mode switching is triggered when a programmed upper rate limit is exceeded. The pacemaker then switches to VVIR mode until the atrial rate returns to the physiologic range. Successful mode switching requires bipolar leads and high sensitivity in patients with low-amplitude atrial fibrillation. Management of atrial fibrillation in elderly people may involve fewer medications and interventions than in younger patients.<sup>8</sup>

## DATABASE SUPPORT

Pacemaker and ICD data are needed for billing, operative notes, device tracking, programming, and follow-up. Data should be available in real time in the event of an emergency room visit involving device malfunction. Commercial and homegrown software packages are available for this. Security, audit trails, 24/7 availability, and multiuser wireless capability are important characteristics for such systems.

## GENERAL SURGERY AND PACEMAKERS

General surgery in a pacemaker-dependent patient raises important questions,<sup>42</sup> especially when surgery requires unipolar cautery. The following must be documented: (1) model and manufacturer of the pacemaker, from pacemaker ID card, monitoring service, medical record, or x-ray appearance;<sup>43,44</sup> (2) magnet mode behavior and any peculiarities related to impedance sensing monitors; (3) successful testing of programmer on the pacemaker; (4) programmed parameters, polarity, battery life, and lead characteristics; (5) degree of pacemaker dependence; (6) a backup plan transthoracic pacing or chronotropic agents if the pacemaker fails; (7) reprogramming to VOO, DOO, or VVT mode intraoperatively with rate response off to prevent inhibition or pacemaker acceleration<sup>44</sup> by electromagnetic interference (EMI); (8) a physician to deal with any intra-operative pacemaker problem; and (9) restored pacemaker program, thresholds, and function postoperatively. Regarding pacemaker dependence, if the preoperative ECG reveals 100% pacing, the pacemaker should be reprogrammed while monitoring to determine the presence and rate of an escape rhythm. Pacemaker dependence may increase during anesthesia, with withdrawal of sympathetic stimulation. The Heart Rhythm Society has defined guidelines for perioperative management of these patients.

## ELECTROCAUTERY

Manufacturers recommend against using electrocautery in pacemaker patients because of possible EMI or pacemaker damage. If electrocautery must be used, unipolar cautery is likely to cause EMI, whereas bipolar cautery is not. Unipolar pacemakers are more susceptible to EMI than bipolar units. EMI effects include (1) pacemaker oversensing, confusing EMI with a rapid heart rate. Pacemaker inhibition results but reverses when the EMI stops. (2) Pacemaker reprogramming. (3) Acceleration of impedance-sensing pacemakers to the upper rate limit. (4) Reversion to a “backup mode” or “magnet mode.” (5) Permanent loss of pacing, fortunately rare.<sup>43</sup>

Programming sensing off and increasing the pacing rate above the intrinsic heart rate anticipated during surgery can minimize EMI pacemaker inhibition. However, if competition with spontaneous beats does occur, there is a risk of inducing of atrial fibrillation or VT. In view of this, the pacemaker should be returned to an appropriate sensing mode as soon as possible after the completion of surgery.

## MAGNET MODE

A permanent magnet placed over a pacemaker closes a magnetic reed switch and initiates “magnet mode.” In some

pacemakers, magnet mode is VOO, eliminating all sensing. Other pacemakers convert to VOO for a few beats, then revert to the programmed function. A magnet may also induce a threshold margin test; this assesses the adequacy of the pacing margin by decreasing the pulse width in a predictable pattern.

## STEROID-ELUTING LEADS

Fibrosis at the lead tip can be limited by incorporating a dexamethasone pellet that dissolves over months. This improves early pacing thresholds versus conventional leads<sup>2</sup> and has been particularly advantageous in epicardial leads.

## ADULTS WITH CONGENITAL HEART DISEASE

Congenital heart disease may include a persistent left superior vena cava draining to the CS. This favors a right subclavian approach, although the left side can be used.<sup>27</sup> Preoperative echo-Doppler or angiography can define caval and CS anatomy. A left superior vena cava may dislocate the subclavian vein, increasing the risk of subclavian vein puncture and favoring cephalic cut down. Situs inversus and corrected transposition are disorienting, if undetected prior to pacemaker insertion.

Positive fixation leads are particularly useful for atrial pacing after a Mustard operation or a caval-pulmonary anastomosis and for pacing the smooth-walled “right” ventricle in corrected transposition of the great arteries.<sup>27</sup> A CS lead can provide ventricular pacing in some patients after Fontan surgery (Fig. 55-21). Pacing via the CS or middle cardiac vein may be useful in patients with a mechanical tricuspid valve (Fig. 55-21B).

## PACING IN INFANTS AND CHILDREN

Transvenous leads in children should include an intracardiac loop to allow for growth (Figs. 55-4 and 55-15). Unipolar,

A

**FIGURE 55-21A** Duration of lead implantation (Dwell Time) versus incidence of incomplete lead extraction. Incidence decreases from 23% for 12- to 25-year leads to 6% for 0- to 3-year leads. Lead fragments left behind were solid metal tips entrapped connective tissue sheath around lead. This results in tip separation, usually at the level of the innominate vein. There were no clinical complications related to retention of these lead tips.<sup>37</sup>

**FIGURE 55-21B** This 31-year-old male with sinoatrial node dysfunction and third degree heart block had previously undergone closure of atrial and ventricular septal defects, a Maze procedure, and pulmonary and tricuspid valve replacement twice, most recently with a mechanical tricuspid valve. Ventricular pacing was achieved with endocardial lead in posterior cardiac vein, avoiding thoracotomy. (Reproduced with permission from Spotnitz HM, Wang DY: Middle and posterior cardiac veins: an underused option for ventricular pacing, *J Thorac Cardiovasc Surg.* 2012 May;143(5):1223-1225.)

positive fixation leads are ideal for this purpose,<sup>27</sup> but other approaches have been described.<sup>22</sup> We prefer cephalic cut-down, with optical magnification, if needed. A flexible guide-wire is passed centrally and a 7-French introducer introduces the lead. A longitudinal split of the cephalic vein facilitates advancing the introducer (Fig. 55-8). In very small infants, the external jugular vein at the thoracic inlet may be useful. A catheter introduced via the femoral vein can guide subclavian vein puncture. Thoracotomy is a third option.<sup>22</sup> Infants less than 6 months of age are suboptimal candidates for transvenous pacing because of limited long-term lead utility. Subpectoral generator placement in children less than 6 years old reduces infection risk.

## DEMENTIA

Dementia complicates surgery under local anesthesia. Sedation can make dementia worse and exaggerate bradycardia. A demented patient's arms should be secured to prevent groping for the surgical wound. Postoperative confusion and thrashing can cause pacemaker lead displacement. An intracardiac loop decreases this hazard. A family member at the bedside may minimize patient alarm. Every effort should be made to anticipate and avoid such issues.

## ARRHYTHMIA ABLATION

Arrhythmia ablation is the commonest therapeutic intervention in EP laboratories, with hundreds of thousands performed annually. Ablation procedures can result in AV block or sinus bradycardia requiring permanent pacing. Ablation in the vicinity of the AV node is particularly hazardous. Most commonly, temporary pacing supports heart rate until a permanent pacemaker can be inserted. If ventricular escape rhythm is poor, overnight observation on telemetry and high

initial pacemaker output are desirable. Alternatively, a pacemaker can be inserted and allowed to heal before ablation, if high-grade block is anticipated.

## TRANSPLANT RECIPIENTS

The usual indication for pacemaker insertion in cardiac transplant recipients is sinus bradycardia or sinus arrest, managed with AAIR pacing.<sup>45</sup> Patients frequently outgrow the need for pacing within 2 years.<sup>45</sup> The surface ECG may be confusing, showing P waves from the atria of both the donor and the recipient and AV dissociation of the recipient atrium and donor ventricle. If a 1:1 ventricular response is observed with atrial pacing at 150 bpm, a ventricular lead is not essential. The atrial appendage is located toward the midline in these patients (Fig. 55-22).

## IMPLANTABLE CARDIOVERTER DEFIBRILLATOR RECIPIENTS

In the early evolution of ICDs, crosstalk with pacemakers could lead to inappropriate ICD shocks or ICD undersensing of VF. Independent implantation of pacemakers and ICDs is described,<sup>46</sup> but with availability of integrated ICD-DDD pacemakers, such techniques are now rarely indicated.

## LONG QT SYNDROME

Long QT is a genetically determined repolarization abnormality that is associated with sudden death. Recommended therapies include stellate ganglionectomy and/or adrenergic blockade.<sup>47</sup> In severe cases, the pacing threshold may be too high for ventricular pacing, and atrial pacing may be preferable. ICD therapy is now common, and techniques for implantation in infants have been described.

**FIGURE 55-22** DDDR pacing system in a cardiac allograft recipient illustrates a shift of the atrial appendage toward the midline, characteristic of these patients.

### IDIOPATHIC HYPERTROPHIC SUBAORTIC STENOSIS

Idiopathic hypertrophic subaortic stenosis (obstructive cardiomyopathy), with severe left ventricular outflow obstruction, causes angina and/or syncope. Right ventricular pacing with a short AVD preexcites the ventricle and decreases outflow gradients in some patients<sup>16,17</sup> (Fig. 55-23). ICD therapy is increasingly common in this population.

### PERMANENT BIVENTRICULAR PACING

End-stage cardiomyopathy and heart failure progress with time, leading ultimately to cardiac transplantation, cardiac assist devices, or death. CRT is a lower cost option for class III or IV and possibly class II failure. Clinical trials demonstrate modest subjective and objective benefits of CRT in dilated cardiomyopathy with left ventricular ejection fraction less than 36% and QRS intervals greater than 120 ms.<sup>5,18,29,34</sup> Mortality benefits are suggested by recent trials.<sup>5,34</sup> Marked clinical improvement is seen in some patients (Fig. 55-11), but up to 40% of patients are nonresponders. Endocardial LV lead insertion fails in 5 to 10% of candidates, usually because of difficulty cannulating the CS. These failures often result in referrals to thoracic surgeons for epicardial lead insertion. More than 100,000 patients undergo CRT annually in the United States, which could lead to 5000 referrals yearly for epicardial lead insertion. Minimal access<sup>48</sup> and robotic<sup>49</sup> LV lead insertion have been developed. Referrals might increase if better techniques for epicardial LV lead insertion were available.

### TEMPORARY BIVENTRICULAR PACING

Clinical success with CRT and the potential to increase cardiac output while reducing myocardial oxygen consumption

make temporary biventricular pacing attractive for management of low-output states after cardiac surgery. Preliminary results<sup>50,51</sup> indicate that this approach is promising. Temporary biventricular pacing can be recommended and is readily achievable for patients in low-output states with second- or third-degree block after cardiac surgery.<sup>18</sup>

### ATRIAL AND VENTRICULAR TACHYARRHYTHMIAS

Overdrive pacing can be effective for ventricular tachyarrhythmias, Wolff-Parkinson-White syndrome, or atrial flutter. Implantable defibrillators are under development for atrial fibrillation. Antitachycardia ventricular pacing for ventricular tachyarrhythmia has been integrated into ICD therapy. Ablation procedures are available for many supraventricular and ventricular arrhythmias.

## Environmental Issues

### ELECTROMAGNETIC INTERFERENCE

EMI<sup>43</sup> can be caused by electrocautery, cellular telephones, magnetic resonance imagers, microwaves, diathermy, arc welders, powerful radar or radio transmitters, and theft detectors in retail stores. Any defective, sparking electrical appliance or motor, electric razor, lawn mower, or electric light can be problematic. EMI is most concerning in pacemaker dependent patients and ICD recipients. Pacemaker recipients who are not pacemaker dependent will not be distressed by brief periods of pacemaker inhibition, but pacemaker-dependent patients can lose consciousness in 5 to 15 seconds. Bipolar pacing systems provide added protection against EMI. Cellular telephones should be separated by several inches from pacemaker generators, preferably on the contralateral side. ICD circuits are insulated against inappropriate firing precipitated by EMI. During surgery using unipolar cautery, the defibrillation circuit of an ICD should be temporarily disabled. MRI compatible pacemakers and defibrillators are now available but require specific facility protocols.

### MECHANICAL INTERFERENCE

Lithotripsy, trauma, dental equipment, and even bumpy roads can affect pacemakers. Automobile accidents have caused pacemaker damage and disruption of pacemaker wounds. Vibration causes inappropriately high heart rates in rate-responsive units. Patients with poor escape rhythms should be discouraged from exposure to deceleration injury in contact sports, basketball, handball, downhill skiing, surfing, diving, mountain climbing, and gymnastics. Participants in these activities should realize that abrupt pacemaker failure could occur in the event of lead displacement related to trauma.

### RADIOACTIVITY

The integrated circuits of current pacemakers can be damaged by radiotherapy.<sup>2</sup> If the pacemaker cannot be adequately shielded from the radiation field, it may be necessary to remove and replace it or move the pacing system to a remote site.

**FIGURE 55-23** (A) Effect of reducing AVD in DDD pacing from 125 (*left*) to 100 ms (*right*) on left ventricular outflow gradient in idiopathic hypertrophic subaortic stenosis. (B) Effect of time and DDD pacing on left ventricular outflow gradient in idiopathic hypertrophic subaortic stenosis. (Reproduced with permission from Fananapazir L, Epstein ND, Curiel RV, et al: Long-term results of dual-chamber (DDD) pacing in obstructive hypertrophic cardiomyopathy. Evidence for progressive symptomatic and hemodynamic improvement and reduction of left ventricular hypertrophy, *Circulation* 1994 Dec;90(6):2731-2742.)

## QUALITY OF LIFE

Quality of life is not a major concern for most pacemaker recipients. This preferred system involves transtelephonic monitoring, a preoperative visit, a 10-day postoperative visit, a 1-year visit to adjust output, and yearly visits unless functional problems or impending battery depletion are detected. Some recipients are never happy with their pacemakers because of body image problems, vague symptoms, or concern that life will be artificially prolonged. The value of continued pacing or generator

replacement in patients with advanced debilitation is a subject of debate.<sup>4</sup>

## IMPLANTABLE CARDIAC DEFIBRILLATORS

### Background

More than 400,000 deaths in the United States each year are classified as sudden and likely to be caused by arrhythmias.<sup>7</sup> Michel Mirowski conceptualized the implantable defibrillator

in the late 1960s. Overcoming theoretical, engineering, and financial obstacles, he participated in a successful clinical trial of his device in the early 1980s.<sup>52</sup> Current ICDs reflect a dramatic and expensive growth in technology. The efficacy of the ICD in prevention of sudden death is well established. Clinical trials, experience, and the passage of time emphasize survival advantages of the ICD over other modalities, including antiarrhythmic drugs and subendocardial resection.<sup>7</sup> The ICD is associated with the lowest sudden death mortality (1–2% per year) of any known form of therapy.<sup>53,54</sup> The cost of an ICD plus leads exceeds \$30,000 and has increased with incorporation of CRT. Prophylactic ICD insertion for primary prevention is increasing, despite discomfort and lifestyle issues.

Clinical trials including AVID, MUSST, MADIT I and II, SCD-HeFT, and COMPANION demonstrated benefits of ICD therapy.<sup>7,42,55–58</sup> The CABG Patch Trial,<sup>57</sup> which compared coronary artery bypass graft (CABG) to CABG+ICD, and DINAMIT, which studied ICD implantation early after myocardial infarction, failed to demonstrate advantages of ICD insertion. Trials now focus on prophylactic ICD therapy, CRT-Ds and cost-effectiveness. Accumulating evidence supports prophylactic use of CRT-Ds in patients with coronary disease or dilated cardiomyopathy.<sup>7,58</sup> The appropriate role for prophylactic CRT-Ds is still evolving. The Heart Rhythm Society will not certify surgeons to implant ICDs unless they have passed its certification exam. Patients with prophylactic device insertion are being followed in a national registry. Information about this can

be found at <http://www.acncdr.com/webncdr/ICD>. ICD insertion for primary prevention has doubled or tripled the number of candidates for these devices.

ICD battery life is greater than 5 years. Today's devices are highly programmable. Size and weight are similar to pacemakers of the 1970s. Lead systems have evolved from epicardial patches requiring thoracotomy to endocardial systems.<sup>7,54,59,60</sup> Defibrillation thresholds (DFTs) are reduced by biphasic shocks and “hot can” technology.<sup>7</sup> Pectoral implantation is the current standard, some deep to the pectoralis major. Abdominal implantation is now reserved for special cases (Figs. 55-24 and 55-25). Electrograms can be downloaded to expedite decisions about antiarrhythmics, prevent inappropriate shocks, and detect oversensing. Remote monitoring of ICD function is available from some manufacturers. VVI, DDD, biventricular, and anti-tachycardia pacing have been integrated into ICDs. Accelerated development has pressured the Food and Drug Administration to rapidly approve new technology. When the US Health Care Finance Administration refused in 1995 to allow Medicare reimbursement to support device development, ICD development shifted overseas.

### Physiology

VT associated with ischemic cardiomyopathy is commonly a reentrant arrhythmia that may be prevented by drugs, catheter ablation, or surgical maneuvers that alter the timing and electrical attributes of the reentrant circuit. Myocardial

**FIGURE 55-24** (A) ICD implant in 13-year-old girl with long QT syndrome. Intracardiac loop allows for growth. Strain relief loop is in the shoulder. Single-coil, screw-in lead permitted intracardiac loop. Twin-coil leads are now available. Generator is in posterior rectus sheath. (B) Lateral x-ray.

**FIGURE 55-25** ICD/DDD pacemaker for VT with prior bilateral radical mastectomies. Venous access via external jugular vein. Positive fixation leads tunneled vertically in the midline, the only location on the chest wall with adequate tissue. Generator subcutaneous in abdomen. Cosmetic result acceptable to patient.

infarction creates the areas of scarring and slow conduction needed for reentry. Other forms of VT and VF involve aberrancies of automaticity related to acute myocardial ischemia, increased ventricular wall stress, and myopathic cellular injury. Some class I antiarrhythmics have been shown to increase postinfarction mortality, possibly owing to proarrhythmic effects.

## Indications

Candidates for ICD insertion for secondary prevention therapy have suffered documented VT or VF in the absence of acute myocardial infarction and have been proved unsuitable for antiarrhythmic drug or surgical therapy, based on programmed electrical stimulation studies in the EP laboratory. However, many patients who suffer cardiac arrest do not have inducible VT at EP study, and many patients with a history of syncope and presyncope have inducible VT but no history of a clinical arrhythmia. Many antiarrhythmics have negative inotropic and proarrhythmic effects. Serial EP studies of drug efficacy have been discredited in clinical trials.<sup>7</sup>

In mid-1996 the Food and Drug Administration approved an indication for prophylactic ICD insertion based on early termination of the MADIT trial.<sup>55</sup> If EP studies demonstrate inducible VT in patients with nonsustained VT and a remote history of myocardial infarction, an ICD is indicated. MADIT II results support ICD insertion in all patients with a history of myocardial infarction and

left ventricular ejection fraction less than 30%. Primary prevention indications include ischemic cardiomyopathy with LVEF  $\leq$  35% and NYHA Class II or III  $\geq$  40 days post MI. LVEF  $\leq$  30% and NYHA Class I  $\geq$  40 days after MI also qualifies, as does nonischemic myopathy with LVEF  $\leq$  35% and NYHA Class II or III.

## Device Description

ICDs usually employ one bipolar lead for ventricular pacing/rate sensing and another to deliver the defibrillation current (Fig. 55-26). These are integrated into a single lead body for endocardial insertion.<sup>7</sup> A unipolar ventricular lead paired with an “active can” delivers the defibrillation current in some designs. Rate and waveform identify malignant rhythms for treatment. Up to 30% of ICD shocks are inappropriate, for sinus tachycardia or other supraventricular tachyarrhythmias. A bipolar atrial lead can help differentiate supraventricular arrhythmias from VT. Subcutaneous leads can be added for patients with high DFTs. Most implants are just caudad to the clavicle, but long lead lengths allow abdominal locations. Positive fixation leads are preferred.

The ICD contains a high-energy battery and a capacitor that steps up the output voltage to 600 to 800 V at 35 to 40 J. Shocks with positive and negative phases reduce DFTs. ICDs incorporate integrated circuits and a telemetry antenna. A broad range of programmable diagnostic and therapeutic functions are supported.

## Surgical Procedure

### PATIENT PREPARATION

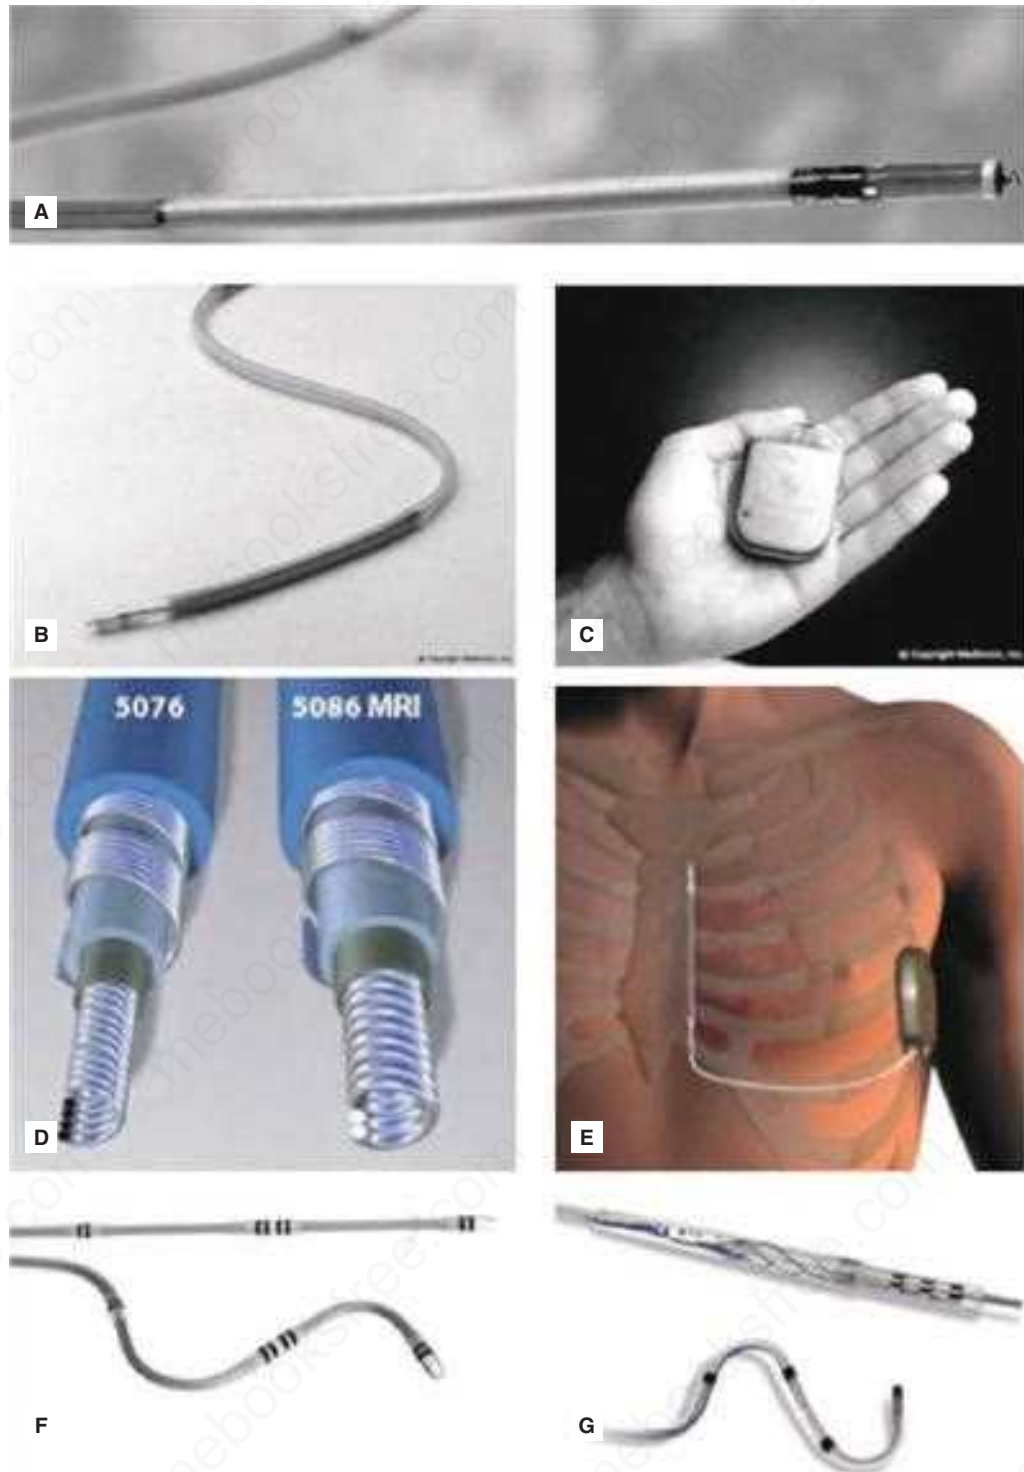

Most ICD recipients are at increased mortality/morbidity risk for any surgery. Preoperative optimization of therapy for ischemia, heart failure, and systemic illnesses is critical. The mortality of ICD implantation in our program has been low since 1983, with ischemia more lethal than severe cardiomyopathy. Ischemia on stress testing mandates CABG, coronary angioplasty, intra-aortic balloon pump, or deferral of DFT testing.

### SURGICAL APPROACH

Epicardial patch leads<sup>59,60</sup> are now rarely used. They fell into disfavor when the CABG Patch Trial demonstrated that infectious complications were more common in ICD recipients than control patients.<sup>57</sup> Extrapericardial ICD patches cause less fibrosis, less impairment of diastolic properties,<sup>61,62</sup> and less potential for graft impingement than intrapericardial patches. Biphasic waveforms, improved leads, high-output “hot can” generators, and subcutaneous leads have made the endocardial approach successful.<sup>7</sup>

### MANUFACTURER’S REPRESENTATIVES

The complexity of current devices and a large number of spare parts, leads, and catheters have legitimized the presence of manufacturer’s representatives during ICD implants.

**FIGURE 55-26** (A) ICD lead (9 French) with Gore-Tex-coated shocking coils. (B) ICD lead (7 French) with retractable screw. (C) ICD/pacemaker. (D) Early design MRI-compatible pacemaker leads. (E) Wireless ICD. (F) and (G) Over-the-wire multielectrode lead for coronary sinus pacing. (A, E: Image provided courtesy of Boston Scientific. © 2016 Boston Scientific Corporation or its affiliates. Reproduced with permission of St. Jude Medical, © 2016. All rights reserved.)

This increases influence of the manufacturer on the implant and warrants oversight. CRS regulations mandate electrophysiologist oversight of DFT measurement.

## TECHNIQUE

We prefer local anesthesia, conscious sedation, and unipolar cautery for endocardial ICD insertion. Invasive, radial artery pressure monitoring is used during DFT measurement. Positioning and draping are similar to that for pacemaker insertion. Adhesive defibrillation pads are added over the right breast and beneath the left scapula. Pads should not be placed directly over the site of a possible subcutaneous ICD patch or array in the lateral axilla; this can result in serious equipment damage from arcing if external defibrillation is necessary. Cefazolin or combined vancomycin/gentamicin is used for antibiotic prophylaxis.

We prefer a cephalic vein cutdown via a 6-cm incision over the deltopectoral groove. If the vein is small, a guidewire is used to insert a 9-French introducer. Enlargement of the cephalic venotomy may be helpful (Fig. 55-8). The guidewire can be left in place if a multiple-lead system is to be employed. Introducer kinking can lead to difficulty passing ICD leads. High central pressures will cause bleeding until the introducer is removed. Aligning the introducer with the course of the subclavian vein before removing the obturator minimizes this.

As the lead enters the ventricle, VT or VF may be triggered. This is less disruptive if an external defibrillator is connected and precharged, with a capable OR nurse or electrophysiologist at the controls. The ventricular lead should be advanced gently as far as possible to the apex. Positive fixation ICD

leads are best for both atrium and ventricle. Fluoroscopic and impedance checks for lead displacement are warranted during DFTs, particularly if external defibrillation is necessary. Intravenous norepinephrine is useful for blood pressure support. In patients under general anesthesia, transesophageal echocardiography is useful for monitoring LV function during DFTs. Swan-Ganz catheters are not useful for monitoring—their removal can dislodge the ICD leads.

If CRT is indicated, we insert the LV lead first, via cephalic cutdown. RV and RA leads are inserted via subclavian puncture. CS localization can be expedited by steerable EP catheters, dye injection to detect blood flow out of the CS, transesophageal echocardiography, and other techniques.<sup>5</sup> The left subclavian location is now the standard of care for generator location, in a subcutaneous or subpectoral pocket.

The left upper quadrant abdominal or posterior rectus sheath (Fig. 55-24) is now a rare pocket option and requires long leads, general anesthesia or sedation/local anesthesia to tunnel leads to the abdomen from the subclavian incision. The tunneler must pass anterior to the costal margin. The lead is looped at the shoulder and firmly secured against displacement by a tug on the abdominal end (Figs. 55-24 and 55-25). A limited thoracotomy may be required to add an epicardial lead for CRT if endocardial CS lead insertion fails (Fig. 55-27).

## DEFIBRILLATION THRESHOLD

DFT testing was previously the standard of care but is increasingly controversial, particularly in primary prevention implants, and should be done in consultation with an electrophysiologist.<sup>5</sup> Vulnerability testing is a described option. DFT testing is also less important as technological advances have

**FIGURE 55-27** Epicardial LV leads inserted in 45-year-old man for treatment of congestive heart failure after two failed endocardial attempts. PM-ICD was required for complete heart block and cardiomyopathy after aortic and mitral valve replacement for bacterial endocarditis.

increased the probability of success. The DFT is the point of maximum risk in ICD insertion and is usually induced twice and reversed by the ICD to confirm a 10-J safety margin and adequate sensing of VF. Backup defibrillation is available through defibrillation pads. If the DFT is too high after optimizing RV lead location, a subcutaneous axillary patch or wire is used to distribute the defibrillation current over the posterolateral left ventricle. High-output generators and reversed shock polarity may also help. DFT testing can depress cardiac function and cause a low-output state.<sup>5,46</sup> The mortality of ICD insertion is about 1%. Complications include myocardial infarction, heart failure, infection, lead displacement, venous occlusion, tamponade, hemopneumothorax, and pocket hematoma.

### REFRACTORY VENTRICULAR FIBRILLATION

VF may become refractory to external defibrillation as a result of iatrogenic pneumothorax, myocardial ischemia, electromechanical dissociation, and inappropriate ICD lead location. Refractory VF rarely may require open cardiac massage or cardiopulmonary bypass until a solution can be found.

### POSTOPERATIVE CARE

Same day discharge or telemetry and an overnight stay are both current practice after ICD insertion for secondary prevention, and DFT testing is controversial. Pacing and sensing properties confirm lead stability before discharge. In some cases, DFTs are also retested. An ICD magnet should be available for treatment of patients with freshly implanted ICDs. The magnet is used to inhibit inappropriate shocks caused by ventricular lead displacement or supraventricular arrhythmias. Patients undergoing ICD insertion for primary prevention may be discharged on the day of surgery. We administer ciprofloxacin for 5 days after discharge to complete prophylaxis based on a historical precedent. A postoperative office visit is scheduled 7 to 14 days after implant.

### SURGICAL FOLLOW-UP

At the postoperative office visit, lead position, patient symptoms, EP follow-up appointments, and the surgical site are assessed. If drainage is present, the wound is cultured and treated. For sterile drainage, ciprofloxacin or trimethoprim-sulfamethoxazole is administered for 10 days, and the patient is asked to keep the site dry until healing is complete. Refractory infection requires hospitalization and ICD removal.

### DEVICE FOLLOW-UP

ICDs require outpatient EP evaluation at 1- to 3-month intervals to cycle the capacitors, confirm battery life, test pacing thresholds, and download electrograms. Data are reviewed for aborted charging cycles arrhythmias. Programming is adjusted accordingly. For any shocks reported, telemetry can confirm proper function, detect inappropriate shocks, and demonstrate electrical noise or oversensing that requires lead revision. Wireless ICD monitoring from home is now a clinical reality for some ICDs.

## Late Follow-up and Generator Replacement

### BATTERY DEPLETION

ICD battery life is now typically more than 60 months. Complications of generator replacement include infection, myocardial infarction, and death. Progression of heart failure and/or coronary artery disease increases the risk of replacement. Replacement is done under local anesthesia, with sedation during DFTs. DFTs may be deferred if the risk is excessive. Patients are discharged on the same day with antibiotic coverage, unless leads are replaced.

### LEAD DYSFUNCTION

The incidence of lead failure increases with time. About 50% of ICD recipients have some lead revision by 10 years of follow-up.<sup>63</sup> Problems include lead fracture,<sup>64</sup> high DFTs, oversensing, undersensing, and exit block. Oversensing can be caused by insulation damage. Oversensing can be corrected by adding a transvenous rate-sensing lead, preferably of the positive-fixation type. Visible insulation damage inside the defibrillator pocket may be repairable with silicone glue, tubing, and ties.

Patch leads can fail because of conductor fracture or distortion by fibrosis. With endocardial leads, DFTs may increase as a result of cardiac enlargement, which shifts the left ventricle laterally, away from the right ventricular lead. Insertion of a subcutaneous patch or array (Fig. 55-28) and/or a high-output generator can correct high DFTs.

## Additional Issues

### BRIDGE TO TRANSPLANT

CRT-D therapy is increasingly common for amelioration of symptoms and protection against VT/VF in patients awaiting cardiac allografting. Cost is an important concern.

### QUALITY OF LIFE

Issues include the discomfort and distress of shocks and inconvenience of outpatient visits. These are particularly trying for elderly patients. ICD generators, though shrinking in size and weight, are bulky compared with pacemakers. Many patients are elated to be rescued by their ICD from a malignant arrhythmia, but others find this distressing.<sup>40,65,66</sup> Many ICD patients do not comply with recommended limitations on driving automobiles.<sup>67,68</sup> Fortunately, the rate of driving accidents in ICD recipients is reportedly low.

### COST-EFFECTIVENESS

ICD therapy is expensive, but VT/VF management in the absence of an ICD is also costly.<sup>69</sup> Low cost of ICD generators and leads would increase the economic appeal of ICD prophylaxis.

**FIGURE 55-28** This illustrates posterolateral accessory lead inserted in chest wall for failure of ICD to defibrillate. Patient is 62-year-old female with prior anteroseptal myocardial infarction. ICD function was initially satisfactory, but progressive CHF and LV dilatation created excessive ICD energy requirement.

## NEW TECHNOLOGY

ICDs and pacemakers that do not require endocardial leads are available or in clinical trials. Functionality of these systems is limited but valuable for selected patients.

# Surgery for Adult Congenital Heart Disease

Redmond P. Burke

Adults with congenital heart disease now outnumber children with this malady. They constitute a growing population of survivors, with increasingly complex treatment requirements for their heart disease. Over the past two decades, the spectrum of complexity for adult congenital heart disease (ACHD) patients has evolved from late primary repairs of patients with simple lesions—including coarctation, patent ductus arteriosus, septal defects, and tetralogy of Fallot—to  $n$ th time reoperations on survivors of complex multistaged palliations. Significant efforts to define the optimal program resources necessary to effectively treat ACHD patients have been made worldwide,<sup>1</sup> yet many congenital heart patients continue to suffer from poor continuity of care as they enter adulthood. This chapter will describe several salient treatment strategies for adult patients undergoing congenital heart surgery.

## REDUCING CUMULATIVE THERAPEUTIC TRAUMA

The optimal venue for ACHD treatment is unknown, and it is fair to say that no two programs are the same. The need for a coordinated and comprehensive programmatic strategy for care has been well described, and should encompass not only the lifetime of a generation of patients with congenital heart defects from fetal to adult life, but also the health of pregnant mothers with congenital heart disease who will give birth to a new generation.<sup>2</sup> Pregnant mothers with fetal diagnoses of congenital heart disease may be asked to undergo invasive intrauterine procedures to palliate their fetal child's heart, thus creating a new group of adult patients dealing with the trauma of congenital heart care.<sup>3</sup>

Our congenital heart program philosophy is to reduce the cumulative trauma of care for each patient with congenital heart disease over their lifetime. To achieve this, we discuss each adult patient referred to our program for surgery or intervention in a combined conference with participation from adult and pediatric interventional cardiologists and surgeons, dedicated cardiac intensivists, cardiac anesthesiologists, cardiac imaging specialists, and the cardiac nursing, pharmacy

and social work teams. Treatment options are selected so that the least traumatic form of effective therapy is chosen as the initial approach. Failure to achieve a good result leads to an escalation to the next least traumatic option. As an example, a patient with a secundum atrial septal defect (ASD) would be put forward for device closure, and if this failed, the patient would then be given the option of a minimally invasive surgical repair.

## INFORMATION SYSTEMS

Adult congenital heart disease patients with complex lesions often have dense medical histories, stored in multimedia formats, which expose the weaknesses of current paper and electronic medical record (EMR) systems. Increasing utilization of EMRs by medical teams, and personal health records (PHRs) by patients and families, has been demonstrated to improve outcomes in some patients with chronic disease.<sup>4</sup> However, pediatric heart patients and their families often have not been educated about their disease, and what to expect as they transition to adulthood. The PHR could be used to enhance patients' understanding, and provide roadmaps for follow-up treatments and diagnostic studies. These information systems could also be linked to national and international registries designed to measure clinical outcomes and performance for centers treating adult congenital heart patients.<sup>5</sup>

The emergence of Web-based hospital EMR systems allows our cardiac team to track patients over their lifetime, and retrieve critical patient information on demand. We have also enabled our patients to access specific data fields from the EMR. We capture intraoperative endoscopic images of each congenital heart lesion, before and after repair,<sup>6</sup> and store these images in our EMR. We also capture and store a daily picture of each hospitalized patient. These images are reviewed in morbidity and mortality conferences, to correlate with other clinical information and imaging techniques. The operative images are reviewed prior to reoperations, to regain familiarity with the patient's anatomy.<sup>7</sup> The operative images from this chapter were retrieved from this online image database (Fig. 56-1).

**FIGURE 56-1** This is a screen image from our first electronic medical record, showing the operative images for a patient with truncus arteriosus. These images were captured in the operating room, and immediately uploaded to a Web-based EMR. These can be retrieved on demand by searching by procedure, diagnosis, or individual patient.

## COMMON ADULT CONGENITAL HEART DISEASE PROCEDURES

### Reoperative Sternotomy

Congenital heart procedures in adults are frequently reoperations, however, standardized protocols for reoperations in patients with acquired heart disease may not match the challenges presented by ACHD patients. Risk factors for traumatic repeat sternotomy in ACHD patients differ from those identified in patients with acquired heart disease, which often focus on dealing with patent coronary artery bypass grafts.<sup>8</sup> Femoral cannulation is often difficult in ACHD patients who have undergone multiple interventional catheterizations during their growth years, resulting in stenotic or occluded femoral vessels. Consequently,

we rarely use elective or emergent peripheral cannulation. Key risk factors for ACHD reoperations include retrosternal ventricular to pulmonary artery conduits, particularly if they are calcified, have multiple stents in place, or are clearly embedded in the sternum. Fusion to the sternum should be suspected when the conduit does not move with the cardiac cycle on lateral angiograms. Patients with pulmonary hypertension, right ventricular enlargement, prior sternal infections, aneurysms of the right or left ventricular outflow tracts, pectus excavatum, or aortopulmonary shunts are at increased risk, and qualify for preliminary vascular access dissection and pursestring placement. Patients with multiple risk factors may be placed on bypass to decompress the right ventricle prior to sternal division.

We excise previous sternotomy scars and remove sternal wires. The xiphoid process is removed, and cautery dissection

is begun at the inferior sternal edge. The oscillating saw is used to divide the anterior sternal table. Rakes are used to elevate the two sides of the sternum and expose the retrosternal scar. Short segments of retrosternal scar are released, followed by gradual sternal division with the oscillating saw, proceeding up the sternum.

In the event of cardiac or great vessel penetration during sternotomy, when we have not already exposed vessels for cannulation, we release the sternal retractors, and immediately extend the neck incision up and to the right to expose the innominate artery and the internal jugular or high innominate vein. These vessels are cannulated through pursestrings, and bypass is initiated. In patients where venous access cannot be achieved in the suprasternal area, we dissect the inferior vena cava just above the diaphragm. This approach has been described as “simplified aortic cannulation.”<sup>9</sup> The sternotomy is completed with the patient in Trendelenburg position. We continuously infuse carbon dioxide into the operative field during every operation to reduce the risk of air embolism, although evidence supporting this technique is not conclusive.<sup>10</sup>

To reduce adhesion formation, and decrease the risk of future sternotomy, we prevent cardiac dessication by covering the heart with saline-soaked gauze throughout each operation. At the completion of ACHD repairs we occasionally place antiadhesion materials to decrease retrosternal adhesions. In some centers, expanded polytetrafluoroethylene (PTFE) is routinely placed behind the sternum prior to closure.<sup>11</sup> Capsule formation may obscure natural tissue planes, making subsequent reoperative dissection more difficult. Bioresorbable films<sup>12</sup> and sheets of extracellular matrix<sup>13</sup> derived from pig jejunum have also been approved for use as pericardial substitutes.

## Atrial Septal Defects

The advent of transcatheter device closure for ASDs has significantly changed the average complexity level of ACHD surgical case volumes. Patent foramen ovale and most secundum defects are effectively closed with devices, and are rarely referred for surgical closure in programs with effective interventional catheterization teams. Sinus venosus and primum defects, transitional and complete atrioventricular canal, common atrium, and secundum defects with deficient inferior and superior rims are referred for surgery and we repair these on cardiopulmonary bypass with bicaval cannulation and ischemic arrest.

Multiple incisional approaches have been described to improve the cosmetic result, and reduce operative trauma, after open-heart surgery. These include partial upper and lower sternotomy, transxiphoid, anterior thoracotomy, and submammary incisions. Despite the visible scar, median sternotomy may be the least traumatic incision for ACHD patients, allowing the surgeon to avoid vascular trauma from peripheral cannulation, intercostal muscle, vessel, and nerve damage, and mitigate the risk of post-thoracotomy pain syndrome. Median sternotomy

allows direct aortic control for safe, effective cannulation, decannulation, deairing, and cardioplegia administration with minimal risk of dissection. Median sternotomy also ensures direct and rapid access to the entire mediastinum, allowing surgeons to deal with unanticipated anatomic variations discovered at surgery, which are not uncommon in ACHD patients.

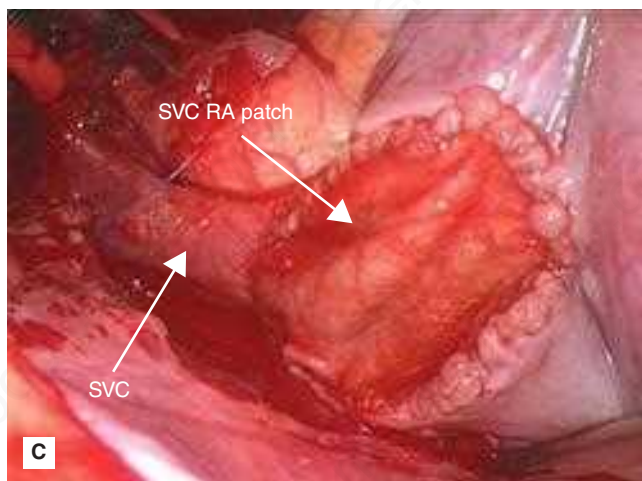

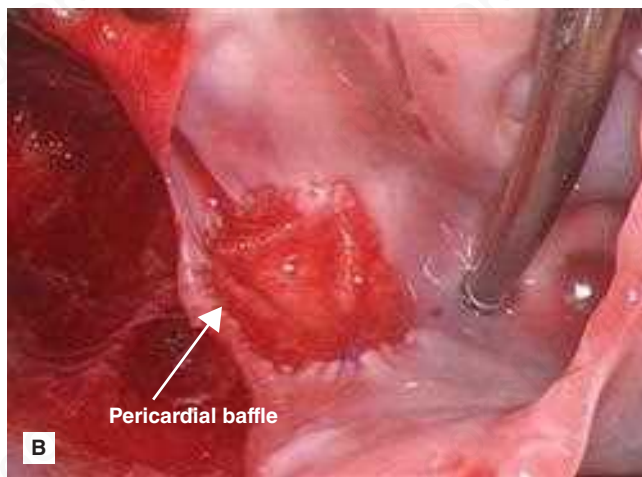

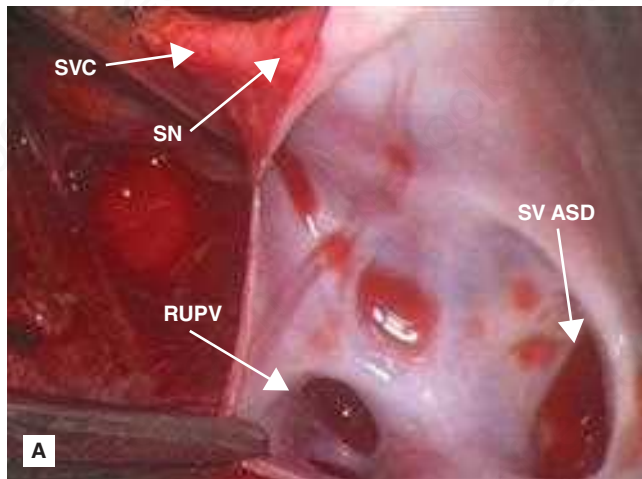

Our venous cannulation strategy for ASDs is bicaval, via the right atrial appendage into the superior vena cava, and down the inferior venal caval junction into the inferior vena cava. Smaller defects, which in the past might have been closed primarily, are now rarely referred for surgery, and we find that repairs are best performed with patch materials, ideally glutaraldehyde-treated pericardium. Placing the smooth surface on the left atrial side, we use running suture lines of fine polypropylene to create tension-free suture lines (Fig. 56-2A).

For sinus venosus defects, we place a right-angled cannula in the innominate vein, to enable exposure of the partial anomalous pulmonary veins entering the superior vena cava. The atrial incision is made laterally to avoid the sinus node area, and is extended superiorly to a point above the entrance of the highest anomalous vein. A native pericardial patch is used to close the atrial incision to avoid superior vena caval stenosis (Fig. 56-2B).

In patients with primum ASDs, the cleft mitral valve is routinely repaired with fine running polypropylene suture lines, approximating the line of contact between the leaflet segments. Even patients with competent valves are repaired, as late onset of cleft regurgitation is known to occur. Patients at risk for mitral stenosis, particularly those with a single papillary muscle in the left ventricle, may have their clefts left open to avoid valvar stenosis. Results for these repairs are excellent, even in patients at advanced ages.<sup>14</sup>

## Ebstein's Anomaly

Surgery for Ebstein's anomaly can be performed in older patients at low risk and with good late outcome. The operation is comprised of tricuspid valve repair or replacement, and concomitant procedures such as ASD closure, arrhythmia surgery, and coronary artery bypass grafting.<sup>15</sup> Repair techniques for these patients continue to evolve. We believe the presence of an untethered and well-developed anterior tricuspid valve leaflet increases the chance of a successful repair, and have used the Cone technique in adult patients.<sup>16</sup> This repair requires dissection of the anterior and posterior tricuspid valve leaflets from their right ventricular attachment. The free edge of the anterior leaflet is then rotated clockwise and sutured to the septal leaflet border. This produces a cone-shaped valve, fixed distally at the right ventricular apex, and proximally at the tricuspid valve annulus. The septal leaflet is incorporated into the cone wall whenever possible, and the ASD is partially closed. Results have been good, with low mortality, significantly less tricuspid regurgitation, and improvement in functional class.

**FIGURE 56-2** (A) Operative image of sinus venosus defect showing the pulmonary vein orifices, the superior vena cava, and the septal defect. (B) Operative image of two patch repair with an internal patch baffling the pulmonary veins to the left atrium, and an external patch to prevent obstruction of the superior venal caval entry into the right atrium.

## Fontan Revision

In the modern era, the primary cause of death for adult patients with cyanotic lesions is arrhythmia, followed by heart failure.<sup>17</sup> Fontan patients may present with arrhythmia and complications related to systemic ventricular failure, protein-losing enteropathy (PLE), systemic venous pathway obstruction, and semilunar and atrioventricular valve dysfunction. Initial evaluations must focus on ensuring a completely unobstructed vascular pathway to the lungs. The different types of surgical technique historically used to create the Fontan circulation each have characteristic complications. Patients with intracardiac baffles and atriopulmonary connections may present with extreme right atrial enlargement, resulting in stagnant flow, right pulmonary vein compression, and arrhythmia.

Fontan conversion involves takedown of the previously created venous connection, and creation of an extracardiac cavopulmonary connection with a conduit. Because the extracardiac Fontan excludes the systemic veins from the heart, any catheterization procedures requiring atrial level intervention, particularly electrophysiology interventions, must be planned before conversion. We therefore plan Fontan conversions with our electrophysiology team, and frequently combine Fontan conversions with arrhythmia surgery,<sup>18</sup> and treatment of atrioventricular valve dysfunction. Valve repairs are often complex in these patients, and replacements are often required to achieve good hemodynamic results.<sup>19</sup> Results depend on the patients' underlying anatomy, right ventricular function, and pulmonary vascular resistance.<sup>20</sup>

We perform extracardiac Fontan procedures with bicaval cannulation, and leave the heart warm and beating whenever possible. The inferior vena cava is transected at the cavo-atrial junction under a clamp, and the cardiac end is oversewn with a running 4-0 polypropylene suture. We use a ring reinforced expanded PTFE graft from 19 to 23 mm in diameter, and leave enough length to avoid right pulmonary vein compression. The superior anastomosis to the superior vena caval junction with the right pulmonary artery is then constructed with a running 6-0 polypropylene suture. Hybrid stenting procedures, where the interventional catheterization team comes into the cardiac operating room to deploy stents, are used to treat stenoses in the retroaortic pulmonary arteries.

In patients with complex cardiac anatomy, these Fontan revision procedures may best be performed with the participation of the electrophysiology team. This ensures effective interruption or ablation of all reentrant pathways, which may not follow the patterns seen in patients with acquired heart disease and normal cardiac anatomic relationships. A variety of Maze type procedures have been described in an effort to disrupt atrial reentrant pathways. The unpredictable anatomy of the conduction tissue in ACHD patients has resulted in frequent need for pacemaker insertion. In many centers, customized pacemaker therapy has been advocated for management of patients following Fontan conversion. However,

based on an experience with 120 Fontan conversion from 1994 to 2008, which began with a flexible approach to each patient's anticipated pacing needs, Tsao et al now recommend routine placement of a dual-chamber antitachycardia pacemaker with bipolar steroid-eluting leads in patients undergoing Fontan revision.<sup>21</sup>

## Right Ventricular Outflow Tract Reconstruction

Right ventricular outflow tract (RVOT) reconstruction after previous repair of tetralogy of Fallot, double outlet right ventricle, pulmonary atresia, truncus arteriosus, and arterial switch procedures are increasingly common, as patients who underwent successful neonatal and infant repairs are returning with pulmonary insufficiency and/or stenosis, resulting in right ventricular dysfunction, exercise intolerance, arrhythmias, and sudden death.<sup>22</sup> The first percutaneous pulmonary valve replacement was performed by Bonhoeffer and colleagues in 2000,<sup>23</sup> and this therapy is increasingly available as clinical trials have demonstrated safety and efficacy, and improvement in the New York Heart Association (NYHA) functional class is evident at 1-month postprocedure.<sup>24</sup> This less invasive therapy has accelerated the study of ACHD patients with pulmonary valve disease who were previously followed for years to avoid the trauma of reoperation. The growing experience with transcatheter pulmonary valve insertion into previously placed RVOT homografts and conduits suggests that homograft infection is rare, and stent fractures are more common (32%), but benign. The percutaneous valves have a median maximum instantaneous gradient across the RVOT of 23 mm Hg.<sup>25</sup> With surgical standby, patients with rupture can be placed on emergent bypass, and undergo surgical repair with good results.<sup>26</sup> Indications for pulmonary valve replacement in ACHD patients are evolving, and optimal indications and timing remain unclear. Preoperative evaluation with echocardiography, magnetic resonance imaging (MRI), and cardiac catheterization are used to identify concomitant lesions, particularly patent foramen ovale, coronary anatomy, and right ventricular dimensions and function.

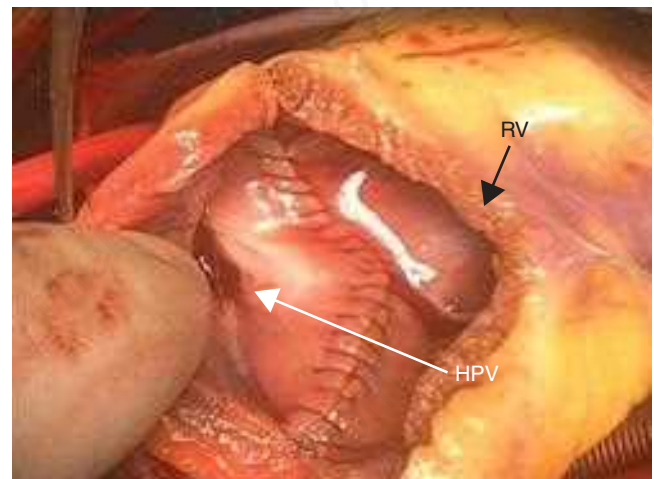

For patients not amenable to transcatheter pulmonary valve implantation, our standard surgical approach includes median sternotomy, bicaval cannulation, and repair on cardiopulmonary bypass with moderate hypothermia. These repairs may be performed without ischemic arrest if provocative preoperative testing (bubble test with Valsalva) is negative; however, we prefer to perform these operations with the aorta cross-clamped. We control the branch pulmonary arteries with tourniquets and place a right ventricular vent in the atrium to create a clear operative field. If a previous right ventricular incision or patch is present, this is used as a safe reentry point, and the incision is extended far enough to inspect the right ventricle and allow resection of obstructing intracavitary muscle bundles. Pulmonary valve replacement options include pulmonary and aortic homografts, bovine

jugular vein grafts, bioprosthetic valves, and mechanical prosthetic valves.

Homografts may be selected based on appropriate size and length to match the patient's anatomy, and echocardiographic estimates of the normal pulmonary valve dimensions for that patient's weight. Conduits must be cut to the appropriate length to prevent tension (too short) and kinking (too long). We perform the distal pulmonary artery anastomosis with a running 6-0 monofilament polypropylene suture, and then trim the proximal homograft muscle cuff to match the right ventricular incision. The proximal anastomosis is constructed with a larger running suture and needle, and care is taken to avoid the left main and anterior descending coronary arteries. When these cannot be visualized due to epicardial scarring, we use intraoperative fluorescent imaging to map the coronary arteries on the surface of the right ventricle.<sup>27</sup> The anterior portion of the outflow tract is completed with a patch of native or bovine pericardium (Fig. 56-3).

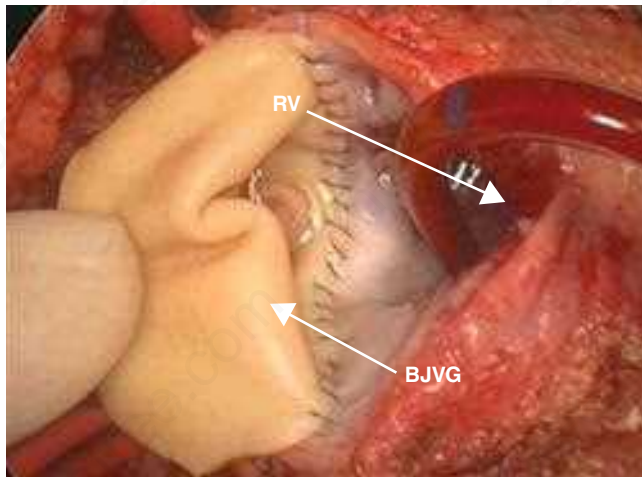

The bovine jugular vein valve is sized and implanted in a similar way to homografts, with a distal running suture line. The proximal graft is beveled, so that a separate hood patch is not necessary. Ten years after implantation, bovine jugular vein grafts have significantly less failure, dysfunction, and explant rates, than pulmonary homografts in matched patient groups (Fig. 56-4).<sup>28</sup>

Bioprosthetic and mechanical valves are positioned in the RVOT at the normal pulmonary valve annulus in patients with normal right ventricular anatomy, or in a position that avoids sternal compression (more distal implantation is often necessary after repair of truncus arteriosus and pulmonary atresia). Compression of the left main coronary artery must also be considered when positioning these rigid valve rings. We have used both an interrupted horizontal mattress suture technique, and a running polypropylene suture technique for these implants. Both require that the valve suture line be constructed so that the valve orients parallel to the main

**FIGURE 56-3** Right ventricular outflow tract reconstruction with a pulmonary homograft.

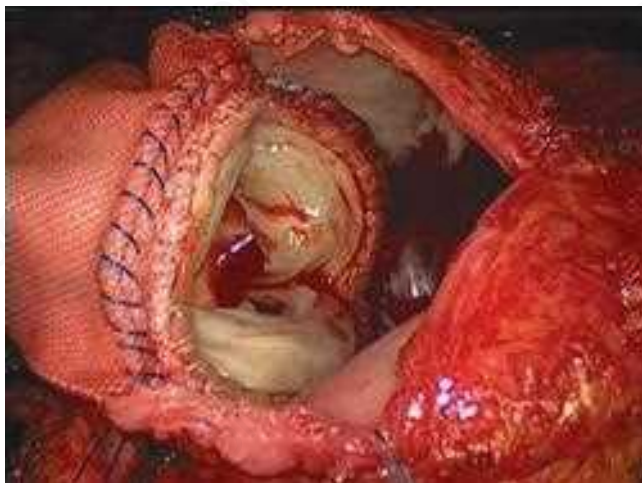

**FIGURE 56-4** Right ventricular outflow tract reconstruction with a bovine jugular vein graft.

pulmonary, avoiding the tendency for the valve to aim up toward the sternum. The surgeon must also ensure that valve struts do not obstruct the branch pulmonary arteries. A patch may be used to close the main pulmonary artery and infundibulum when the implanted valve does not fit in the native outflow tract (Fig. 56-5).

Advantages and disadvantages exist for each pulmonary valve replacement option.<sup>29</sup> Homografts and bovine jugular veins have length and can be used to span long gaps between the right ventricle and the branch pulmonary arteries. The distal anastomosis can be configured to repair stenotic sections of the main pulmonary artery and the proximal branches. They also form suitable conduits for subsequent insertion of transcatheter pulmonary valves in the future if they become stenotic or insufficient. We try to tailor our conduit decisions to meet the implantation requirements for transcatheter pulmonary valve insertion. These evolving requirements

**FIGURE 56-5** Reconstruction of the right ventricular outflow tract with a bioprosthetic valve using a running suture technique and an onlay patch.

are factored into our decision process in selecting a conduit during our current surgical pulmonary valve replacements. Available bioprosthetic valves are also suitable for subsequent insertion of a transcatheter valve, as the valve ring provides a stable landing zone for the transcatheter valve stent. Mechanical valves do not allow subsequent placement of a transcatheter pulmonary valve, and we no longer use them for in the pulmonary position. RVOT reconstruction can now be performed with low morbidity and mortality, and conduit options continue to expand.

## Left Ventricular Outflow Tract Reconstruction

Isolated areas of left ventricular outflow tract obstruction (LVOTO) are less common in ACHD patients than in those with acquired left-sided lesions. ACHD patients with LVOTO must be evaluated for upstream and downstream stenoses, as multiple levels of obstruction are common. Patients with Shone's syndrome often undergo numerous surgical and interventional procedures over their lifetimes, and these interventions are at best palliative. Adult congenital teams must be prepared to perform primary Ross, Ross-Konno, and Konno procedures, and deal with reoperations for each of these palliations. The Ross operation is often used in pediatric patients with complex LVOTO to treat combined valvar and supravalvar lesions, avoid anticoagulation, and maintain some growth potential. These patients may require reoperations as adults to replace or repair failing neo aortic valves, and stenotic or regurgitant pulmonary valves. Follow-up of right ventricular reconstructions after Ross operations shows that 4% of patients will require conduit replacement for right ventricular dysfunction at 10 years. Conduit size less than 14 mm is an independent predictor of allograft dysfunction.<sup>30</sup>

Freedom from reoperation for regurgitation of the pulmonary autograft in the aortic position is quite variable, with reports from 87<sup>31</sup> to 96%.<sup>30</sup> The advent of percutaneous aortic and pulmonary valve options may increase the utilization of the Ross operation, as reinterventions on the autograft and allograft may not require reoperation. Aneurysmal dilation of the neo aortic root after the Ross operation is related to use of the root technique, and may be seen in up to 11% of patients at 7 years after surgery. Good outcomes after reoperation can be achieved, but successful repair of the autograft is more likely if the diagnosis is made early, before the neo aortic valve becomes insufficient.<sup>32</sup>

The Konno aortico ventriculoplasty is used to treat complex LVOTO in patients with supravalvar, valvar, and subvalvar obstruction, and may be encountered in adults who require initial treatment, or reoperations for valve malfunction or outgrown valves. The Ross-Konno, utilizing the transplanted pulmonary autograft with a ventricular septal patch or infundibular extension, has been shown to increase in size as the patients grow, making this an excellent option in small pediatric patients. In a review of 53 patients operated on from 1980 to 2004, with an average age of 19, Suri et al reported risk factors for overall mortality included NYHA

class (hazard ratio 2.22,  $p = .04$ ). The cumulative probability of aortic valve reoperation was 19% at 5 years and 39% at 10 years, occurring in 15 patients at a median of 3.8 years. Pulmonary regurgitation was detected in six patients. Pulmonary valve replacement was performed in three (6%).<sup>33</sup>

Reoperations after Ross, Ross-Konno, and Konno procedures may be particularly challenging. This is especially true if the RVOT has been reconstructed with a large patch covering the anterior aortic wall. Exposure of the aortic root then necessitates reentry into the right ventricle. Given the high incidence of reoperations on these patients, antiadhesion barriers are recommended.

## Arrhythmia Surgery

Maintaining a functional conduction system is a crucial aspect of reducing the cumulative lifetime trauma for a congenital heart patient. Despite efforts to prevent conduction tissue injury, ACHD patients are at risk for a wide array of conduction delays, as well as atrial and ventricular tachyarrhythmias. Pacemaker and defibrillator insertion, lead extractions, and generator changes are frequently complicated in ACHD patients who may have unusual anatomic pathways and stenotic or occluded veins. Epicardial lead placements are often necessary in single ventricle patients who have limited or no venous access to the endocardium. Common indications for lead removal include pocket infection, malfunctioning leads, skin erosion, endocarditis/septicemia, vena cava thrombosis, and painful leads. Lead extraction technology is evolving, and can be safely managed as a hybrid effort with a surgeon and electrophysiologist working together. A number of lead removal catheters are available using blades or laser energy to excise embedded leads. Surgical support is necessary in the event of cardiac perforation. Outcomes are generally good, even in octogenarians,<sup>34</sup> with sepsis being the strongest predictor of death after pacemaker device removal.<sup>35</sup>

Supraventricular and ventricular arrhythmias are a major cause of morbidity and mortality in adult patients with congenital heart disease. For patients with atrial fibrillation or flutter undergoing open-heart repairs, a right-sided Maze procedure can be performed with the expectation of 93% freedom from arrhythmia, and improvement in functional class.<sup>36</sup>

Minimally invasive approaches to arrhythmia surgery, such as the Mini-Maze procedure, are increasingly popular in patients with acquired heart disease and arrhythmia.<sup>37</sup> These approaches may be difficult to accomplish in certain ACHD patients because of unusual anatomic relationships, and extensive reoperative scarring, which may limit exposure through small incisions. The Cox-Maze procedure for supraventricular arrhythmias in ACHD patients is often complex, and an alternative approach using intraoperative monopolar irrigated radiofrequency ablation (IRA) has been described with good results for patients undergoing elective cardiac surgery. Prophylactic arrhythmia surgery for patients undergoing congenital heart repairs has been considered for high risk groups, and these strategies are evolving.<sup>38</sup>

## Hybrid Procedures

We define hybrid procedures as those using combined surgical and interventional personnel and technology during a single operation. Hybrid procedures can be performed in the catheterization laboratory, the operating room, or ideally in a hybrid procedure suite. We select the venue based on which technology is most critical for the success of a given procedure. The advent of percutaneous cardiac valve replacement and endovascular stenting reinforce the need to embrace a unified team approach for adult congenital heart patients. In those requiring interventional, surgical, and electrophysiological procedures, we attempt to integrate the procedures into a single hybrid operation, with the surgical team providing the least traumatic form of vascular access. Surgeons can also provide central vascular and direct cardiac access for sheath placement in patients with stenotic or occluded peripheral vessels, or when placing large devices in small patients. We routinely deploy aortic and pulmonary artery stents in the operating room using direct vision, video assisted cardioscopy, and angiography (Fig. 56-6).

Elective or emergent cardiopulmonary bypass support should be available on demand in the hybrid operating room, catheterization laboratory, and cardiac intensive care unit (Fig. 56-7).

Real-time consultation between surgeons and interventionalists may enhance outcomes for patients undergoing transvascular stent, device, and valve implantations. With a surgeon's input at the time of implantation, pulmonary artery stents may be positioned to facilitate subsequent operations. For example, pulmonary artery stents may be positioned more proximally to avoid damage to small distal branches at the time of reoperation. Aortic arch stent positioning can be optimized to reduce the distance down the distal arch the surgeon must dissect if reoperation is required to open a stent that cannot reach adult size. This type of planning and teamwork has proven to be useful in the emerging experience with transcatheter aortic valve replacements.<sup>39</sup>

**FIGURE 56-6** A hybrid procedure with surgical partial lower sternotomy and transcatheter sheath placement followed by interventional catheterization.

**FIGURE 56-7** A cardiopulmonary bypass circuit is prepared for emergent or elective use during hybrid procedures and complex interventional catheterizations.

### Coarctation of the Aorta

Primary and recurrent coarctation of the aorta in adult patients is increasingly managed percutaneously with balloon dilation and stents.<sup>40</sup> We provide surgical backup for these procedures in the event of device migration, dissection, or rupture, and occasionally to establish vascular access. When transcatheter therapy is not feasible, we proceed with surgical repair of adults with coarctation and aortic arch obstruction. These operations are performed through a left thoracotomy in patients with a left aortic arch, and the perfusion team is on standby for left atrial appendage to descending aortic cardiopulmonary bypass. Three general techniques can be used, including coarctation resection with end-to-end anastomosis, onlay patch enlargement with tissue or prosthetic patch, and synthetic tube interposition. Aortic mobility is limited in adult patients, and tension-free repairs most often require interposition grafts. We use subcutaneous local anesthetic infusion catheters and liposomal bupivacaine to control postoperative pain. We anticipate labile blood pressure responses in patients with long-standing hypertension. Postoperative hypertension is common and responds to sodium nitropruside. Mortality for these procedures is rare, and at follow up 75% of patients will be normotensive without medication.<sup>41</sup>

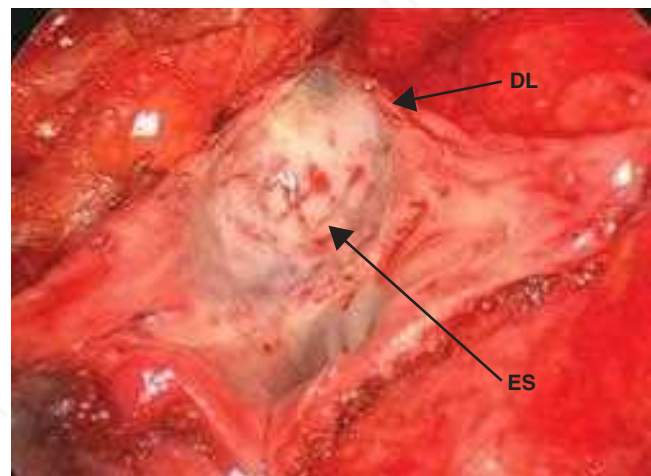

### INTERVENTIONAL DEVICE MANAGEMENT

Cardiac surgeons will increasingly encounter ACHD patients with intravascular devices in the aorta and pulmonary arteries, atrial<sup>42</sup> and ventricular septal occlusion devices, and transcatheter stented valves. Vascular stents are being effectively used in neonates and infants, with the understanding that patients will inevitably outgrow the maximum size these stents can achieve.<sup>43</sup> We have a growing experience with reoperations on patients who have outgrown stents in the aortic arch and the branch pulmonary arteries, and these are far more common than reoperations involving septal occlusion devices. At reoperation early after stent implantation, within 3 months or less, it may be possible to completely remove

the stent by chipping away with the cells using scissors. The stents can be collapsed inward and peeled away from the vessel wall. After 3 months, vascular ingrowth is usually substantial enough that the stent is incorporated into the vessel wall, making removal difficult and traumatic. When patients undergo reoperations to enlarge stents which have reached their maximum diameter, operative planning requires consideration of the optimal location of the longitudinal incision made to open the stent, anticipating that the stent will have to be spread open like a hot dog bun to create space for an onlay patch. This requires that every link be cut to the distal ends of the stent to avoid leaving a persistent complete ring of metal in the vessel wall (Fig. 56-8).

Stents often end close to branch points, so the distal extension of the stent incision must be planned to avoid spiral tears into smaller branch vessels, which may result in branch occlusion. Onlay patches may be constructed with native or bovine pericardium, PTFE grafts, pulmonary or aortic homografts, or extracellular matrix grafts. If the final vessel reconstruction does not achieve a full adult-sized vessel lumen, or is compressed by adjacent structures, the patched split stent is a safe landing zone for subsequent placement of an adult-sized stent. We have placed these stents immediately in the operating room as a hybrid procedure, or later, after the patched vessel has time to heal, thus reducing the risk of suture line rupture and bleeding.

Atrial septal stents are occasionally used to achieve unrestricted flow across the atrial septum when restriction develops after previous surgical septectomy.<sup>44</sup> At late reoperation, these stents are firmly encased in septal tissue, and may extend into the pulmonary vein orifices. When necessary, these stents can be removed with scissor dissection, trimming the exposed metal, peeling out the embedded sections, and enucleating the ingrown scar tissue. The atrium must be inspected for full thickness tears, which are repaired with polypropylene suture.

**FIGURE 56-8** An operative image of reoperation on a stented pulmonary artery, requiring an incision through the front wall of the stent and through the most distal cells.

## IMPROVED OUTCOMES USING CONGENITAL HEART SURGEONS TO TREAT ADULT CONGENITAL HEART DISEASE

Management guidelines for adults with congenital heart disease have been developed by the American Heart Association and the American College of Cardiology.<sup>45</sup> In a review of 72 US centers performing ACHD surgery, Patel and Kogon reported 2800 operations performed per year, ranging from 0 to 230 (median 28) per program. There were a median of two surgeons per program, with each surgeon averaging 20 cases per year.<sup>46</sup> While individual surgeon and program results will vary, patients with ACHD appear to have better outcomes when they are repaired by surgeons who primarily perform pediatric congenital heart surgery (1.87% mortality), compared to surgeons who primarily operated on acquired adult heart disease (4.84% mortality,  $p < .0001$ ).<sup>47</sup> Patients with congenital heart disease are living longer. Arrhythmia remains the primary contributing cause of death for those with cyanotic lesions. Myocardial infarction is now the leading contributing cause for adults with noncyanotic congenital heart disease consistent with late survival and an increasing impact of acquired heart disease. With increasing experience and a team approach synthesizing surgery, intervention, electrophysiology, anesthesia, nursing and intensive care, adults with congenital heart disease should experience improved outcomes with less cumulative lifetime therapeutic trauma.

# Pericardial Disease

Eric N. Feins • Jennifer D. Walker

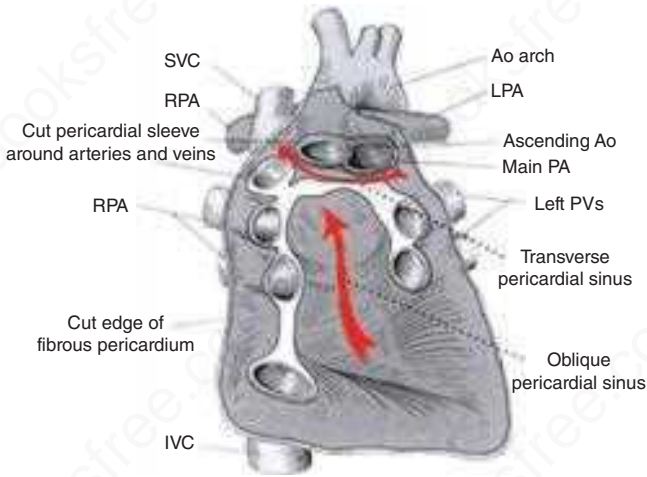

The pericardium envelops the heart and portions of the great vessels as a protective capsule. When incised longitudinally and transversely along the diaphragm it can be suspended to present the heart for surgical procedures. The surgical importance of the pericardium stems from its involvement in alterations of cardiac filling. When the limited space between the noncompliant pericardium and heart acutely fills with fluid, cardiac compression and tamponade may ensue. Constrictive disorders arise when inflammation and scarring cause the pericardium to shrink and densely adhere to the surface of the heart. This chapter discusses pericardial anatomy and function and describes the conditions that commonly give rise to the surgical problems of pericardial constriction and tamponade. The chapter also describes the diagnosis and therapy of these entities, the management of effusions and tamponade early and late after cardiac surgery, and the rationale for and against pericardial closure at the time of cardiac surgery.

## ANATOMY AND FUNCTION

The pericardium serves two major functions. It maintains the position of the heart within the mediastinum and prevents cardiac distention by sudden volume overload. The pericardium attaches to the ascending aorta just inferior to the innominate vein and the superior vena cava (SVC) several centimeters above the sinoatrial node. The pericardial reflection encompasses the superior and inferior pulmonary veins and encircles the inferior vena cava (IVC), thereby making it possible for the surgeon to control the IVC from within the pericardium. The pericardial reflection attaches to the left atrium near the entrances of the pulmonary veins just below the atrioventricular groove (Fig. 57-1). The pericardiophrenic arteries that travel with the phrenic nerves as well as the branches of the internal mammary arteries and feeder branches directly from the aorta perfuse the pericardium. It is innervated by vagal fibers from the esophageal plexus, and the phrenic nerves course within it.

The pericardium is a conical fibroserous sac made up of two intimately connected layers. The inner layer (serous pericardium) is a transparent monolayer of mesothelial cells. The visceral portion of the serous pericardium, or epicardium, and the parietal portion, which lines the fibrous pericardial sac, are continuous. The oblique sinus lies within the venous confluence and the transverse sinus lies between the arterial (aorta and pulmonary artery) and venous reflections (dome of left atrium and SVC). Such potential spaces allow the pericardium to expand and accommodate a limited amount of fluid. Normal pericardial fluid volume is approximately 10 to 20 mL. The pericardial mesothelial cells contain dense microvilli, which are 1  $\mu\text{m}$  wide and 3  $\mu\text{m}$  high, and facilitate fluid and ion exchange.<sup>1</sup> Visceral pericardial lymphatic drainage occurs via the tracheal and bronchial mediastinal nodes, whereas lymphatic drainage of the parietal pericardium occurs via the anterior and posterior mediastinal lymph nodes.

The parietal layer, or fibrous pericardium, is composed mostly of dense parallel bundles of collagen, which render this layer relatively noncompliant. Because the pericardium is stiffer than cardiac muscle, it tends to equalize the compliance of both ventricles. By doing so, the pericardium contributes to the resting cavitory diastolic pressure of both ventricles, maximizing diastolic ventricular interaction.<sup>2</sup> An example of this phenomenon is the diminution of systemic arterial pressure during inspiration. Intrapericardial pressure tends to approximate pleural pressure, and varies with respiration. The negative intrathoracic pressure generated during inspiration augments right ventricular filling. The interventricular septum shifts leftward to accommodate the increase in right ventricular volume and therefore impairs left ventricular filling. Impaired left ventricular filling translates to decreased cardiac output and a slight diminution in systemic blood pressure during inspiration. This phenomenon is greatly magnified with an increase in intrapericardial pressure (eg, during acute filling of the pericardial space or circulatory volume overload), resulting in pulsus paradoxus.<sup>3</sup>

**FIGURE 57-1** Pericardial attachments, reflections, and sinuses. Ao, aorta; IVC, inferior vena cava; LPA, left pulmonary artery; PA, pulmonary artery; PV, pulmonary vein; RPA, right pulmonary artery; SVC, superior vena cava.

## CONGENITAL ABNORMALITIES

Most congenital abnormalities of the pericardium are asymptomatic and are often incidentally discovered at the time of surgery or investigation of unrelated problems.<sup>4,5</sup> They are rare, and one-third are associated with cardiac, skeletal, and pulmonary abnormalities.<sup>6</sup> Partial absence of the pericardium can occur and is most commonly seen on the left (70%) due to premature atrophy of the left common cardinal vein. Right-sided and complete defects of the pericardium account for 17 and 13% of these defects, respectively. The right duct of Cuvier goes on to form the SVC and ensures closure of

the right pleuropericardial membrane.<sup>7</sup> Accordingly, right-sided defects tend to be lethal. Magnetic resonance imaging (MRI), CT, and echocardiography are useful for evaluating patients with pericardial defects. MRI provides excellent pericardial imaging without contrast and is therefore the imaging modality of choice. CT and echocardiography are useful for evaluation of pericardial thickening and the extent and location of defects.<sup>4</sup> Although complete pericardial agenesis is rarely clinically significant, unilateral absence is potentially problematic because it may accentuate cardiac mobility, allowing the heart to be displaced into the pleural space with consequent incarceration of the left atrial appendage or left ventricle. Treatment may involve pericardial resection or replacement with a prosthetic patch.<sup>6</sup> Both therapies appear to yield good outcomes.

Pericardial cysts are the most common congenital pericardial disorder, surpassed only by lymphoma as the most prevalent of middle mediastinal masses.<sup>8</sup> They occur as asymptomatic incidental findings in 75% of patients; 70% occur in the right costophrenic angle and 22% in the left.<sup>5</sup> They do not communicate with the pericardial space and are typically unilocular, smooth, and less than 3 cm in diameter (Fig. 57-2). When present, symptoms may include chest pain, dyspnea, cough, and arrhythmias, probably owing to compression and inflammatory involvement of adjacent structures. They can also become secondarily infected.<sup>9</sup> Contrast CT is the imaging modality of choice for diagnosis and surveillance.<sup>10,11</sup> Observation with serial CT scanning in asymptomatic patients is suggested. Percutaneous aspiration is associated with a 30% recurrence rate at 3 years. Sclerosis has been reported to decrease recurrence after aspiration.<sup>12</sup> Indications for resection include large size, symptoms, patient concern, and question of malignancy.<sup>8</sup> Video-assisted

**FIGURE 57-2** Transthoracic echocardiogram of large pericardial cyst.

thoracoscopy is the surgical approach most commonly used for excision. Infrasternal mediastinoscopy can be used for anterior cysts. Thoracotomy is also an acceptable technique. Surgery is the only definitive cure.<sup>12</sup>

## PATHOPHYSIOLOGY OF PERICARDIAL COMPRESSION

Pericardial compression results from disturbance of the normal anatomical and physiologic relationships among the pericardium, pericardial cavity, and heart. Because the pericardium is relatively noncompliant and pericardial fluid noncompressible, the heart alone must compensate for acute changes in pericardial pressure. Acute volume overload within the fixed pericardial space results in a rapid, nonlinear increase in intrapericardial pressure (Fig. 57-3), producing cardiac compression.<sup>13</sup> The anatomic basis for pericardial compression involves either a space-occupying lesion (eg, cyst or excessive fluid) within the pericardial space or pericardial constriction.

### Tamponade

Although blood in the pericardial space is the most common etiology, effusions, clot, pus, gas, or any combination of these can also produce tamponade. As fluid entering the pericardial space rapidly exceeds the pericardial reserve volume intrapericardial pressure rises abruptly. At this point, pericardial fluid volume can only increase by reducing cardiac chamber volumes. Because of its lower filling pressures, the right heart is more susceptible to compression (Fig. 57-4). The physiologic consequences are impaired diastolic filling with decreased cardiac output and increased central venous pressure.<sup>14</sup> Clinical manifestations include hypotension, jugular venous distention, and decreased heart sounds (Beck's triad).

To preserve cardiac output, higher pressures are required to fill the cardiac chambers, which may be partially achieved

**FIGURE 57-3** Relationship of pressure and volume in pericardial cavity. Normal pericardium will tolerate small amounts of fluid with a minimal increase in intrapericardial pressure. Above this small volume, small increases in volume result in large nonlinear increases in pressure. Gradual accumulation of fluid coincides with pericardial accommodation of much larger volumes of fluid up to a critical pressure.

**FIGURE 57-4** Transesophageal echocardiogram with right atrial inversion and cardiac tamponade.

by parallel increases in systemic and pulmonary venous pressure by vasoconstriction.<sup>15</sup> Other compensatory mechanisms include tachycardia, chronic pericardial stretch, and blood volume expansion.<sup>16</sup> The latter two mechanisms have little impact in acute tamponade. As tamponade progresses, right heart filling becomes increasingly volume dependent and limited to inspiration, when pericardial pressure is lower. Increased right ventricular filling causes it to encroach on, and impair, left ventricular filling. However, during expiration the converse is true, and left ventricular filling and output increase. This exaggeration of physiologic ventricular interdependence is the basis of pulsus paradoxus.<sup>13</sup>

The clinical presentation of tamponade varies widely depending on the severity of hemodynamic impairment and the degree of physiologic reserve. Rapid accumulation of as little as 100 mL of fluid in the pericardial space (eg, after a penetrating cardiac wound) may exceed the limited compliance of the parietal pericardium and produce critical tamponade. On the other hand, in chronic inflammatory conditions (eg, rheumatoid arthritis) the pericardium may compensate for large pericardial effusions, exceeding 1 L. The cardiac silhouette may appear normal in acute tamponade, but chronic pericardial distension is often obvious on plain chest radiography (Fig. 57-5), chest CT (Fig. 57-6), and echocardiography (Fig. 57-7). Low-pressure tamponade can also occur, in which a pericardial effusion is not hemodynamically significant until the patient becomes hypovolemic, typically from dehydration, blood loss, or diuretic therapy. Venous filling pressures may be normal or mildly elevated in this setting, making this diagnosis difficult.<sup>17</sup>

### Pericardial Constriction

A variety of conditions promote pericardial scar formation, the pathologic process underlying constrictive pericarditis (CP). As with tamponade, the physiologic basis is compromised cardiac filling leading to systemic venous congestion and low cardiac output. In contrast with tamponade, however, onset

**FIGURE 57-5** Slowly enlarging pericardial effusion detected on chest x-ray. (A) At discharge; (B) 3 weeks after discharge.

is often insidious and symptoms may be present for months to years.<sup>18</sup> Common complaints include fatigue, decreased exercise tolerance with dyspnea/orthopnea, as well as peripheral edema and ascites from hepatic congestion in advanced disease. The principal etiologies behind pericardial scar formation have shifted over time, with a declining incidence of infectious cases (eg, tuberculosis) and an increasing incidence of iatrogenic cases (eg, mediastinal radiation therapy, cardiac surgery).<sup>19</sup>

Pericardial constriction exerts its pathophysiologic effects by limiting cardiac filling. Unlike tamponade, in which cardiac filling is limited from the onset of diastole, pericardial constriction does not restrict filling in early diastole. Later in diastolic filling the ventricles are prevented from reaching full

capacity as they encounter the contracted and noncompliant pericardium. As a result, 70 to 80% of diastolic filling occurs in the first 25 to 30% of diastole, after which diastolic pressures increase abruptly.<sup>20</sup> The ventricular free walls are then immobilized, leaving the interventricular septum as the last yielding structure; it is rapidly displaced in response to the sudden interventricular pressure differential. This produces the characteristic “septal bounce” seen echocardiographically. Other echocardiographic findings include pericardial thickening, caval plethora, and small chamber volumes. Inspiration exaggerates leftward septal deviation and reciprocal Doppler flows between the right and left sides (the echocardiographic correlate of pulsus paradoxus).

Modern axial imaging with CT (Fig. 57-8) and MRI (Fig. 57-9) are often able to visualize thickened and/or calcified pericardium, with or without coexisting effusion. Dynamic CT and MRI also demonstrate many of the physiologic features seen with echocardiography.<sup>21</sup> Importantly, although pericardial thickening is usually present in CP, it is possible to have CP with normal pericardial thickness, as well as pericardial thickening without CP.<sup>22</sup>

Prior to the modern era of echocardiography and axial imaging, the diagnosis of CP was dependent on hemodynamic tracings obtained during cardiac catheterization. The sudden increase in diastolic ventricular pressure is reflected in the dip and plateau, or “square-root” sign (Fig. 57-10). Similarly, right atrial pressure tracings reveal a steep *y* descent, which correlates with the nadir of the square-root sign. Under normal circumstances, inspiration results in a 3 to 7-mm Hg drop in right atrial pressure. The high pressure of pericardial constriction prevents the right atrium from accepting inspiratory acceleration of blood from the central veins. Instead, neck veins become distended during inspiration in patients with CP, a phenomenon known as *Kussmaul's sign*.

**FIGURE 57-6** CT scan with large circumferential pericardial effusion and bilateral pleural effusions.

**FIGURE 57-7** Transesophageal echocardiogram with very large pericardial effusion.

Catheterization can help differentiate CP from restrictive cardiomyopathy (RCM).<sup>23,24</sup> RCM is characterized by noncompliant ventricular muscle and diastolic dysfunction, which impede cardiac filling. RCM is caused by a variety of infiltrative or fibrosing conditions (eg, amyloidosis, sarcoidosis, radiation, and carcinoid). Although RCM may mimic many of the presenting features of CP, it is not a surgical disease and therefore must be distinguished from CP

(Table 57-1). Systolic ventricular function may be normal or near-normal in both conditions, but pulmonary and hepatic congestion are often present in RCM. Evidence of pericardial thickening (>2 mm) favors but does not confirm the diagnosis of CP over RCM. There are instances, particularly in radiation-induced CP, in which the conditions can coexist, making diagnosis challenging. Amyloidosis and other infiltrative conditions that cause RCM may demonstrate distinctive myocardial speckling on echocardiography. Endomyocardial biopsy is useful to establish the presence of one of the

**FIGURE 57-8** CT scan showing pericardial thickening and calcification.

**FIGURE 57-9** MRI showing pericardial thickening with pericarditis.

**FIGURE 57-10** Square-root sign in right ventricular pressure tracing in constrictive pericarditis. (Modified with permission from Spodick DH: *The Pericardium: A Comprehensive Textbook*. New York: Marcel Dekker; 1997.)

conditions known to be associated with RCM; unfortunately, a negative biopsy does not rule it out.

In an attempt to provide additional criteria to differentiate CP from RCM, Hurrell et al measured respiratory variation of the gradient between left ventricular pressure and pulmonary capillary wedge pressure during the rapid filling phase of diastole.<sup>25</sup> This was done to assess the dissociation of intrathoracic and intracardiac pressures that accompanies CP. A difference of 5 mm Hg in the gradient between inspiratory and expiratory cycles had a 93% sensitivity and a 81% specificity for CP. Furthermore, increased ventricular interdependence was assessed by comparing left and right ventricular systolic pressures during respiration. Although concordant increases in left and right ventricular systolic pressure are expected during inspiration, discordant pressures are encountered during

inspiration in patients with CP. This finding has 100% sensitivity and 95% specificity for CP.

## ACQUIRED ABNORMALITIES

Pericarditis, the most common pericardial disorder, has many etiologies (Table 57-2), including infectious (viral, bacterial, fungal), metabolic (uremic, drug induced), autoimmune (arthritis, thyroid), postradiation, neoplastic, traumatic, postinfarction (Dressler's syndrome, 10–15%), postpericardiotomy (5–30%), and idiopathic (Fig. 57-11). The clinical syndrome for all causes is similar. Chest pain (dull, aching, pressure, tightness) is usually present and may be associated with constitutional symptoms (eg, weakness and malaise), fever (occasionally with rigors), and other symptoms, such as cough or odynophagia. The pain may be pleuritic, and thus exacerbated by inspiration, cough, or recumbency. These patients therefore often sit up and lean forward for relief. Acute disease may become chronic. The cardinal sign of pericarditis is a pericardial rub, which may be positional and muffled because of an effusion.<sup>26</sup>

Electrocardiography, chest x-ray, and echocardiography are useful in making the diagnosis. The electrocardiogram may range from normal, to nonspecific ST-segment deviations, to diffuse concave elevation of the ST segments without reciprocal depressions or Q waves (Fig. 57-12). PR-segment depression may also be present. Troponin may be elevated with a normal CPK. Ventricular arrhythmias and conduction abnormalities are uncommon and if present are suggestive of an underlying cardiac abnormality. Echocardiography may reveal fibrinous thickening of the pericardium with or without a small effusion.

**TABLE 57-1: Differentiation between Constrictive Pericarditis and Restrictive Cardiomyopathy**

Finding	Pericardial constriction	Restrictive cardiomyopathy
<b>Physical examination</b>		
Pulsus paradoxus	Variable	Absent
Pericardial knock (high frequency)	Present	Absent
S3 (low frequency)	Absent	Present
<b>Hemodynamics</b>		
Prominent $\gamma$ descent	Present	Variable
Equalization of right and left side filling pressures	Present	Left > right

**FIGURE 57-11** Etiologies and frequency of pericardial constriction.

Nonsteroidal anti-inflammatory drugs (NSAIDs) are the mainstay of treatment, although recent clinical studies support the routine use of colchicine. A recent, large, multicenter randomized controlled trial (ICAP), in which patients with a first attack of pericarditis were randomized to conventional anti-inflammatories with either placebo or colchicine, demonstrated significantly reduced rates of incessant or recurrent pericarditis in those patients who received colchicine.<sup>27</sup> Other recent clinical trials focusing on recurrent pericarditis (CORP and CORP-2) have also demonstrated a significant benefit

with the use of colchicine.<sup>28,29</sup> Chronic pericardial effusion or CP may follow acute pericarditis as well as tuberculosis (TB), malignancy, radiation, rheumatoid arthritis (RA), or surgery.<sup>26</sup> Chronic, relapsing pericarditis that fails medical therapy can effectively be managed surgically with pericardiectomy.<sup>30</sup>

## Infectious Pericarditis

### VIRAL PERICARDITIS

Infectious pericarditis is most often viral and results from immune complex deposition, direct viral attack, or both. It is often difficult to diagnose and is therefore labeled as “idiopathic.” Treatment is expectant, and symptoms generally resolve within 2 weeks. Surgical intervention is rarely required.

### BACTERIAL PERICARDITIS

This is uncommon because of the availability of effective antibiotic therapy. Microorganisms may invade the pericardial space from contiguous infections in the heart (endocarditis), lung (pneumonia, abscess), subdiaphragmatic space (liver or splenic abscess), or wounds (traumatic, surgical). Hematogenous seeding may also occur in the setting of bacteremia and immune compromise.

The most common bacteria implicated are *Haemophilus influenzae*, meningococci, pneumococci, staphylococci, or streptococci.<sup>31</sup> Gram-negative rods, *Salmonella*, and opportunistic sources of infection must be excluded. Regardless of the source or organism, acute suppurative pericarditis is life threatening. A toxic presentation with a high fever is typical with an acute, fulminant clinical course. Purulent pericarditis with tamponade or septicemia may require acute surgical intervention via pericardial window or pericardiectomy and treatment of the inciting cause (eg, removal of foreign body

**FIGURE 57-12** ECG demonstrating diffuse ST segment elevations, characteristic of pericarditis.

**FIGURE 57-13** Intraoperative photo of a patient with septic pericarditis undergoing pericardiectomy. The pericardium is severely thickened.

or drainage of abscess) (Fig. 57-13). In adults, pneumopy-pericardium is often caused by fistula formation between a hollow viscus and the pericardium. However, invasion from contiguous foci, implantation at the time of surgery, trauma, mediastinitis, endocarditis, and subdiaphragmatic abscess can also cause this condition. Scarring with resultant pericardial constriction may require pericardiectomy. These patients have an excellent outcome when treated appropriately.<sup>31</sup>

### TUBERCULOUS PERICARDITIS

Although the incidence of TB has significantly declined in industrialized countries, it has increased dramatically in Africa, Asia, and Latin America, accounting for 95% of all cases of active TB. This resurgence in TB reflects the increasing incidence of human immunodeficiency virus (HIV) infection.<sup>32</sup> The immune response to the acid-fast bacilli penetrating the pericardium induces a delayed hypersensitivity reaction with lymphokine release and granuloma formation. The cause of the exudative TB pericarditis is complement-fixing antibodies, which initiate cytolysis mediated by antimyolemmal antibodies.<sup>32</sup> The definitive diagnosis is established by examining the pericardium or pericardial fluid for mycobacteria.

Four pathologic states are recognized:

1. Fibrinous exudation, with robust polymorphonuclear infiltration and abundant mycobacteria.
2. Serous or serosanguineous effusions with a mainly lymphocytic exudation and foam cells (Fig. 57-14).
3. Absorption of effusion, with organization of caseating granulomas, and pericardial thickening caused by fibrin and collagen deposition and fibrosis.

**FIGURE 57-14** CT scan of chronic pericardial thickening and calcification and larger pericardial effusion in a patient with TB.

4. Constrictive scarring, often with extensive calcification occurring over a period of years (Fig. 57-15 A, B).

The clinical course of TB pericarditis is variable. An effusion usually develops insidiously along with fever, night sweats, fatigue, and weight loss. Children and immunocompromised patients can have a more fulminant presentation, often demonstrating both constrictive and tamponade physiology. Despite prompt anti-TB antibiotic treatment, CP, one of the most severe sequelae, occurs in 30 to 60% of patients. Echocardiography is useful for diagnosing effusive and subacute constrictive TB pericarditis. Standard anti-TB therapy is instituted promptly. Steroids remain controversial, especially in HIV-infected patients. Based on physiology and response to therapy, immediate or interval pericardiectomy is performed to avoid chronic CP. If calcific pericarditis is present, surgery is undertaken earlier.<sup>33</sup>

### FUNGAL PERICARDITIS

Fungal pericarditis is uncommon. *Nocardia*, *Aspergillus*, *Candida*, and *Coccidioides* are implicated, with regional specification, in the setting of immunocompromise, debilitation, HIV, severe burns, infancy, or steroid therapy. *Candida* and *Aspergillus* generate an insidious clinical picture, which may develop into tamponade or constriction. Fungi that tend to be endemic to certain geographic regions (eg, *Histoplasma*) may cause pericarditis in young, healthy, immunocompetent patients. This is usually self-limited and resolves within 2 weeks. Similarly, *Coccidioides* can infect healthy individuals in the setting of pneumonia, osteomyelitis, meningitis, or adenopathy. These

**FIGURE 57-15** (A) PA CXR in patient with TB showing calcification of pericardium around LV apex. (B) CT scan of chronic pericardial thickening and calcification in patient with TB.

conditions often resolve either spontaneously or in response to antifungal therapy. Surgical intervention is not usually required in the acute setting.

### Metabolic Causes of Pericarditis

Pericarditis is known to occur in the setting of renal failure, pharmacotherapy with certain drugs, autoimmune diseases (eg, rheumatoid arthritis), and hypothyroidism.

#### UREMIC PERICARDITIS

Uremic pericarditis was first recognized by Bright in 1836.<sup>34</sup> Although it is recognized that nitrogen retention (blood urea nitrogen levels generally >60 mg/dL) is required for uremic pericarditis, the inciting agent remains unknown. The clinical profile typically involves a patient with chronic renal insufficiency who develops pain, fever, and a friction rub.<sup>35</sup> There is usually a pericardial fluid collection, which can be exudative or transudative and is often hemorrhagic. Although the incidence of tamponade is decreasing because of the more widespread use of renal replacement therapy, it still occurs.<sup>36</sup> Initial therapy includes NSAIDs and aggressive dialysis. Pericardial drainage is reserved for cases of tamponade or refractory effusions (more than 2 weeks despite intensive dialysis), but the latter is the subject of debate.<sup>37</sup> Heparin should be administered cautiously, if at all, during dialysis because of the risk of hemorrhagic pericarditis and tamponade.<sup>38</sup> Pericardial effusions may also develop in this population because of a variety of conditions such as heart failure,

volume overload, and hypoproteinemia. Nonuremic pericarditis can also occur in patients on long-standing dialysis.<sup>39</sup> Finally, pericardial effusion increases the risk of low-pressure tamponade during dialysis by mechanisms described above.<sup>17</sup>

#### DRUG-INDUCED PERICARDITIS

Pericarditis may occur in the setting of a drug-induced hypersensitivity reaction or lupus-like syndrome.<sup>40</sup> Procainamide, hydralazine, isoniazid, methysergide, cromolyn, penicillin, and emetine (among others) have been associated with pericardial inflammation. Minoxidil has been associated with pericardial effusions.<sup>41</sup> The clinical presentation and guidelines for management are similar to those for other types of pericarditis. The inciting agent should be discontinued.

#### PERICARDITIS ASSOCIATED WITH RHEUMATOID ARTHRITIS

Pericarditis is common in patients with RA. Approximately half of patients with RA have pericardial effusions, and almost half of all patients with RA have significant pericardial adhesions at autopsy.<sup>42</sup> The condition is encountered more often with advanced RA and is thought to be caused by the higher rheumatoid factor titers seen with more severe disease. Immune complex deposition in the pericardium appears to be the inciting event underlying the inflammatory response.<sup>43</sup> The diagnosis is often complicated by the many clinical variants and possible concurrent diseases, such as drug-induced and viral pericarditis. Pericardial drainage is often employed early for symptomatic effusions because

response to medical treatment of the underlying RA is slow and unpredictable. Pericardiectomy should be considered in patients with long-standing RA who have developed constriction.<sup>44</sup>

## Hypothyroidism

Severe hypothyroidism produces large, clear, high-protein, high-cholesterol, and high-specific-gravity effusions in 25 to 35% of patients.<sup>45</sup> The effusion may precede other signs of hypothyroidism. Clinical tamponade is rare because fluid accumulation is slow. However, acute exacerbations owing to acute pericarditis, hemorrhage, or cholesterol pericarditis can induce tamponade.<sup>46</sup>

## Radiation Pericarditis

Radiation is now the most common etiology of CP in the United States. This was first recognized in patients who received high-dose mantle radiation for Hodgkin's lymphoma in the 1960s and 1970s and developed cardiac and pericardial pathology, approximately 10 to 15 years after therapy. Radiation induces acute pericarditis, pancarditis, and accelerated coronary artery disease in a dose-dependent relationship.<sup>47</sup> Patients may present with a combination of pericardial constriction, RCM, valvular heart disease, and coronary artery disease with a predilection for ostial lesions.<sup>48</sup> When symptomatic effusions are drained, fluid should be analyzed to clarify the etiology (ie, malignancy vs radiation effect). CP can develop several years later and is best treated by pericardiectomy.<sup>49</sup>

## Neoplastic Pericardial Disease

Secondary neoplasms of the pericardium (ie, from metastasis or adjacent infiltration) account for more than 95% of pericardial neoplastic diseases. Primary pericardial tumors are rare. Paraneoplastic effusions can also occur in response to tumors.<sup>50</sup>

The most common secondary tumors involving the pericardium in males (including both metastasis and local extension) are carcinoma of the lung (31.7%), esophagus (28.7%), and lymphoma (11.9%). In females, carcinoma of the lung (35.9%), lymphoma (17.0%), and carcinoma of the breast (7.5%) are the most common. Benign tumors are generally encountered in infancy or childhood. Malignant tumors (eg, mesotheliomas, sarcomas, and angiosarcomas) typically present in the third or fourth decade of life.<sup>51</sup>

In both primary and secondary tumor involvement, the clinical presentation is usually silent, and may be associated with large pericardial effusions. Tamponade can result from hemorrhage into a malignant effusion. Occasionally tumors can induce constriction because of neoplastic tissue, adhesions, or both. The role of surgery is limited to diagnosis and palliation in most cases. Large refractory effusions associated with tamponade may need surgical drainage. In such cases, a fluid sample should be submitted to confirm the presence of malignant cells or evaluate for other causes of effusion in patients

with cancer because this may influence management.<sup>52</sup> Simple pericardiocentesis has a high failure rate, while subxiphoid drainage and percutaneous balloon pericardiectomy are only transiently effective.<sup>53</sup> Although extensive resection and debulking may be necessary in persistent or recurrent malignant pericardial constriction, it has only transient benefit without adjunctive chemotherapy and/or radiation therapy. There is no consensus about the optimal therapeutic approach for patients with malignant, symptomatic pericardial effusions. A recent study compared chemotherapy alone versus chemotherapy plus pericardiocentesis versus chemotherapy plus surgical pericardial window. It showed that patients undergoing a pericardial window had better response rates compared to those receiving chemotherapy alone or chemotherapy with percutaneous drainage.<sup>54</sup> While pericardial window has had a better/lower recurrence rate than simple pericardiocentesis, prolonged percutaneous pericardial drainage has improved recurrence rates while minimizing the morbidity associated with surgery.<sup>55</sup> Life expectancy of patients with malignant pericardial involvement averages less than 4 months.<sup>56</sup> The surgeon should individualize decisions regarding how aggressively to pursue diagnostic or therapeutic interventions.

## Traumatic Pericardial Conditions

### PENETRATING TRAUMA

Knives, bullets, needles, and intracardiac instrumentation are the main causes of penetrating trauma to the pericardium and heart. Tamponade is more common in stab wounds than gunshot wounds. The right ventricle is most often involved in anterior chest wounds. Because tamponade provides hemostasis and prevents exsanguination, patients with tamponade have better survival rates than those with uncontrolled hemorrhage. Diagnosis is often made on clinical grounds supplemented by ultrasonography.<sup>57</sup> Unstable patients should undergo thoracotomy in the emergency department. Stable patients can be explored in the operating room. The timing of induction of anesthesia is critical. Anesthetic induction can lead to hemodynamic collapse in the setting of tamponade and preload dependence. Therefore, the patient should be positioned, prepped, and draped before induction of anesthesia, in order to allow prompt opening of the chest and pericardium should hemodynamics rapidly deteriorate.

### BLUNT TRAUMA

Blunt cardiac and pericardial injuries rarely occur in isolation. Trauma owing to compression (including cardiopulmonary resuscitation), blast, and deceleration can produce a spectrum of injuries ranging from cardiac contusion to cardiac rupture and pericardial laceration with herniation or luxation of the heart. Patients with pericardial rupture and cardiac herniation typically have suffered high-energy deceleration trauma and are hypotensive from associated injuries. Hypovolemia may lead to rapid decompensation because cardiac filling becomes increasingly volume dependent in the setting of tamponade. Likewise, patients may initially respond to

volume resuscitation. Chest imaging may demonstrate displacement of the heart or free air or intra-abdominal organs within the pericardium. If the heart herniates into the pleura, positioning the patient with the contralateral side down may reduce the herniation. Thoracotomy is required for definitive treatment and repair of associated injuries.<sup>58</sup>

## Acute Postinfarction Pericarditis and Dressler's Syndrome

Postinfarction pericarditis is thought to occur in almost half of patients suffering a transmural myocardial infarction (MI), although it is symptomatic in far fewer. The incidence is decreasing because of more aggressive revascularization in recent decades. Chest pain is almost universally present, and it is therefore important to distinguish the pain of pericarditis from ischemic pain by its positional and pleuritic nature. The pain of early post-MI pericarditis occurs in the first 24 to 72 hours. Dressler's syndrome is a diffuse pleuropericardial inflammation thought to have an autoimmune etiology that occurs weeks to months after infarction. A pericardial rub and effusion may be present but tamponade is rare. A pleural rub and effusion may also be present. The ECG signs of pericarditis may be obscured by those of infarction. Post-MI pericarditis is typically treated with aspirin and/or NSAIDs.<sup>59,60</sup> Steroids or colchicine may be used for persistent or recurrent symptoms; however, glucocorticoid use is associated with recurrence of pericarditis.<sup>61</sup>

## Cardiac Surgery and the Pericardium

### POSTINFARCTION PERICARDITIS

Postinfarction pericarditis is an important entity for the surgeon to consider in the evaluation of patients with acute coronary syndromes. To the unwary it may masquerade as post-infarction angina and prompt an unnecessarily early operation after MI. Extensive fibrinous adhesions and murky gelatinous fluid may be present in the pericardial space and obscure epicardial vessels. When the pericardium is opened late in such a patient, the surgeon should expect dense pericardial adhesions.

### POSTOPERATIVE PERICARDIAL EFFUSION AND POST-PERICARDIOTOMY SYNDROME

Pericardial effusions not infrequently develop following cardiac surgery, occurring in 1 to 6% of patients. They range from small, asymptomatic, and clinically insignificant effusions to larger effusions that cause dyspnea, malaise, chest pain, or presyncope/syncope. Risk factors for the development of postoperative pericardial effusions include increased body surface area, pulmonary embolism, immunosuppression, surgery type (heart transplant, aortic aneurysm surgery), increased cardiopulmonary bypass time, urgency of surgery, and renal failure. Medical therapy for late effusions that are smaller and do not require drainage has traditionally involved NSAIDs. Some data, however, suggest that NSAID therapy is of limited benefit.<sup>62</sup> Management of large, symptomatic effusions involves pericardiocentesis, especially

when these are detected late (more than 7 days postoperatively). A pericardial drain is left in place for 1 to 3 days with periodic drainage. Surgical drainage can also be performed, and is generally undertaken for large effusions that develop early (within 7 days of surgery).<sup>63</sup> Beyond just an effusion, some patients develop Dressler's syndrome postoperatively. Although this condition is benign, it is important (and sometimes difficult) to distinguish between postoperative pericarditis and myocardial ischemia. This distinction can often be made on clinical grounds based on symptoms, hemodynamics, and ECG patterns.<sup>64</sup> Echocardiography or angiography may be used in borderline cases.

Prevention of postoperative pericardial effusions and post-pericardiotomy syndrome has also been studied. There may be a benefit to perioperative indomethacin for preventing pericardial effusions after aortic surgery, although the side effects of indomethacin must be considered, and further study is required before its routine perioperative use can be recommended.<sup>65</sup> Postoperative colchicine administration has been shown to reduce the incidence of post-pericardiotomy syndrome and pericardial effusions, and its routine use postoperatively should be considered.<sup>66</sup> Preoperative colchicine administration also reduces the rate of post-pericardiotomy syndrome; however, there is an increased incidence of adverse gastrointestinal side effects and drug discontinuation, which limits its beneficial effect.<sup>67</sup>

### POSTOPERATIVE TAMPONADE

Early postoperative tamponade rarely goes undetected for long because of the high level of vigilance and close hemodynamic monitoring that attend the patient during this time. A vital feature of postoperative tamponade is that a circumferential fluid collection is not required for compromised cardiac function. Hemodynamic deterioration can occur in the setting of localized clot within the pericardium, particularly if it is impinging upon the right heart.<sup>68</sup> Surgeons must also be aware of the potential for late cardiac tamponade that presents after hospital discharge—often to a clinician other than the cardiac surgeon. This entity is a potentially lethal complication and occurs in 0.5 to 6% of patients after heart surgery, almost exclusively in those on anticoagulation. It is more common in younger patients following isolated valve surgery. Patients present on average 3 weeks after surgery, frequently in the setting of an elevated prothrombin time. They are often severely symptomatic, with declining exercise tolerance, dyspnea, oligo/anuria, and sometimes hypotension. Any patient on anticoagulation whose recovery takes an otherwise unexplained decline in this interval should be suspected of having late tamponade and should undergo echocardiographic examination. Nearly all patients with late tamponade respond favorably to pericardiocentesis and can safely resume anticoagulation.<sup>69</sup>

### PERICARDIAL CLOSURE

Redo sternotomy may be more hazardous when the heart is adherent to the inner sternal table. Closing the pericardium

at the time of surgery interposes a protective tissue layer between the sternum and the heart and may reduce the risks of redo sternotomy. The value of any added protection against cardiac injury on sternal reentry is limited by the relative infrequency of reoperation and the already low incidence of cardiac injury at repeat sternotomy when the pericardium is left open. On the negative side, closing the pericardium can cause kinking of bypass grafts after coronary artery bypass surgery and may result in hemodynamic compromise caused by cardiac compression. Rao et al demonstrated the adverse effects of pericardial closure on postoperative hemodynamics.<sup>70</sup> In this ingenious study, the pericardial edges were marked with radiopaque markers and the pericardium was closed with a running suture, the ends of which were exteriorized. After obtaining a postoperative chest x-ray that demonstrated pericardial approximation, a set of baseline hemodynamics was measured. The suture was then removed, another x-ray was taken to demonstrate distraction of the pericardial edges, and the hemodynamic measurements were repeated. Pericardial closure resulted in transient, moderate hemodynamic compromise in the first 8 hours postoperatively (Table 57-3). Although this and other studies have demonstrated adverse short-term hemodynamic consequences of pericardial closure, they have yet to report clinical evidence of worse outcomes.<sup>71</sup> Therefore, the risks of pericardial closure must be weighed against its potential benefits, and clinical practice should be individualized to the patient.

**TABLE 57-3: Structural and Hemodynamic Changes after Pericardial Closure in Patients Undergoing Elective Isolated Coronary Artery Bypass Grafting**

Parameters measured	Open pericardium	Closed pericardium	p-value
Retrosternal space at 1 week (cm)	13 ± 5	20 ± 7	.0003
Retrosternal space at 3 months (cm)	7 ± 3	14 ± 7	.0001
CI L/min/m <sup>2</sup> 1 hour postoperation	3.1 ± 0.8	2.3 ± 0.6	.003
CI L/min/m <sup>2</sup> 4 hours postoperation	3.1 ± 0.9	2.7 ± 0.7	.156
CI L/min/m <sup>2</sup> 8 hours postoperation	3.0 ± 0.8	2.8 ± 0.5	.402
LVSWI g/m/m <sup>2</sup> 1 hour postoperation	72 ± 18	52 ± 13	.002
LVSWI g/m/m <sup>2</sup> 4 hours postoperation	68 ± 17	54 ± 8	.016

CI, cardiac index; LVSWI, left ventricular stroke work index.

## PERICARDIAL IMAGING

Multiple modalities are utilized to image the pericardium, including echocardiography, CT, and MRI. Each modality has strengths and weaknesses, and each has particular applicability to certain pericardial conditions. As such, multimodality imaging is recommended. Transthoracic echocardiography (TTE) is typically the first-line imaging test for any patient suspected of having pericardial disease. TTE is simple, cost-effective, and noninvasive. Moreover, it provides both imaging and functional/hemodynamic data. CT and/or MRI should be considered in the following circumstances<sup>72</sup>:

1. Acute or recurrent pericarditis with: (a) inconclusive TTE imaging, (b) failed response to NSAID therapy, (c) atypical presentation, (d) concern for CP, (e) prior trauma, (f) associated MI, neoplasm, infection, or pancreatitis.
2. Pericardial effusions that: (a) are complex with subacute tamponade requiring drainage, (b) have suspected hemo-pericardium, clot, malignancy, or inflammation, (c) cause regional tamponade postoperatively (TEE should also be considered).
3. Constrictive pericarditis: (a) with inconclusive TTE imaging, (b) when pericardial thickness or tissue assessment is necessary.
4. Pericardial masses to: (a) more fully characterize tissue, (b) assess for metastases, (c) evaluate for pericardial diverticulum or cyst.
5. Congenital absence of the pericardium, when pericardial morphology must be assessed.

## OPERATIONS

### Mediastinal Reexploration

Postoperative hemorrhage complicates approximately 3 to 5% of cardiac operations, a risk that nearly doubles in the setting of reoperations or valve surgery.<sup>73</sup> Common management for the postoperative cardiac surgical patient involves placing anterior and posterior mediastinal drains. Despite this, postoperative tamponade may still occur. The typical scenario involves declining chest tube output after a period of early postoperative bleeding, tachycardia, narrowed pulse pressure, increased right-sided filling pressures, oliguria, acidosis, escalating inotrope and/or vasopressor requirement, and decreased cardiac index. Echocardiography is not routinely helpful because the pericardial space and any associated thrombus may be difficult to visualize in the immediate postoperative period. Subtle echocardiographic findings have been reported, including an inspiratory increase in right ventricular end-diastolic diameter and a reciprocal decrease in left ventricular end-diastolic diameter, as well as an increase in early peak tricuspid flow velocity and reduction in flow across the mitral valve.<sup>74,75</sup> Because postoperative hemorrhage and tamponade can precipitate rapid deterioration, expedient mediastinal drainage is imperative. The importance of

simultaneous correction of coagulopathy, hypothermia, acidosis, and hypovolemia is critical.<sup>76</sup> Extreme circumstances may dictate that temporizing decompression be performed in the ICU followed by definitive management in the operating room. Reported outcomes among patients explored in the ICU include perioperative survival of 85% and a sternal wound infection rate of 2%.<sup>77</sup>

During reexploration the first priority is to relieve tamponade by evacuating retained mediastinal blood and controlling life-threatening hemorrhage. Dramatic hemodynamic improvement is frequently observed upon chest reopening. Mediastinal reexploration is then undertaken in a thorough and methodical manner with careful attention paid to all suture lines. Complete mediastinal evaluation should be performed even if the culprit source is thought to be identified. Inspection proceeds from top down while simultaneously obtaining hemostasis; this prevents “run-down” from obscuring small sources of bleeding. Copious warm saline irrigation and judicious use of gauze packing are helpful adjuncts.

### Pericardiocentesis

Pericardiocentesis is usually performed in a procedure suite under fluoroscopic, sonographic, or CT guidance. Arterial and right heart catheterizations are often performed for hemodynamic monitoring. After administration of 1% lidocaine to the skin and soft tissues of the left xiphocostal area, a 25-mL syringe is affixed to a three-way stopcock and then to an 18-gauge spinal needle. This pericardial needle is connected to an ECG V lead. Under electrocardiographic and imaging guidance, the needle is advanced from the left of the subxiphoid area aiming toward the left shoulder. ST-segment elevation may be seen on the V lead when the needle touches the epicardium. Under these circumstances, the needle is retracted slightly until ST-segment elevation disappears. Once the pericardial space is entered, a guidewire is introduced into the pericardial space. The needle is removed and a catheter is inserted into the pericardial sac over the guidewire. At our institution, a pigtail-shaped drainage catheter with an end hole and multiple side holes is used. Intrapericardial pressure is measured with pressure transducer system connected to the intrapericardial catheter. Pericardial fluid may then be removed. Symptom relief may be immediate and dramatic. In the presence of pericardial tamponade, aspiration of fluid is continued until there is clear clinical and hemodynamic improvement. If blood is withdrawn, 5 mL should be placed on a sponge to see if it clots. Clotting blood suggests that the needle has either inadvertently entered a cardiac chamber or caused epicardial injury. Defibrinated blood that has been present in the pericardial space for even a short time usually does not clot. The pericardial space is drained every 8 hours; the catheter is flushed with heparinized solution and is typically removed within 24 to 72 hours. Pneumothorax is a potential complication, and chest radiography is mandatory post-procedure.

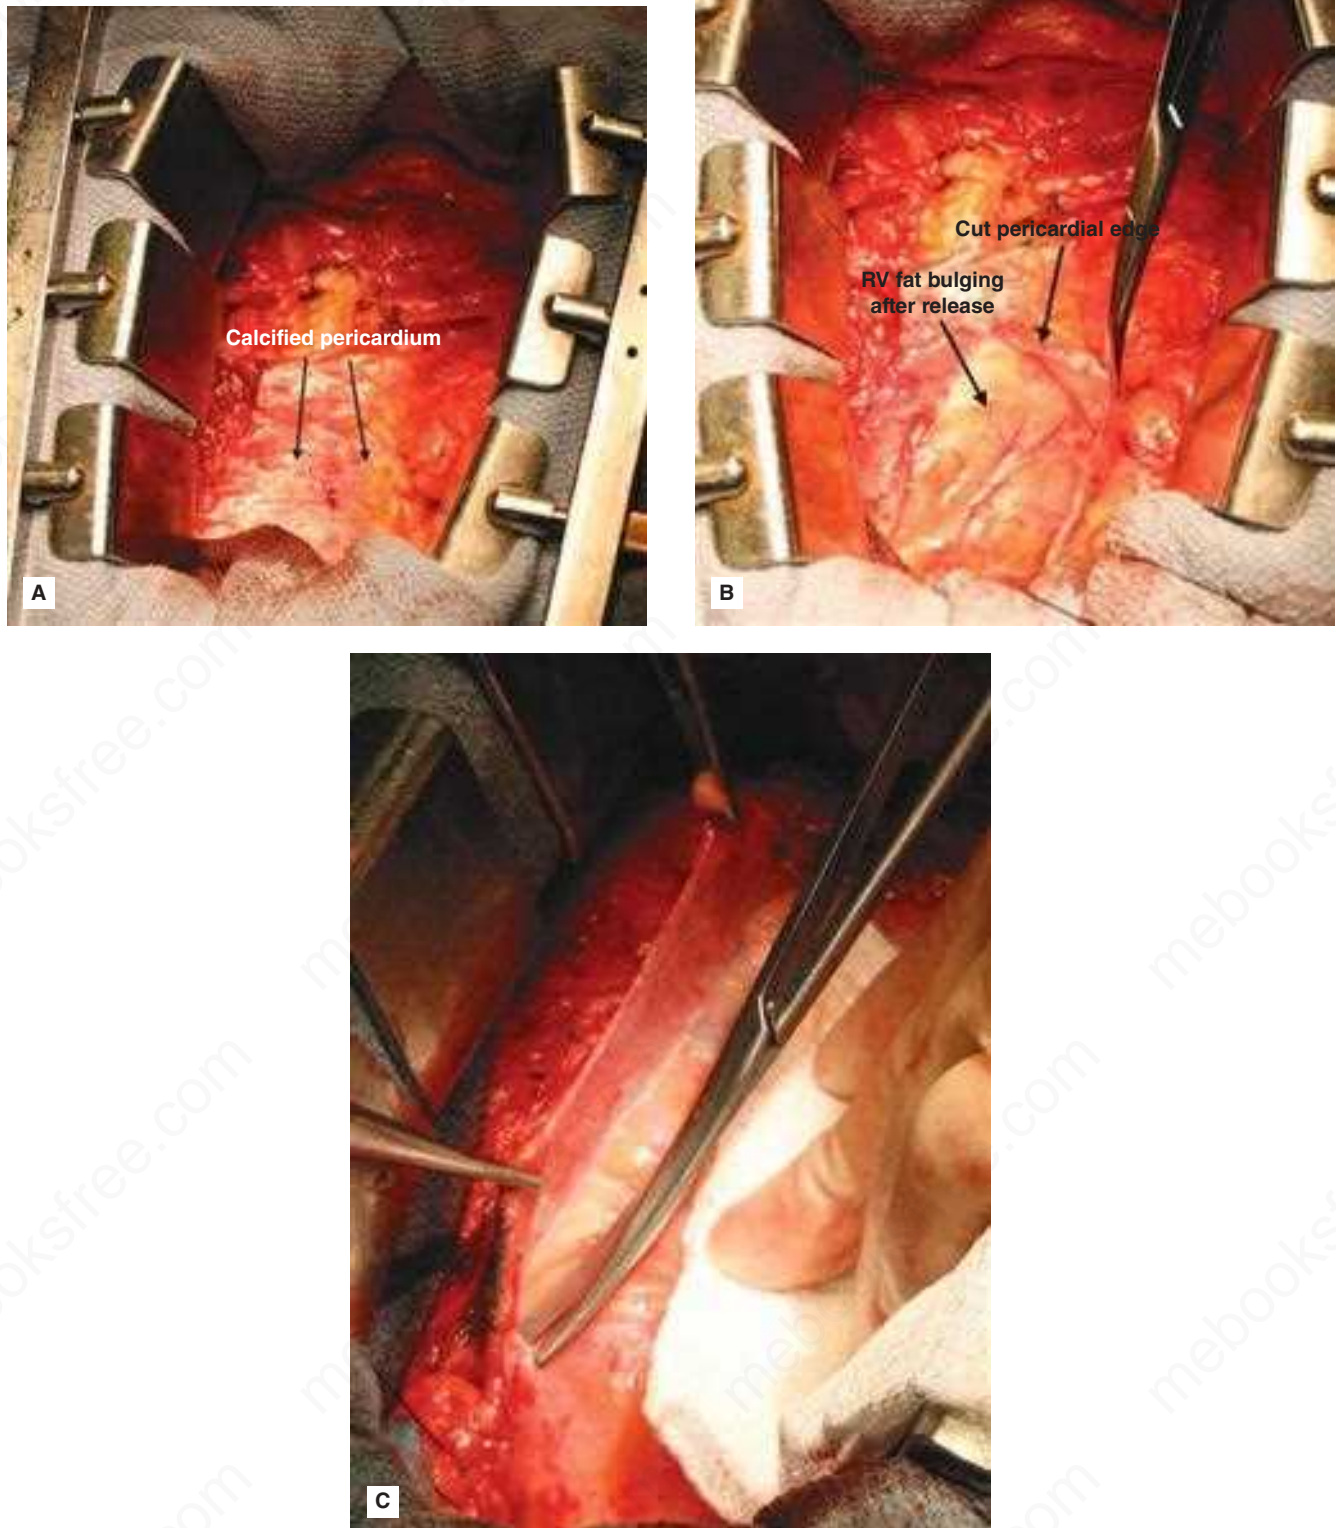

### Pericardial Window

The purpose of partial pericardial resection (window) is to drain fluid into the pleural or peritoneal compartment to prevent reaccumulation. The procedure can be performed via thoracoscopy, anterior thoracotomy, or subxiphoid incision; although each approach has its unique merits, reported outcomes among the three are relatively similar.<sup>78,79</sup> General anesthesia may not be tolerated by some patients in tamponade, in which case the subxiphoid approach under local anesthesia in a semirecumbent position can be employed. When the pericardium is incised, fluid will invariably drain under pressure. The excised portion of pericardium should be as large as is feasible to prevent recurrence.<sup>80</sup> The surgeon should remain mindful of the rare possibility of cardiac prolapse. With the transthoracic or thoracoscopic approaches, all accessible pericardium ventral to the phrenic nerve should be excised. Similarly, via the subxiphoid approach, as much diaphragmatic pericardium should be excised as possible.

Surgical pericardial window, when compared to pericardiocentesis, is a more definitive procedure with much lower recurrence rates. Complications rates have also been reported to be lower with surgery; although more recent studies demonstrate less morbidity with pericardiocentesis. This likely reflects increased experience and decreased complication rates with percutaneous techniques.<sup>81</sup> When considering whether to pursue percutaneous versus surgical drainage, the risks and benefits of each procedure must be weighed.

### Pericardiectomy

Chronic pericardial constriction is treated by pericardial excision (Fig. 57-16). Because dense adhesions and calcification can penetrate into the myocardium, pericardial resection can be technically challenging. The procedure is usually done via median sternotomy with the capability to use cardiopulmonary bypass as needed.<sup>33</sup> Practice is variable, as some use cardiopulmonary bypass routinely, whereas others prefer to avoid the additional burden of coagulopathy unless absolutely necessary. Also, some surgeons prefer the countertraction provided by the filled heart, which facilitates pericardial stripping. Some surgeons use a left anterior thoracotomy, the approach taken by Edward Churchill, who reported the first pericardiectomy for CP done in the United States.<sup>82</sup> The objective of the procedure is to release the ventricles from the densely adherent pericardial shell. The lack of a surgical plane can make this a bloody operation, and attention must be paid to salvage and reinfusion of blood. Epicardial coronary vessels are at risk in this dissection, and particular care must be taken to avoid injuring them. The goal is to excise all anterior pericardium between the phrenic nerves and the posterior pericardium around its reflection on the venae cavae and pulmonary veins. Complete resection should restore pressure-volume loops to their normal position. Complete pericardial resection is not feasible in all cases, especially radiation-induced disease, and leaving densely adherent scar, particularly over the venae cavae and atria, may be safer.

**FIGURE 57-16** (A) Intraoperative photograph of TB pericardial thickening and calcification causing severe constriction. (B) Intraoperative photograph of pericardiectomy for constrictive TB pericarditis with RV free wall bulging through opening in pericardium, thick pericardial edge. (C) Adhesive pericarditis discovered incidentally in CABG patient. Technique for dividing adhesions over left ventricle and pulmonary artery.

Number at risk				
Idiopathic	75	48	30	21
Miscellaneous	12	10	10	5
Post-surgical	60	38	24	9
Post-radiation	15	6	0	0

**FIGURE 57-17** Kaplan-Meier curve showing a significant difference (log-rank test,  $p = .0075$ ) in overall survival of patients after pericardiectomy, based on the presumed cause of constrictive pericarditis. (Reproduced with permission from Bertog S, Thambidorai S, Parakh K, et al: Constrictive pericarditis: etiology and cause-specific survival after pericardiectomy, *J Am Coll Cardiol.* 2004 Apr 21;43(8):1445-1452.)

Outcomes vary with the etiology and severity of the disease. Operative mortality has been reported as high as 10 to 20%, but is typically 5 to 6% in most contemporary series, and varies based on severity of heart failure, elevation of right atrial pressure, and comorbidities.<sup>83-85</sup> Although surgery alleviates or improves symptoms in most patients, long-term survival is diminished in patients who have had prior heart surgery, and particularly in patients with radiation-induced CP, in whom concurrent RCM may exist (Fig. 57-17).<sup>86</sup>

### Waffle Procedure

In some cases of pericardial constriction patients have thickening and calcification of the epicardium (ie, visceral pericardium), and conventional pericardiectomy may not improve cardiac function. Little-to-no improvement in diastolic constriction is seen because the heart is still constricted by the thickened epicardial layer. If pericardiectomy does not result in prompt hemodynamic improvement intraoperatively, then a waffle procedure can be performed. This involves creation of intersecting longitudinal and transverse incisions through the epicardium across the entire surface of the ventricles, resulting in small islands of epicardial scar tissue (~1 cm<sup>2</sup> in size). These incisions relieve constriction and enable proper ventricular dilation/filling (Fig. 57-18). Results following a waffle procedure have been encouraging, although published data are relatively limited.<sup>87,88</sup>

**FIGURE 57-18** Waffle procedure demonstrating intersecting epicardial incisions to create small islands of epicardial scar tissue. Large epicardial vessels are preserved. The incisions allow for stretching of the epicardium and improved diastolic filling of the ventricles. (Reproduced with permission from Shiraishi M, Yamaguchi A, Muramatsu K, et al. Validation of waffle procedure for constrictive pericarditis with epicardial thickening, *Gen Thorac Cardiovasc Surg.* 2015 Jan;63(1):30-37.)

### KEY POINTS

- Tamponade occurs when intrapericardial pressure impedes cardiac filling, causing increased venous pressure, decreased cardiac output, and progression to shock and death if left untreated.
- Pericardial reserve volume is limited; therefore, acute fluid accumulation can rapidly produce tamponade.
- Constrictive pericarditis, the end result of several inflammatory conditions, is characterized by a prominent y descent, square-root sign, septal bounce, and exaggerated respiratory variation in right- and left-sided flows; it is best treated with pericardiectomy.

- Restrictive cardiomyopathy, a myocardial disorder causing diastolic heart failure, is differentiated from pericardial constriction by the presence of pulmonary hypertension, biatrial enlargement, and ventricular thickening; it is not treated surgically.
- Patients with pericardial disease should undergo echocardiography supplemented as needed with CT and/or MRI, and catheter-based hemodynamic measurements or drainage for diagnosis.
- Acute pericarditis is often self-limited and responds to NSAIDs ± colchicine.
- The underlying disorder in secondary pericarditis can often be modified to improve the course of the pericardial disease.
- Intervention for postoperative hemorrhage and tamponade is required in less than 5% of cardiac surgeries. It should be undertaken promptly (in the ICU if necessary) with concurrent correction of coagulopathy, hypovolemia, hypothermia, and acidosis.
- Pericardiectomy is associated with decreased short- and long-term survival because of the severity of associated illnesses.

## ACKNOWLEDGMENT

The authors would like to thank Mark S. Adams for the preparation of the figures, echocardiographic images, and photographs for the chapter.

# Cardiac Neoplasms

Basel Ramlawi • Michael J. Reardon

Neoplasms of the heart can be divided into primary cardiac tumors arising in the heart and secondary cardiac tumors from metastasis. Primary cardiac tumors can be further stratified into benign and malignant tumors. Between 10 and 20% of patients dying of disseminated cancer have metastatic involvement of the heart or pericardium.<sup>1,2</sup> Surgical resection is seldom possible or advisable for these tumors, and intervention usually is limited to drainage of malignant pericardial effusions and/or diagnostic biopsies.

The incidence of primary cardiac neoplasm ranges between 0.17 and 0.19% in unselected autopsy series.<sup>3-5</sup> Seventy-five percent of primary cardiac tumors are benign, and 25% are malignant.<sup>2,6</sup> Fifty percent of the benign tumors are myxomas, and 75% of malignant tumors are sarcomas.<sup>2,6</sup> The clinical incidence of these tumors is 1 in 500 cardiac surgical patients. With the exception of myxomas, most surgeons will rarely encounter primary cardiac tumors. The purpose of this chapter is to summarize useful information for the evaluation and management of patients with cardiac tumors and to provide a reference for additional study.

## HISTORICAL BACKGROUND

A primary cardiac neoplasm was first described by Realdo Colombo in 1559.<sup>7</sup> Alden Allen Burns of Edinburgh described a cardiac neoplasm and suggested valvular obstruction by an atrial tumor in 1809.<sup>8</sup> A series of six atrial tumors, with characteristics we now recognize as myxoma, was published in 1845 by King.<sup>9</sup> In 1931, Yates reported nine cases of primary cardiac tumor and established a classification system similar to what we use today.<sup>10</sup> The first antemortem diagnosis of a cardiac tumor was made in 1934 when Barnes diagnosed a cardiac sarcoma using electrocardiography and biopsy of a metastatic lymph node.<sup>11</sup> In 1936, Beck successfully resected a teratoma external to the right ventricle,<sup>12</sup> and Mauer removed a left ventricular lipoma in 1951.<sup>13</sup> Treatment of cardiac tumors was profoundly influenced by two events: the introduction of cardiopulmonary bypass (CPB) in 1953 by John Gibbon, which allowed a safe and reproducible approach to the cardiac chambers, and the introduction of cardiac echocardiography, which allowed safe and noninvasive

diagnosis of an intracardiac mass. The first echocardiographic diagnosis of an intracardiac tumor was made in 1959.<sup>14</sup> An intracardiac myxoma was diagnosed by angiography in 1952 by Goldberg, but attempts at surgical removal were unsuccessful.<sup>9</sup> A large right atrial myxoma was removed by Bhanson in 1952 using caval inflow occlusion, but the patient died 24 days later.<sup>15</sup> Crafoord in Sweden first successfully removed a left atrial myxoma in 1954 using CPB,<sup>16</sup> and Kay in Los Angeles first removed a left ventricular myxoma in 1959.<sup>17</sup> By 1964, 60 atrial myxomas had been removed successfully, with improved results owing to the increasing safety of CPB and use of echocardiography for detection. Operations are currently performed routinely on patients with atrial myxoma with minimal mortality.<sup>6,18-21</sup> Primary malignant tumors, however, continue to represent a challenge.

## CLASSIFICATION

A pathologic classification is listed in Table 58-1. Mural thrombus is listed as a pseudotumor, although not really a cardiac tumor, its presentation may mimic myxoma clinically and pathologically. Most mural thrombi are associated with underlying valvular disease, myocardial infarction, dysfunction, or atrial fibrillation.<sup>22</sup> Mural thrombi also have been noted in hypercoagulable syndromes, particularly antiphospholipid syndrome.<sup>23</sup> With increasing use of long-term central catheters, we have seen several right atrial masses that were difficult to define and upon removal were mural thrombi.

Heterotopias and tumors of ectopic tissue include cystic tumors of the atrioventricular (AV) node consisting of multiple benign cysts in the region of the AV node that can cause heart block or sudden death. Most are diagnosed at autopsy, but a biopsy diagnosis of AV nodal tumor has been reported.<sup>24</sup> Germ cell tumors of the heart usually are teratomas, occurring within the pericardial sac, but yolk sac tumors have been described in infants and children.<sup>25</sup> Ectopic thyroid tissue may occur within the myocardium and is referred to as *struma cordis*. Right ventricular outflow track obstruction may be present, but most patients are asymptomatic.

Most of the remaining tumors arise in the mesenchymal, fat, fibrous, neural, or vascular cells of the heart, with myxoma

**TABLE 58-1: Types of Cardiac Tumors by Pathology**

Pseudotumors
Mural thrombi
Heterotopias and tumors of ectopic tissue
Tumors of the atrioventricular nodal region
Teratoma
Ectopic thyroid
Tumors of mesenchymal tissue
Hamartoma of endocardial tissue
Papillary fibroelastomas
Hamartomas of cardiac muscle
Rhabdomyoma
Histiocytoid cardiomyopathy (Purkinje cell hamartoma)
Tumors and neoplasms of fat
Lipomatous hypertrophy, interarterial septum
Lipoma
Liposarcoma
Tumors and neoplasms of fibrous and myofibroblastic tissue
Fibroma
Inflammatory pseudotumor (inflammatory myofibroblastic tumor)
Sarcomas (malignant fibrous histiocytoma, fibrosarcoma, leiomyosarcoma)
Vascular tumors and neoplasms
Hemangioma
Epithelioid hemangioendothelioma
Angiosarcoma
Neoplasm of uncertain histogenesis
Myxoma
Neoplasms of neural tissue
Granular cell tumor
Schwannoma/neurofibroma
Paraganglioma
Malignant schwannoma/neurofibrosarcoma (rare)
Malignant lymphoma
Malignant mesothelioma
Metastatic tumors to the heart

representing a tumor of undetermined histogenesis. Primary cardiac lymphoma, mesothelioma, and metastatic tumors to the heart represent the remaining pathologic categories that comprise the greater part of this chapter.

## PRIMARY BENIGN TUMORS

### Myxoma

Myxomata comprise 50% of all benign cardiac tumors in adults and 15% of such tumors in children. Occurrence during infancy is rare (Tables 58-2 and 58-3). A vast majority of myxomas occur sporadically and tend to be more common in women.<sup>4,21</sup> The peak incidence is between the third and sixth decades of life, and 94% of tumors are solitary.<sup>26</sup> Approximately 75% occur in the left atrium<sup>27</sup> and 10 to 20% occur

**TABLE 58-2: Benign Cardiac Neoplasms in Adults**

Tumor	No.	Percentage
Myxoma	118	49
Lipoma	45	19
Papillary fibroelastoma	42	17
Hemangioma	11	5
AV node mesothelioma	9	4
Fibroma	5	2
Teratoma	3	1
Granular cell tumor	3	1
Neurofibroma	2	<1
Lymphangioma	2	<1
Rhabdomyoma	1	<1
Total	241	100

in the right atrium. The remaining proportion are equally distributed between the ventricles.<sup>2</sup> The deoxyribonucleic acid (DNA) genotype of sporadic myxomas is normal in 80% of patients.<sup>28</sup> Myxomas are unlikely to be associated with other abnormal conditions and have a low recurrence rate.<sup>4,27</sup>

About 5% of myxoma patients show a familial pattern of tumor development based on autosomal dominant inheritance.<sup>29-31</sup> These patients and 20% of those with sporadic myxoma have an abnormal DNA genotype chromosomal pattern.<sup>28</sup> In contrast to the “typical” sporadic myxoma profile, familial patients are more likely to be younger, equally likely to be male or female, and more often (22%) have multicentric tumors originating from either the atrium or ventricle.<sup>32-36</sup> Although familial myxomas have the same histology, they have a higher recurrence rate after surgical resection (21-67%).<sup>27,37</sup> Approximately 20% of familial patients have associated conditions such as adrenocortical nodule hyperplasia, Sertoli cell tumors of the testes, pituitary tumors, multiple myxoid breast fibroadenomas, cutaneous myomas, and facial or labial pigmented spots.<sup>26,37</sup> These conditions often are described as *complex myxomas* within the group of familial myxoma.<sup>28</sup> A familial syndrome with autosomal X-linked inheritance characterized by primary pigmented nodular adrenocortical disease with hypercortisolism, cutaneous pigmentous lentiginos, and cardiac myxoma is referred to as *Carney's complex*.<sup>26,37</sup>

### PATHOLOGY

Both biatrial and multicentric myxomas are more common in familial disease. Biatrial tumors probably arise from bidirectional growth of a tumor originating within the atrial septum.<sup>38</sup> Atrial myxomas generally arise from the interatrial septum at the border of the fossa ovalis but can originate anywhere within the atrium, including the appendage.<sup>4</sup>

**TABLE 58-3: Benign Cardiac Neoplasms in Children**

Tumor	0 to 1-year-old		1 to 15-year-olds	
	Number	Percentage	Number	Percentage
Rhabdomyoma	28	62	35	45.0
Teratoma	9	21	11	14.0

In addition, isolated reports confirm that myxomas can arise from the cardiac valves, pulmonary artery (PA) and vein, and vena cava.<sup>30,31</sup> Right atrial myxomas are more likely to have broad-based attachments than left atrial tumors; they also are more likely to be calcified,<sup>34</sup> and thus visible on chest radiographs. Ventricular myxomas occur more often in women and children and may be multicentric.<sup>2,39</sup> Right ventricular tumors typically arise from the free wall, and left ventricular tumors tend to originate in the proximity of the posterior papillary muscle.

Grossly, about two-thirds of myxomas are round or oval tumors with a smooth or lobulated surface (Fig. 58-1).<sup>21</sup> Most are polypoid, compact, pedunculated, mobile, and not likely to fragment spontaneously.<sup>2,4</sup> Mobility depends on stalk length, the extent of attachment to the heart, and the amount of tumor collagen.<sup>4</sup> Most are pedunculated with a short, broad base, and sessile forms are unusual.<sup>2,40</sup> Less common villous or papillary myxomas are gelatinous and fragile and prone to fragmentation and embolization, occurring

**FIGURE 58-1** Large in situ left atrial myxoma as seen from the surgeon's perspective just before removal.

about one-third of the time.<sup>21,41</sup> Myxomas are white, yellow, or brown in color, and are frequently covered with thrombus.<sup>2</sup> Focal areas of hemorrhage, cyst formation, or necrosis may be seen in cut section. The average size is about 5 cm in diameter, but growth to 15 cm in diameter and larger has been reported.<sup>4</sup> Myxomatous tumors appear to grow rapidly, but growth rates vary, and occasionally, tumor growth arrests spontaneously.<sup>4</sup> Weights range from 8 to 175 g, with a mean between 50 and 60 g.<sup>5</sup>

Histologically, myxomas are composed of polygonal-shaped cells and capillary channels within an acid mucopolysaccharide matrix.<sup>4</sup> The cells appear singularly or in small clusters throughout the matrix, and mitoses are rare.<sup>42,43</sup> The matrix also contains occasional smooth muscle cells, reticulocytes, collagen, elastin fibers, and a few blood cells. Cyst, areas of hemorrhage, and foci of extramedullary hematopoiesis are also found.<sup>37,41</sup> Ten percent of the tumors have microscopic deposits of calcium and metastatic bone deposits, as well as sometimes glandular-like structures.<sup>37,41</sup> The base of the tumor contains a large artery and veins that connect with the subendocardium but do not typically extend deep beyond the subendocardium.<sup>37</sup> A coronary angiography in our own institution revealed a large feeding vessel and was suspected originally of being an angiosarcoma but on histology proved to be a typical benign myxoma. Myxomas tend to grow into the overlying cardiac cavity rather than into the surrounding myocardium. Myxomas arise from the endocardium and are considered derivative of the subendocardial multipotential mesenchymal cell.<sup>44-46</sup> This accounts for the occasional presence of hematopoietic tissue and bone in these tumors. Interestingly, myxomas have developed after cardiac trauma, including repair of atrial septal defects and trans-septal puncture for percutaneous dilatation of the mitral valve.

#### CLINICAL PRESENTATION

The classic clinical presentation of a myxoma is intracardiac obstruction with congestive heart failure (67%); signs of embolization (29%); systemic or constitutional symptoms

of fever (19%); weight loss or fatigue (17%); and immunologic manifestations of myalgia, weakness, and arthralgia (5%).<sup>21</sup> Cardiac rhythm disturbances and infection occur less frequently.

**Constitutional Symptoms.** Nearly all myxoma patients admit to a variety of constitutional symptoms. These complaints may be accompanied by a leukocytosis, elevated erythrocyte levels and sedimentation rate, hemolytic anemia, thrombocytopenia, and elevated C-reactive protein. Immunoelectrophoresis may reveal abnormal immunoglobulin levels with increased circulating IgG.<sup>47</sup> The recent discovery of elevated levels of interleukin-6 in patients with myxoma has been linked to a variety of associated conditions, including lymphadenopathy, tumor metastasis, ventricular hypertrophy, and development of constitutional symptoms.<sup>39,48,49</sup> Other less frequent complaints include Raynaud's phenomenon, arthralgias, myalgias, erythematous rash, and clubbing of the digits.<sup>4,50</sup>

Possible etiologies of such varied complaints and symptoms include tumor embolization with secondary myalgias and arthralgias and elevated immunoglobulin response.<sup>51</sup> Circulating antibody-tumor antigen complexes with complement activation also may play a role.<sup>43</sup> Such symptom complexes tend to resolve following surgical resection of the tumor.<sup>52</sup>

**Obstruction.** Obstruction of blood flow in the heart is the most common cause of acute presenting symptoms. The nature of these symptoms is determined by which of the chambers is involved and the size of the tumor. Myxomas in the left atrium tend to mimic mitral disease. These produce positional dyspnea and other signs and symptoms of heart failure associated with elevated left atrial and pulmonary venous pressures. Clinically, mitral stenosis often is suspected and leads to echocardiography and diagnosis of myxoma. Syncopal episodes occur in some patients and are thought to result from temporary occlusion of the mitral orifice.<sup>34,53</sup> Right atrial myxomas can produce a clinical picture of right-sided heart failure with signs and symptoms of venous hypertension, including hepatomegaly, ascites, and dependent edema and can cause tricuspid valve stenosis by partially obstructing the orifice.<sup>34,53</sup> If a patent foramen ovale is present, right-to-left atrial shunting may occur with central cyanosis, and paradoxical embolization has been reported.<sup>54</sup> Large ventricular myxomas may mimic ventricular outflow obstruction. The left ventricular myxoma may produce the equivalent of subaortic or aortic valvular stenosis,<sup>54,55</sup> whereas right ventricular (RV) myxomas can simulate RV outflow track or pulmonic valve obstruction.

**Embolization.** Systemic embolization is the second most common mode of myxomatous presentation, occurring in 30 to 40% of patients.<sup>2,4,34</sup> Because the majority of myxomas are left-sided, approximately 50% of embolic episodes affect the central nervous system owing to both intra- and extracranial vascular obstruction. The neurologic deficits following

embolization can be transient but are often permanent.<sup>56</sup> Specific central nervous system consequences include intracranial aneurysms, seizures, hemiparesis, and brain necrosis.<sup>57-59</sup> Retinal artery embolization with visual loss has occurred in some patients.<sup>60</sup>

Embolic myxomatous material has been found blocking iliac and femoral arteries.<sup>61,62</sup> Other sites of tumor embolization include abdominal viscera and the renal and coronary arteries.<sup>63</sup> Histologic examination of surgically removed peripheral myxoma that has embolized provides the diagnosis of an otherwise unsuspected tumor.<sup>34</sup> Renal artery specimens from a nephrectomy have shown viable enlarging embolic myxoma after excision of the primary tumor. Right-sided myxomatous emboli mainly obstruct PAs and cause pulmonary hypertension and even death from acute obstruction.<sup>4,54</sup>

**Infection.** Infection arising in a myxoma is a rare complication and produces a clinical picture of infectious endocarditis.<sup>64,65</sup> Infection increases the likelihood of systemic embolization,<sup>4</sup> and an infected myxoma warrants urgent surgical resection.

## DIAGNOSIS

**Clinical Examination.** Findings at the time of clinical assessment of a patient with cardiac myxoma vary according to the size, location, and mobility of the tumor. Left atrial myxomas may produce auscultatory or clinical findings similar to mitral disease. The well-described "tumor plop" can be confused with a third heart sound,<sup>66</sup> occurring just after the opening snap of the mitral valve created from contact between the tumor and endocardial wall.<sup>66</sup> Left atrial myxomas that cause partial obstruction of left ventricular filling may result in elevated pulmonary vascular pressures with augmentation of the pulmonary component of the second heart sound.<sup>67</sup>

Right atrial myxomas may produce similar auscultatory findings as left atrial myxomas with the exception that they are best heard along the lower right sternal border rather than at the cardiac apex. In addition, right atrial hypertension may produce a large *a* wave in the jugular venous pulse and, when severe, may mimic superior vena caval syndrome.

**Chest Radiograph and Electrocardiogram.** The findings on chest roentgenogram may include generalized cardiomegaly, individual cardiac chamber enlargement, and pulmonary venous congestion. More specific rare findings are density within the cardiac silhouette caused by calcification within the tumor (see Fig. 58-3) occurring more often with right-sided myxomas.<sup>4</sup>

**Electrocardiographic Findings.** Nonspecific abnormalities such as chamber enlargement, cardiomegaly, bundle-branch blocks, and axis deviation can be found.<sup>68</sup> Fewer than 20% of patients have atrial fibrillation.<sup>39</sup> Evaluation of nonspecific electrocardiographic abnormalities occasionally leads to an incidental diagnosis of myxoma which most electrocardiograms are not helpful in establishing a diagnosis.

**Echocardiography.** Cross-sectional echocardiography is the most useful test employed for the diagnosis and evaluation of myxoma. The sensitivity of two-dimensional (2-D) echocardiography for myxoma is 100%, and this imaging technique largely has supplanted angiocardiography.<sup>69</sup> However, coronary angiography usually is performed in myxoma patients more than 40 years of age to rule out significant coronary disease. Transesophageal echocardiography (TEE) provides the best information concerning tumor size, location, mobility, and attachment.<sup>70</sup>

Transesophageal echocardiograms detect tumors as small as 1 to 3 mm in diameter.<sup>71</sup> Most surgeons obtain a transesophageal echocardiogram in the operating room before the operation (Fig. 58-2). We particularly evaluate the posterior left atrial wall, atrial septum, and right atrium, which often are not well displayed on transthoracic examination, to exclude the possibility of biatrial multiple tumors. Additionally, postoperative TEE ensures a normal echocardiogram before leaving the operating room.

**Computed Tomography and Magnetic Resonance Imaging.** Although myxomas have been identified using computed tomography (CT),<sup>69,72</sup> this modality is most useful in malignant tumors of the heart because of its ability to demonstrate myocardial invasion and tumor involvement of adjacent structures.<sup>68</sup> Similarly, magnetic resonance imaging (MRI) has been employed in the diagnosis of myxomas and may yield a clear picture of tumor size, shape, and surface characteristics.<sup>68-72</sup> MRI is particularly useful in detecting intracardiac and pericardial extension, invasion of malignant secondary tumors, and the evaluation of ventricular masses that occasionally turn out to be myxoma. Both CT and MRI detect tumors as small as 0.5 to 1.0 cm and provide information regarding the composition of the tumor.<sup>4</sup>

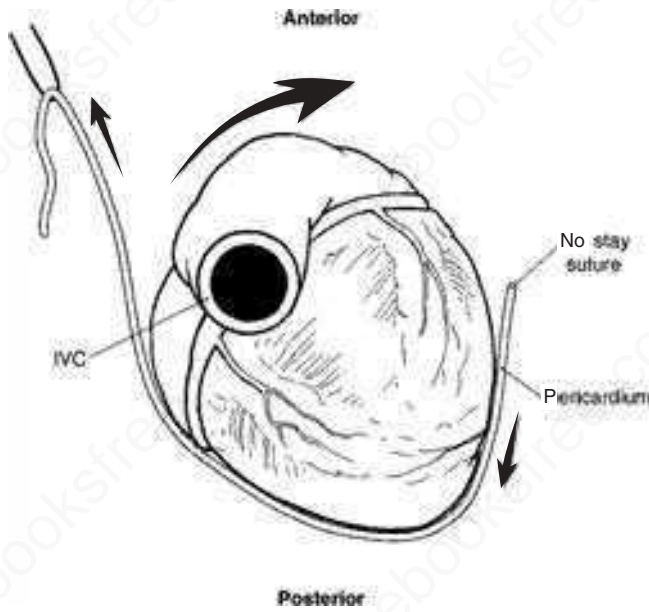

**FIGURE 58-2** Transesophageal echocardiogram of a giant left atrial myxoma that does not appear attached to the mitral valve.

Neither CT nor MRI is needed for atrial myxomas if an adequate echocardiogram is available. The exception is the occasional right atrial myxoma that extends into one or both caval or tricuspid orifices. CT or MRI should be reserved for the situation in which the diagnosis or characterization of the tumor is unclear after complete echocardiographic evaluation.

## SURGICAL MANAGEMENT

Surgical resection is the only effective therapeutic option for patients with cardiac myxoma and should not be delayed because death from obstruction to flow within the heart or embolization may occur in as many as 8% of patients awaiting operation.<sup>73</sup> A median sternotomy approach with ascending aortic and bicaval cannulation usually is employed. Manipulation of the heart before initiation of CPB is minimized in deference to the known friability and embolic tendency of myxomas. In the event of preoperative known cerebral embolization without hemorrhage, the tumor should be resected approximately seven days after the event to prevent further embolization and yet allow time for stabilization of the brain for CPB. For left atrial myxomas, the venae cavae are cannulated through the right atrial wall, with the inferior cannula placed close and laterally to the inferior vena cava (IVC)–right atrial junction. Caval snares are always used to allow opening of the right atrium, if necessary. If extensive exposure of the left atrium is needed or a malignant left atrial tumor is suspected, we mobilize and directly cannulate the superior vena cava (SVC), which allows it to be transected if necessary for additional exposure. Body temperature is allowed to drift down, but there is no attempt to induce systemic hypothermia unless the need for reduced perfusion flow is anticipated. Modern cardioplegic techniques yield a quiet operative field and protect the myocardium from ischemic injury during aortic cross-clamping. CPB is started, and the aorta is clamped before manipulation of the heart.

Exposure of left atrial myxomas is maximized by using several principles from mitral valve repair surgery. The surgeon desires the right side of the heart to rotate up and the left side of the heart to rotate down. Therefore, stay sutures are placed low on the pericardium on the right side, and no pericardial stay sutures are placed on the left before placing the chest retractor. This rotates the heart for optimal exposure of both the right and, particularly, the left atrium (Fig. 58-3). For left atrial tumors, the SVC is mobilized extensively, as is the IVC–right atrial junction, allowing increased mobility and exposing the left atrial cavity. Left atrial myxomas can be approached by an incision through the anterior wall of the left atrium anterior to the right pulmonary veins (Fig. 58-4). This incision can be extended behind both cavae for greater exposure (Fig. 58-5). Exposure and removal of large tumors attached to the interatrial septum may be aided by a second incision parallel to the first in the right atrium. This biatrial incision allows easy removal of tumor attached to the fossa ovalis with a full-thickness Ro (margin-negative) excision at

**FIGURE 58-3** Rotation of the heart with pericardial stay sutures for left atrial exposure. IVC = inferior vena cava.

the site of attachment and easy patch closure of the atrial septum if necessary (Fig. 58-6).

Right atrial myxomas pose special venous cannulation problems, and intraoperative echocardiography may be beneficial. Both venae cavae may be cannulated directly. When low- or high-lying tumor pedicles preclude safe transatrial cannulation, cannulation of the jugular or femoral vein can provide venous drainage of the upper or lower body. In general, we always can cannulate the SVC distal enough from the right atrium to allow adequate tumor resection, but occasionally femoral venous cannula drainage has been necessary. If the tumor is large or attached near both caval orifices, peripheral cannulation of both jugular and femoral veins may be used to initiate CPB and deep hypothermia. After the aorta

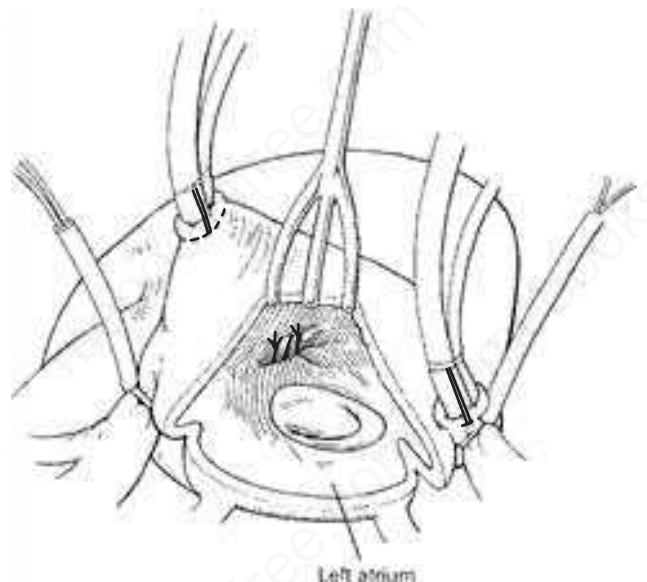

**FIGURE 58-4** Left atriotomy and exposure of myxoma.

**FIGURE 58-5** Left atrial atriotomy posterior to the interatrial groove to expose the left atrial tumor.

is cross-clamped and the heart is arrested with antegrade cardioplegia, the right atrium may be opened widely for resection of the tumor and reconstruction of the atrium during a period of circulatory arrest if this is needed for a dry field. Resection of large or critically placed right atrial myxomas often requires careful preoperative planning, intraoperative TEE, and special extracorporeal perfusion techniques to ensure complete removal of the tumor, protection of right atrial structures, and reconstruction of the atrium. Because myxomas rarely extend deep in the endocardium, it is not necessary to resect deeply around the conduction tissue. The tricuspid valve and the right atrium, as well as the left atrium

**FIGURE 58-6** Repair of left atrial wall after removal of myxomas.

**FIGURE 58-7** Giant left atrial myxoma just before removal.

and ventricle, should be inspected carefully for multicentric tumors in patients with right atrial myxoma. Regardless of the surgical approach, the ideal resection encompasses the tumor and a portion of the cardiac wall or interatrial septum to which it is attached (Fig. 58-7). Our policy is to perform a full-thickness resection whenever possible. However, partial-thickness resection of the area of tumor attachment has been performed when anatomically necessary without a noted increase in recurrence rate.<sup>74,75</sup>

Ventricular myxomas usually are approached through the AV valve<sup>76</sup> or by detaching the anterior portion of the AV valve for exposure and resection and reattachment after resection. Occasional small tumors in either outflow tract can be removed through the outflow valve.<sup>76</sup> If necessary, the tumor is excised through a direct incision into the ventricle, but this is unusual and the least preferred approach. It is not necessary to remove the full thickness of the ventricular wall because no recurrences have been reported with partial-thickness excisions. As with right atrial myxoma, the presence of ventricular myxoma prompts inspection for other tumors because of the high incidence of multiple tumors.

Every care should be taken to remove the tumor without fragmentation. Following tumor removal from the field, the area should be liberally irrigated, suctioned, and inspected for loose fragments. There are rare instances of distant metastases from myxoma many years after tumor resection, and these reports raise the issue of potential intraoperative dissemination of tumor.<sup>77</sup> Cardiotomy suction can be used during the operation, but wall suction should strictly be used during the brief time that the tumor is exposed. The low malignant potential of the vast majority of myxomas and the rarity of metastasis support the author's current policy of retaining rather than discarding blood, and we believe that most cases of metastatic implantation of myxoma represent a preoperative embolic event.

**Minimally Invasive Approaches to Surgical Removal.** Minimally invasive approaches are being applied with increasing frequency in all areas of cardiac surgery, and

cardiac tumors are no exception. Experience is confined to benign tumors and is quite limited. Approaches have included right parasternal or partial sternotomy exposure with standard cardioplegic techniques,<sup>78</sup> right submammary incision with femoral–femoral bypass and nonclamped ventricular fibrillation,<sup>79</sup> and the right submammary port access method with antegrade cardioplegia and ascending aortic balloon occlusion.<sup>80</sup> Thoracoscopic techniques have been used to aid in visualization and removal of ventricular fibroelastomas<sup>81,82</sup> (Fig. 58-8). Myxoma removal is possible via thoracoscopy.<sup>83</sup> Results in this limited number of selected patients have been good, but more experience and longer follow-up are needed before this can be recommended as a standard approach.

Minimally invasive cardiac surgical (MICS) approaches are possible for myxomas and fibroelastomas in appropriate anatomic locations in the right and left atria or AV valves. A right chest (nonsternal) approach is used to gain access to the atria or the ventricles through the mitral or tricuspid valves. Fibroelastomas are also amenable to excision through a MICS approach to the aortic valve and left ventricular outflow tract (LVOT).

MICS approaches are generally performed through a limited right lateral third or fourth intercostal space (ICS) incision (5–8 cm) for exposure of the right and left atria. Exposure of the aortic valve and LVOT is achieved via an upper mini-sternotomy toward the third ICS or anterior thoracotomy with disarticulation of the third rib at the sternum.

In mini-sternotomy approaches, the patient is positioned supine with arms at the side and full exposure to the femoral and axillary spaces. In right lateral approaches, the patient is positioned supine with a bump placed vertically to elevate the right hemi-thorax; exposing the lateral ribs as well as the axillary and femoral spaces.

**FIGURE 58-8** Thoracoscopic view of left atrial fibroelastoma.

Safe and complete CPB is essential to achieve optimal clinical outcomes. Complete tumor resection, adequate venous drainage, aortic clamping, and complete de-airing are essential for a successful result. In left-sided tumors, CPB can be safely performed via femoral vessel Selinger access (percutaneously or cut-down) and multistage venous drainage. In patients where right-sided cardiac access is necessary, a separate SVC cannula can be inserted and snared separately via the right mini-thoracotomy. Optimal venous drainage is essential for adequate visualization and RV myocardial protection. Arterial cannulation can be performed femorally, directly into the ascending aorta or via the axillary artery.

Myocardial protection in MICS procedures, similar to MICS valve surgery, is dependent on delivery of cardioplegia. Antegrade cardioplegia is usually administered directly into the ascending aorta. Retrograde cardioplegia is performed via direct catheterization of the coronary sinus (CS) through the right atrium. Alternatively, a percutaneous CS catheter can be inserted via a neck approach prior to surgery. Aortic clamping is optimally performed via standard Chitwood clamp inserted through an axillary stab. Endovascular balloon aortic occlusion may also be performed if the aortotomy is not required. Venting of the LV may be performed through direct cannulation of the LA/LV via right superior pulmonary vein or percutaneously through PA drainage (Fig. 58-37a and 58-37b).

Excellent preoperative imaging (optimally through cardiovascular magnetic resonance) is necessary to delineate tumor anatomy and involvement prior to MICS procedures and surgical planning. If performed adequately, MICS tumor resection is a viable and safe option for complete removal of tumors. With these approaches, patients may benefit from decreased transfusions, length of stay, and pain medication requirement.

## Results

Removal of atrial myxomas carries an operative mortality rate of 5% or less.<sup>21</sup> Operative mortality is related to advanced age or disability and comorbid conditions. Excision of ventricular myxomas can carry a higher risk (approximately 10%). Our experience over the last 15 years with 85 myxomas shows no operative or hospital mortality.

Recurrence of nonfamilial sporadic myxoma is approximately 1 to 4%.<sup>4,74,75</sup> Many large series report no recurrent tumors.<sup>74,83-86</sup> The 20% of patients with sporadic myxoma and abnormal DNA have a recurrence rate estimated at between 12 and 40%.<sup>4</sup> The recurrence rate is highest in patients with familial complex myxomas, all of whom exhibit DNA mutation, and this is estimated to be about 22%.<sup>4</sup> Overall, recurrences are more common in younger patients. The disease-free interval averages about 4 years and can be as brief as 6 months.<sup>75</sup> Most recurrent myxomas occur within the heart, in the same or different cardiac chambers, and may be multiple.<sup>19,34,87</sup> Extracardiac recurrence after resection of tumor, presumably from embolization and subsequent tumor growth and local invasion, has been observed.<sup>19,87,88</sup> The biology of the tumor, dictated by gene expression rather than

histology, may be the only reliable factor predicting recurrence. DNA testing of all patients with cardiac myxoma may prove to be the best predictor of the likelihood of recurrence.<sup>89</sup>

Myxomas generally classified as “malignant” are often found on subsequent review to be sarcomas with myxoid degeneration.<sup>90</sup> However, this issue also remains unsettled because of reports of metastatic growth of embolic myxoma fragments in the brain, arteries, soft tissue, and bones.<sup>56,88,91-97</sup> Symptomatic lesions of possible metastatic myxoma should be excised if feasible.<sup>56,91</sup>

The extent to which patients should be subjected to long-term echocardiographic surveillance after myxoma resection is not standardized. It would seem prudent to closely follow patients who are treated initially for multicentric tumors, those whose tumors are removed from unusual locations in the heart, all tumors believed to have been incompletely resected, and all tumors found to have an abnormal DNA genotype. Patients undergoing resection of tumors thought to be myxomas but with malignant characteristics at pathologic examination should have long-term, careful follow-up.

## Other Benign Cardiac Tumors

As shown in Table 58-2, myxomas comprise approximately 41% of benign cardiac tumors, with three other tumors (ie, lipoma, papillary fibroelastoma, and rhabdomyoma) together contributing a similar proportion. A number of rarely encountered tumors account for the remainder.

### LIPOMA

Lipomas are well-encapsulated tumors consisting of mature fat cells that may occur anywhere in the pericardium, sub-endocardium, subepicardium, and intra-atrial septum.<sup>2</sup> They may occur at any age and have no sex predilection. Lipomas are slow growing and may attain considerable size before producing obstructive or arrhythmic symptoms. Many are asymptomatic and are discovered incidentally on routine chest roentgenogram, echocardiogram, or at surgery or autopsy.<sup>98,99</sup> Subepicardial and parietal lipomas tend to compress the heart and may be associated with pericardial effusion. Subendocardial tumors may produce chamber obstruction. The right atrium and left ventricle are the sites affected most often. Lipomas lying within the myocardium or septum can produce arrhythmias or conduction abnormalities. Large tumors that produce severe symptoms should be resected. Smaller, asymptomatic tumors encountered unexpectedly during cardiac operation should be removed if excision can be performed without adding risk to the primary procedure. These tumors are not known to recur.

### Lipomatous Hypertrophy of the Interatrial Septum

Nonencapsulated hypertrophy of the fat within the atrial septum is known as *lipomatous hypertrophy*.<sup>2</sup> This abnormality is

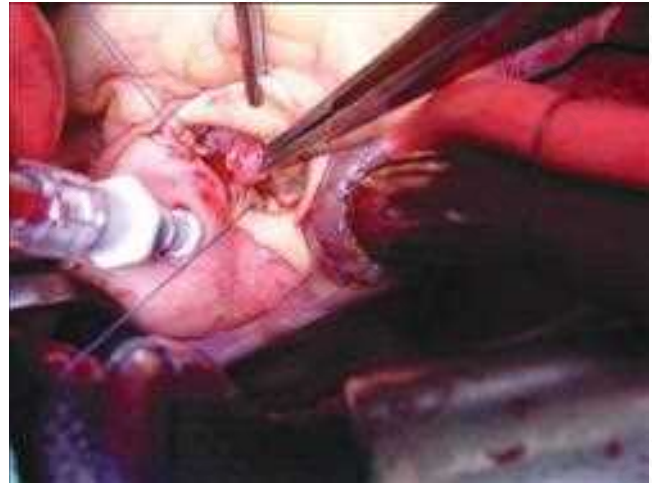

more common than cardiac lipoma and is usually encountered in elderly, obese, or female patients as an incidental finding during a variety of cardiac imaging procedures.<sup>84</sup> Various arrhythmias and conduction disturbances have been attributed to its presence.<sup>85,100</sup> The main difficulty is differentiating this from a cardiac neoplasm on echocardiography.<sup>101</sup> After the demonstration of a mass by echocardiography, the typical T1 and T2 signal intensity of fat on MRI usually can establish a diagnosis.<sup>102,103</sup> Arrhythmias and heart block are considered by some as indications for resection, but data are lacking as to the long-term benefits from resection.<sup>104</sup>

### Papillary Fibroelastoma of the Heart Valves

Papillary fibroelastomas are tumors that arise characteristically from the cardiac valves or adjacent endocardium.<sup>105</sup> These tumors are described as resembling sea anemones with frond-like projections in gross description (Fig. 58-9). The AV and semilunar valves are affected with equal frequency. It is now known that these are capable of producing obstruction of flow, particularly coronary ostial flow, and may embolize to the brain and produce stroke.<sup>106-115</sup> They are usually asymptomatic until a critical event occurs. Papillary fibroelastomas of the cardiac valve should be resected whenever diagnosed, and valve repair rather than replacement should follow the resection of these benign tumors whenever technically feasible (Fig. 58-10). Cytomegalovirus has been recovered in these tumors, suggesting the possibility of viral induction of the tumor and chronic viral endocarditis.<sup>111</sup>

**FIGURE 58-9** Additional enhanced view of an in situ left atrial fibroelastoma.

**FIGURE 58-10** Surgical removal of a papillary fibroelastoma.

### RHABDOMYOMA

Rhabdomyoma is the most frequently occurring cardiac tumor in children. It usually presents during the first few days after birth. It is thought to be a myocardial hamartoma rather than a true neoplasm.<sup>116</sup> Although rhabdomyoma appears sporadically, it is associated strongly with tuberous sclerosis, a hereditary disorder characterized by hamartomas in various organs, epilepsy, mental deficiency, and sebaceous adenomas. Fifty percent of patients with tuberous sclerosis have rhabdomyoma, but more than 50% of patients with rhabdomyoma have or will develop tuberous sclerosis.<sup>117</sup> More than 90% of rhabdomyomas are multiple and occur with approximately equal frequency in both ventricles.<sup>118</sup> The atrium is involved in fewer than 30% of patients. Pathologically, these tumors are firm, gray, and nodular and tend to project into the ventricular cavity. Micrographs show myocytes of twice normal size filled with glycogen, containing hyperchromatic nuclei and eosinophilic-staining cytoplasmic granules.<sup>2,119</sup> Scattered bundles of myofibrils can be seen within cells by electron microscopy.<sup>118</sup>

Clinical findings may mimic valvular or subvalvular stenosis. Arrhythmias, particularly ventricular tachycardia and sudden death, may be a presenting symptom.<sup>119</sup> Atrial tumors may produce atrial arrhythmias.<sup>119</sup> The diagnosis is made by echocardiography. Rarely, no intramyocardial tumor is found in a patient with ventricular arrhythmias, and the site of rhabdomyoma is located by electrophysiologic study.<sup>119</sup>

Early operation is recommended in patients who do not have tuberous sclerosis before 1 year of age.<sup>86</sup> The tumor usually is removed easily in early infancy, and some can be enucleated.<sup>86</sup> Unfortunately, symptomatic tumors often are both multiple and extensive, particularly in patients with tuberous sclerosis, who, unfortunately, have a dismal long-term outlook. In such circumstances, surgery offers little benefit.

### FIBROMA

Fibromas are the second most common benign cardiac tumor, with more than 83% occurring in children. These tumors are

**FIGURE 58-11** Left ventricular fibroma as seen from an external view of the heart.

solitary, occur exclusively within the ventricle and the ventricular septum, and affect the sexes equally. Fewer than 100 tumors have been reported, and most are diagnosed by age 2 years. These tumors are not associated with other disease, nor are they inherited. Fibromas are nonencapsulated, firm, nodular, gray-white tumors that can become bulky. They are composed of elongated fibroblasts in broad spiral bands and whirls mixed with collagen and elastin fibers. Calcium deposits or bone may occur within the tumor and occasionally are seen on roentgenography (Figs. 58-11 and 58-12).

Most fibromas produce symptoms through chamber obstruction, interference with contraction, or arrhythmias. Depending on size and location, such a tumor may interfere with valve function, obstruct flow paths, or cause

**FIGURE 58-12** MRI of left ventricular fibroma.

sudden death from conduction disturbances in up to 25% of patients.<sup>114</sup> Intracardiac calcification on chest roentgenograms suggests the diagnosis, which is confirmed by echocardiogram.

Surgical excision is successful in some patients, particularly if the tumor is localized, does not involve vital structures, and can be enucleated.<sup>86,120-122</sup> However, it is not always possible to remove the tumor completely, and partial removal is only palliative, although some patients have survived many years.<sup>86,121</sup> Operative mortality may be high in infants. Most cases are in adolescents and adults.<sup>186,120,121</sup> Successful, complete excision is curative.<sup>120,121</sup> Children with extensive fibromas have been treated with cardiac transplantation.<sup>122,123</sup>

### MESOTHELIOMA OF THE AV NODE

Mesothelioma of the AV node is also termed *polycystic tumor*, *Purkinje tumor*, or *conduction tumor*. It is a relatively small, multicystic tumor that arises in proximity to the AV node and may extend upward into the interventricular septum and downward along the bundle of His.<sup>2</sup> Mesothelioma is associated with heart block, ventricular fibrillation,<sup>124</sup> and sudden death. Cardiac pacing alone does not prevent subsequent ventricular fibrillation. Surgical excision has been reported.<sup>24</sup>

### PHEOCHROMOCYTOMA

Cardiac pheochromocytomas arise from chromaffin cells of the sympathetic nervous system and produce excess amounts of catecholamines, particularly norepinephrine. Approximately 90% of pheochromocytomas are in the adrenal glands. Fewer than 2% arise in the chest. Only 32 cardiac pheochromocytomas had been reported by 1991.<sup>125</sup> The tumor predominantly affects young and middle-aged adults with an equal distribution between the sexes. Approximately 60% occur in the roof of the left atrium. The remainder involve the interatrial septum or anterior surface of the heart. The tumor is reddish brown, soft, lobular, and consists of nests of chromatin cells.

The patients usually present with symptoms of uncontrolled hypertension or are found to have elevated urinary catecholamines. The tumor usually is located by scintigraphy using [<sup>131</sup>I] metaiodo-benzylguanidine<sup>126</sup> and CT or MRI.<sup>126</sup> Cardiac catheterization with differential blood chamber sampling sometimes is necessary in addition to coronary angiography.<sup>125</sup> After the tumor is located, it should be removed using CPB with cardioplegic arrest. Patients require preanesthetic alpha and beta-blockade and careful intraoperative and immediate postoperative monitoring. Most tumors are extremely vascular, and uncontrollable operative hemorrhage has occurred.<sup>126</sup> Resection may require removal of the atrial and/or ventricular wall or a segment of a major coronary artery.<sup>127</sup> Explantation of the heart to allow resection of a large left atrial pheochromocytoma has been attempted.<sup>128</sup> Transplantation has been performed for unresectable tumor and complete excision produces cure.<sup>121-123</sup>

**FIGURE 58-13** Paraganglioma blush of tumor during cardiac catheterization.

### PARAGANGLIOMA

Paragangliomas are endocrine tumors that can secrete catecholamines. As a result, their presentation is often similar to that of pheochromocytomas. When found within the thoracic cavity, they are located most often in the posterior mediastinum. Paragangliomas typically present with atypical chest pain.<sup>129,130</sup> On echocardiography, they are often large and highly vascular tumors.<sup>131</sup> On cardiac catheterization, they may be intimately associated with the coronary arteries (Fig. 58-13).<sup>132</sup> Between March 2004 and October 2010, 7 male patients from our institution who underwent surgical resection of cardiac paraganglioma were retrospectively reviewed. In 5 patients, paragangliomas originated from the roof of the left atrium, and in 2 patients, they originated from the aortic root. Hospital mortality was 14%. Complete surgical resection remains the mainstay of therapy and can be curative, but carries a significant risk of intraoperative bleeding and usually requires CPB and often complex resection techniques, including cardiac autotransplantation (Fig. 58-14).

### HEMANGIOMA

Hemangiomas of the heart are rare tumors (24 clinical cases reported), affect all ages, and may occur anywhere within the heart.<sup>133,134</sup> These are vascular tumors composed of capillaries or cavernous vascular channels. Patients usually develop dyspnea, occasional arrhythmias, or signs of right-sided heart failure.<sup>135</sup> Diagnosis is difficult, and echocardiography or cardiac catheterization can establish a diagnosis of cardiac tumor by showing an intracavity filling defect.<sup>127</sup> CT and MRI show axial T2-weighted; MRI should show a high signal mass owing to vascularity (Fig. 58-15). Coronary angiography typically shows a tumor blush and maps the blood supply to the tumor. During resection, meticulous ligation of feeding vessels is required to prevent postoperative residual arteriovenous fistulas or intracavity communications. Partial resections have produced long-term benefits.<sup>133</sup> Tumors rarely resolve spontaneously.<sup>136</sup>

**FIGURE 58-14** MRI of left atrial paraganglioma that required an autotransplant for removal.

### TERATOMA

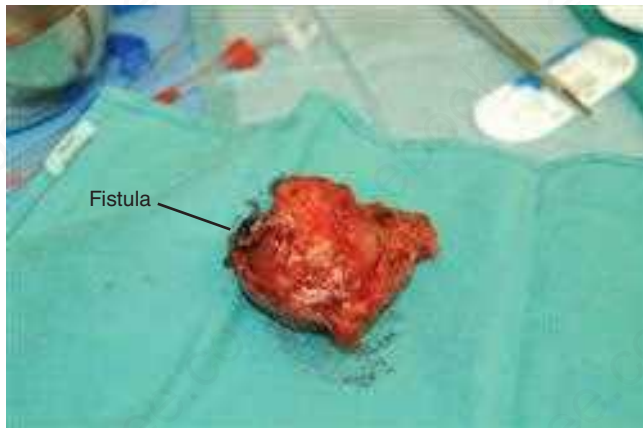

Cardiac teratoma is a rare tumor that typically presents in infants and young children.<sup>137</sup> About 80% of the tumors are benign.<sup>138</sup> These tumors are discovered by echocardiography after a variety of symptoms lead to cardiac or mediastinal evaluation. There is little experience with surgical removal, which should be possible.

### CASTLEMAN TUMOR

Castleman disease is a poorly understood lymphoproliferative disorder. The disease was first described by Castleman

**FIGURE 58-15** Axial T2-weighted magnetic resonance image showing high signal mass of left atrial hemangioma. (Reproduced with permission from Lo JJ, Ramsay CN, Allen JW, et al: Left atrial cardiac hemangioma associated with shortness of breath and palpitations, *Ann Thorac Surg* 2002 Mar;73(3):979-981.)

**FIGURE 58-16** Castleman tumor showing fistula site indicated by insertion of a coronary probe.

and colleagues in 1956.<sup>139</sup> It typically presents as a solitary lesion in the mediastinum. The most common histologic type is hyaline vascular, which accounts for approximately 90% of cases and often behaves in a benign fashion. The more aggressive subgroups are the plasma and mixed-cell types, which have a more malignant behavior.<sup>140</sup> Patients may have a localized or multicentric disease with lymph node involvement, typically in the mediastinum. These tumors typically present as well-circumscribed masses. There have been reports of Castleman disease with myocardial and coronary artery invasion or development of a coronary pseudoaneurysm.<sup>141</sup> In these more aggressive cases, cardiac assist devices have been used as a bridge to recovery<sup>141</sup> (Figs. 58-16 and 58-17). CT imaging of the lesions reveals atypical or target-like enhancement that corresponds to various degrees of degeneration, necrosis, and fibrosis. Technetium-99m tetrofosmin and

**FIGURE 58-17** MRI of Castleman tumor.

[I<sup>123</sup>] beta-methyliodophenyl pentadecanoic acid (BMIPP) imaging may aid in the diagnosis. On BMIPP, these tumors show reduced uptake compared with the surrounding normal myocardium.<sup>142</sup> Complete surgical resection is considered curative.<sup>143</sup>

## PRIMARY MALIGNANT TUMORS

Primary cardiac malignancy is very uncommon, with only 21 surgically treated cases noted in a 25-year surgical experience from 1964 to 1969, combining the experience of two large institutions, the Texas Heart Institute and the MD Anderson Cancer Center in Houston.<sup>144</sup> Additional current reports from the Texas Medical Center include a series from the Methodist DeBakey Heart and Vascular Center and MD Anderson Cancer Center of 27 patients selected from 1990 to 2006.<sup>144</sup> Approximately 25% of primary cardiac tumors are malignant, and of these, about 75% are sarcomas. McAllister's survey of cardiac tumors found the most common to be angiosarcomas (31%), rhabdomyosarcomas (21%), malignant mesotheliomas (15%), and fibrosarcomas (11%),<sup>2</sup> see Table 58-4.

Rather than histologic classification of cardiac sarcoma, we propose a classification system based on anatomic location. Histology does not greatly affect treatment or prognosis as much as anatomic location.<sup>144,145</sup> The revised classification system divides primary cardiac sarcomas into right heart sarcomas, left heart sarcomas, and PA sarcomas, and these are the categories that will be used in the discussion to follow.

Right heart sarcomas tend to metastasize early, present as bulky masses (Fig. 58-18), and are characteristically infiltrative.<sup>145</sup> Right heart sarcomas often occupy much of the right atrium growing largely in an outward pattern, and often avoid heart failure until the latest stage of presentation. This presentation often allows time for neoadjuvant chemotherapy

**TABLE 58-4: Primary Malignant Cardiac Neoplasms in Adults**

Tumor	Number	Percentage

**FIGURE 58-18** CT scan of a right heart tumor.

in an attempt to shrink the tumor and sterilize the infiltrating edges to increase the chances of obtaining a resection with microscopically negative margins.

Left heart sarcomas tend to be more solid with less infiltration than right heart sarcomas and tend to metastasize later in the course of disease.<sup>146</sup> Left-sided sarcomas are most often located in the left atrium, and tend to grow into the wall. Diminution of blood flow quickly results in life-threatening heart failure. Neoadjuvant chemotherapy can rarely be used because of this presentation. Most left atrial sarcomas are initially clinically diagnosed as myxomas, have a positive resection margin, rapidly recur, and require repeat resection.

Primary malignant cardiac tumors arise sporadically, showing no inherited linkage. Although they may span the entire age spectrum, they usually occur in adults more than 40 years of age. The patients usually present with symptoms of congestive heart failure, pleuritic chest pain, malaise, anorexia, and weight loss.<sup>137,147</sup> The most common symptom has been dyspnea<sup>148</sup> (Table 58-5). Some develop refractory arrhythmias, syncope, pericardial effusion, and tamponade.<sup>148</sup> The chest x-ray may be abnormal and even show a mass lesion, but the definite diagnosis usually is made with cardiac echocardiography.<sup>147,149</sup> Right atrial lesions are more frequently malignant (usually angiosarcoma) than left-sided lesions (usually myxoma but, when malignant, often malignant fibrous histiocytoma [MFH]). If malignancy is suspected, chest CT or MRI may suggest histology and provide detailed anatomy and help in staging and assessing resectability. The current status of positron-emission tomographic (PET) scans in evaluating these patients remains controversial. We perform cardiac catheterization on all patients older than 40 years of age presenting with intracardiac masses and on all patients with

**TABLE 58-5: Symptoms of Primary Malignant Cardiac Tumors**

Symptom	Number	Percentage
Dyspnea	13/21	61.9

large right atrial masses. Malignancy may be suggested and coronary involvement suspected by tumor blush. This is not pathognomonic because we have seen a large feeding vessel and tumor blush in a histologically confirmed myxoma.

Unfortunately, primary cardiac malignancy may grow to a large size before detection and involve portions of the heart not amenable to resection. Some of these patients have been considered for transplantation and will be discussed later. Otherwise, palliative medical therapy can be attempted with radiation therapy, although success in both symptom relief and longevity has been somewhat limited. Whether the tumor is primary or secondary, the decision to resect is based on tumor size and location and an absence of metastatic spread seen on complete evaluation. Unfortunately, most primary cardiac malignancies that have been referred to our center were considered to be benign initially and were resected incompletely at presentation. If malignancy is suspected or confirmed, and if the lesion appears anatomically resectable and there is no metastatic disease, then resection should be considered. If complete resection is possible, surgery provides better palliation and potentially can double survival.<sup>150</sup> After resection, we recommend adjuvant chemotherapy and believe that this can improve survival.<sup>138,150</sup> Complete resection will depend on the location of the tumor, the extent of involvement of the myocardium and/or fibrous skeleton of the heart, and histology.

## Angiosarcoma

Angiosarcomas are two to three times more common in men than in women and have a predilection for the right side of the heart. Eighty percent arise in the right atrium.<sup>148,151,152</sup> These tumors tend to be bulky and aggressively invade adjacent structures, including the great veins, tricuspid valve, RV free wall, interventricular septum, and right coronary artery<sup>151</sup> (Fig. 58-19). Obstruction and right-sided heart failure are not uncommon. Pathologic examination of resected specimens demonstrates anastomosing vascular channels lined with typical anaplastic epithelial cells. Unfortunately, most of these tumors have spread by the time of presentation, usually to the lung, liver, and brain.<sup>148</sup> Without resection, 90% of the

**FIGURE 58-19** Pathology specimen photograph of a right atrial tumor.

patients are dead within 9 to 12 months of diagnosis despite radiation or chemotherapy.<sup>22,148</sup> We have seen carefully selected patients without evidence of spread on metastatic evaluation who have undergone complete surgical resection with subsequent chemotherapy (Fig. 58-20). In addition to surgical resection of the right atrium, right coronary bypass and even tricuspid valve repair or replacement may be undertaken (Fig. 58-21). We have had no hospital mortality in this small group, and most patients die from metastasis rather than recurrence at the local site.<sup>153</sup>

### Malignant Fibrous Histiocytoma

MFH is the most common soft tissue sarcoma in adults. Its occurrence as a cardiac primary malignancy has been relatively recently accepted as a specific entity. It is characterized histologically by a mixture of spindle cells in a storiform pattern, polygonal cells resembling histiocytes, and malignant giant cells. The cell of origin is the fibroblast or histioblast.<sup>149,154</sup> It usually occurs in the left atrium and often mimics myxoma. In fact, every left atrial MFH referred to our institution has been previously incompletely resected when thought to represent a myxoma. The tendency to metastasize early is not as prominent as with angiosarcoma. Several reports document rapid symptomatic recurrence after incomplete resection despite chemotherapy. These patients often die of local cardiac disease before the development of metastases. We believe that if complete resection can be obtained (particularly if the malignant nature is recognized and complete resection can be done at the original operation) and adequate chemotherapy can be provided, we may improve survival in this otherwise dismal disease.

### Rhabdomyosarcoma

Rhabdomyosarcomas do not evolve from rhabdomyomas and occur equally in the sexes. The tumors are multicentric in 60% of patients and arise from either ventricle. These tumors frequently invade cardiac valves or interfere with valve

function because of their intracavitary bulk. Microscopically, tumor cells demonstrate pleomorphic nuclei and spidery, wispy, streaming eosinophilic cytoplasm, usually in a muscle-like pattern.

The tumors are aggressive and may invade pericardium. Surgical excision of small tumors may be rational, but local and distant metastases and poor response to radiation or chemotherapy limit survival to less than 12 months in most of these patients.<sup>120,137,138,150,155</sup>

### Other Sarcomas and Mesenchymal-Origin Tumors

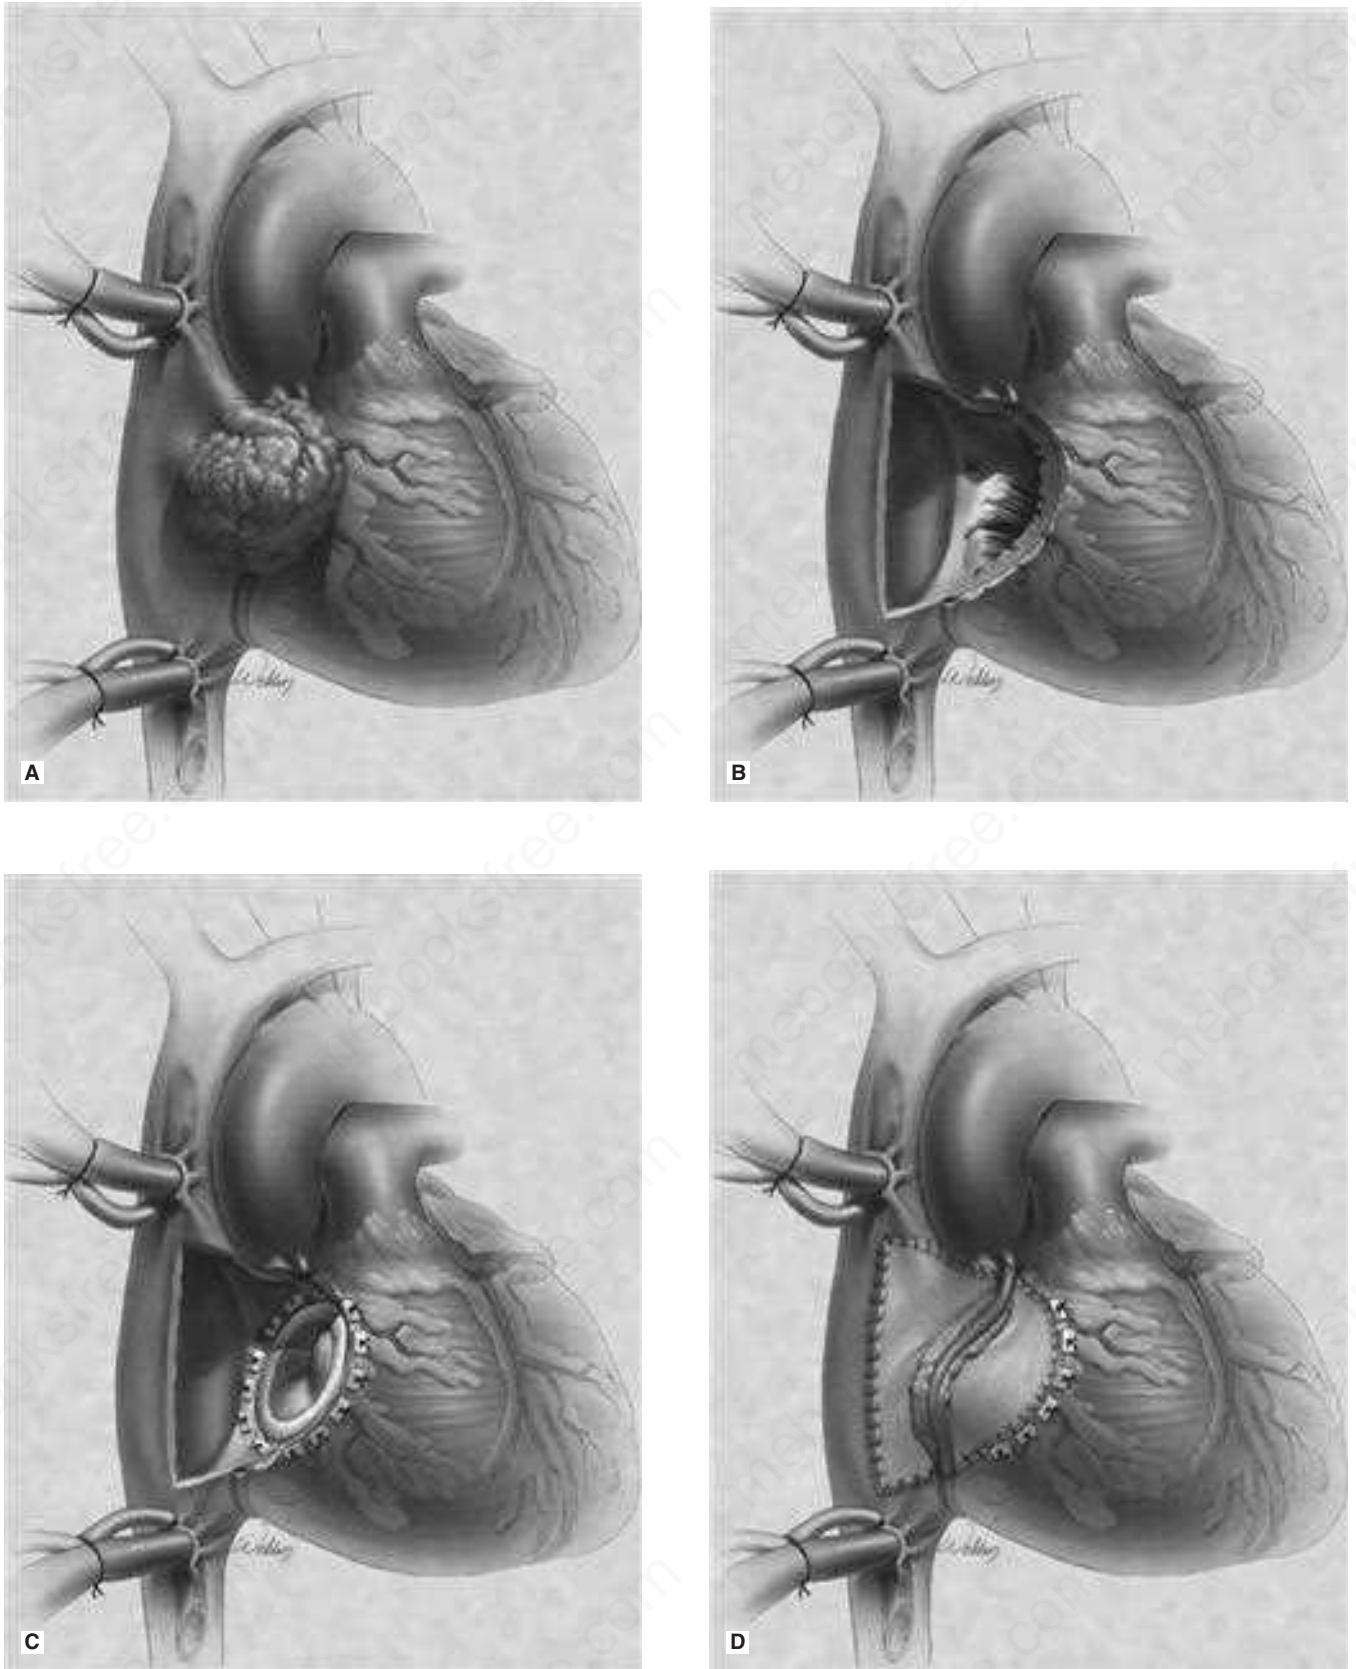

McAllister and Fenoglio found that malignant mesotheliomas arising from the heart or pericardium and not from the surrounding pleura were the third most common malignant cardiac tumors and that fibrosarcomas were fourth.<sup>2</sup> However, in the two decades since their work, clinicians have rarely encountered these tumors. This apparent decrease in incidence may be related to changes in histologic criteria for classifying primary malignant neoplasms since their study.<sup>5,133,138,148-150,155,156</sup>

The histology of these tumors can be ambiguous and difficult. These neoplasms can resemble other sarcomas, and some might be deemed fibrous histiocytomas today. The behavior of these tumors is more important, and as with other cardiac sarcomas, resection of small tumors in the absence of known metastasis perhaps is justified, but data are scarce.<sup>22,148,150,155</sup> This being said, it is important to rule out more diffuse thoracic involvement with mesothelioma before considering resection of an isolated cardiac or pericardial mesothelioma. A PET scan may be considered, and any suspicious pleural thickening or effusion should be evaluated carefully both radiographically and histologically.

Myosarcoma, liposarcoma, osteosarcoma, chondromyxosarcoma, plasmacytoma, and carcinosarcoma arising from the heart all have been reported,<sup>156-159</sup> but by the time diagnosis is made, only palliative therapy usually can be offered, and surgery is indicated only occasionally. Regardless of therapy, it is unusual for patients with these diagnoses to survive more than a year.

### Right-Sided Cardiac Sarcomas

The prognosis without surgery for right heart sarcoma is dismal, and surgical resection is the only treatment modality shown to increase survival. Complete surgical resection is complicated both by the bulky infiltrative nature of right heart sarcoma and the high incidence of metastatic disease at presentation. The author's current approach to right heart sarcomas has been to begin with neoadjuvant chemotherapy once a definitive tissue diagnosis of sarcoma is made using a right heart catheterization biopsy. Occasionally, a diagnosis of lymphoma or other tumor is made. Multidisciplinary treatment planning based on the *correct* diagnosis is imperative. After 4 to 6 rounds of chemotherapy (with repeat imaging

**FIGURE 58-20** (A) Right atrial angiosarcoma involving right coronary artery and tricuspid valve, (B) excision of tumor with right coronary artery and tricuspid valve, (C) tricuspid valve replaced, (D) completed repair using bovine pericardium.

**FIGURE 58-21** Right atrial angiosarcoma (final repair with right coronary artery bypass positioned over bovine pericardium).

every other cycle to assess for tumor response), the patient is evaluated for surgical resection. This treatment regimen aims to improve on the current microscopic complete resection rate of 33%. The initial diagnostic test for right heart sarcomas is transthoracic echocardiography, which rarely misses these usually large tumors. Unlike large left atrial masses that are usually benign myxomas, the majority of large right atrial masses are typically malignant (Fig. 58-22). The majority of right heart sarcomas referred to our specialty center have yet to undergo attempted resection, unlike left-sided heart tumors which are typically resected under the presumption they are benign myxomas. The primary reason for local failure of a right heart sarcoma is incomplete resection, typically because of surgical hesitancy to achieve complete resection because of involvement of the right coronary artery.

Most right heart sarcomas are angiosarcomas<sup>2</sup> (Fig. 58-23). These tumors may occur in the right atrium (Fig. 58-24) or the right ventricle but far more commonly arise from the right atrium. They replace the right atrial wall and frequently grow

**FIGURE 58-22** Transthoracic echocardiogram of a right atrial mass measuring 4.45 by 2.69 centimeters.

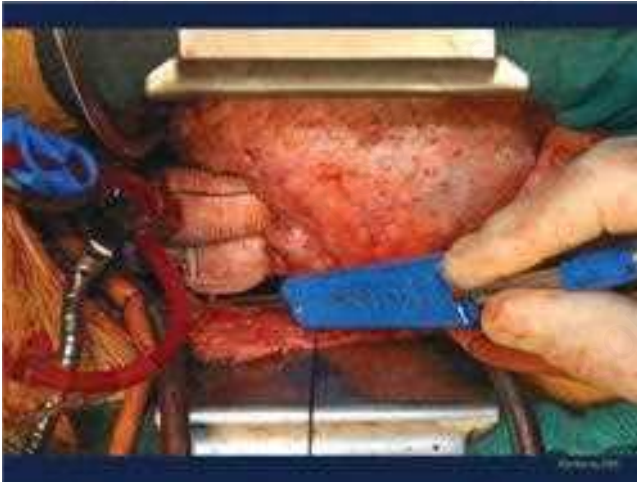

**FIGURE 58-23** CT scan of a right atrial mass with the pathology specimen oriented in a similar fashion over the image.

into the cardiac chamber and into adjacent tissues. Right heart tumors tend to be infiltrative and form microscopic “fingers” of tumor extending beyond the margins of gross disease. Diffuse pericardial involvement, RV involvement, or encasement of great vessels or veins often precludes surgical resection. The tricuspid valve, right coronary artery, and up to about 30% of the RV muscle mass may be resected and replaced or reconstructed with reasonable risk to achieve a complete resection. Thus, all patients are evaluated preoperatively with coronary arteriography. In patients treated without surgical resection, the survival is approximately 10% at 12 months.<sup>160</sup> A microscopically negative surgical resection margin has been shown to extend survival<sup>150</sup> and remains standard therapy. Although some patients having a radical resection still locally recur, the leading cause of death is distant metastatic disease. Complete resection followed by adjuvant chemotherapy has been shown to extend survival.<sup>150,160</sup>

Patients with even limited metastatic disease that did not respond well to chemotherapy or who developed new metastatic disease while on treatment are not considered

**FIGURE 58-24** Right atrial sarcoma.

**FIGURE 58-25** Bovine pericardium reconstruction of the superior vena cava (created by folding the pericardium in half and then firing an endo-GIA stapler longitudinally to form the conduit).

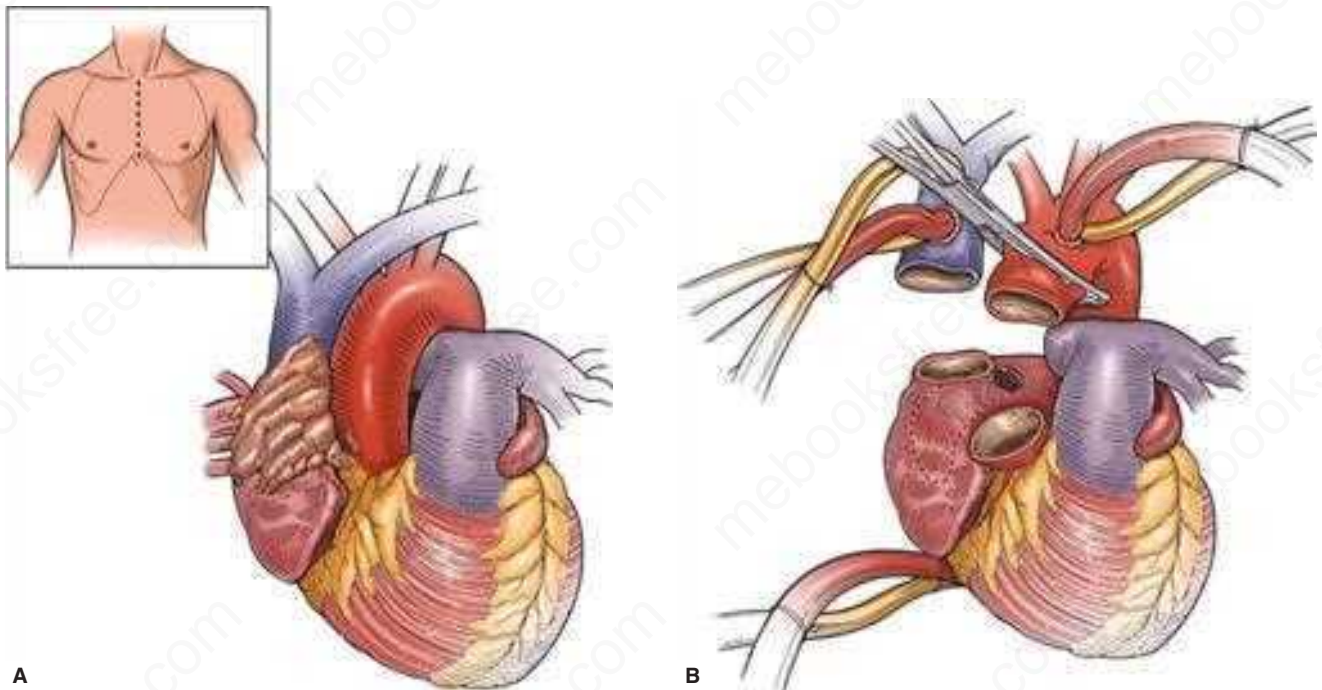

candidates for surgery. Patients with widely metastatic disease are not considered candidates unless palliative surgery because of severe symptoms is recommended. Every patient should be referred to oncology for potential continuation of chemotherapy after recovery from surgery.

Based on the anatomic extent of tumor and the needed margins for resection, venous cannulation for CPB must be carefully planned and individualized to each patient. Directly cannulating the high SVC for upper body drainage and

cannulating directly into the IVC at the diaphragm usually allows adequate exposure for complete inferior resection, but occasionally femoral cannulation aids in exposing the more caudal structures of the right heart. Aortic cannulation is standard, as it is distant from the tumor. The right atrium can be completely resected and replaced with bovine pericardium. If the resection involves the SVC or IVC, a vascular stapler can be used to staple lengthwise, creating a tube from bovine pericardium to recreate the vein segment (Fig. 58-25). One particular area of danger is at the right atrial junction with the root of the aorta, as overzealous resection in this area will result in damage to the fibrous skeleton of the heart, which is characteristically difficult to repair. Incomplete resection leaving gross disease rapidly leads to regrowth of the tumor and should be avoided if at all possible. When right coronary artery involvement is suspected, mobilization of the right internal mammary artery is performed at the beginning of the operation. Right ventricular wall can be simply partially replaced with bovine pericardium or incorporated into a prosthetic tricuspid valve used for valve replacement. For an illustration of the steps involved in the resection and later reconstruction of a right heart sarcoma, refer to Fig. 58-26.

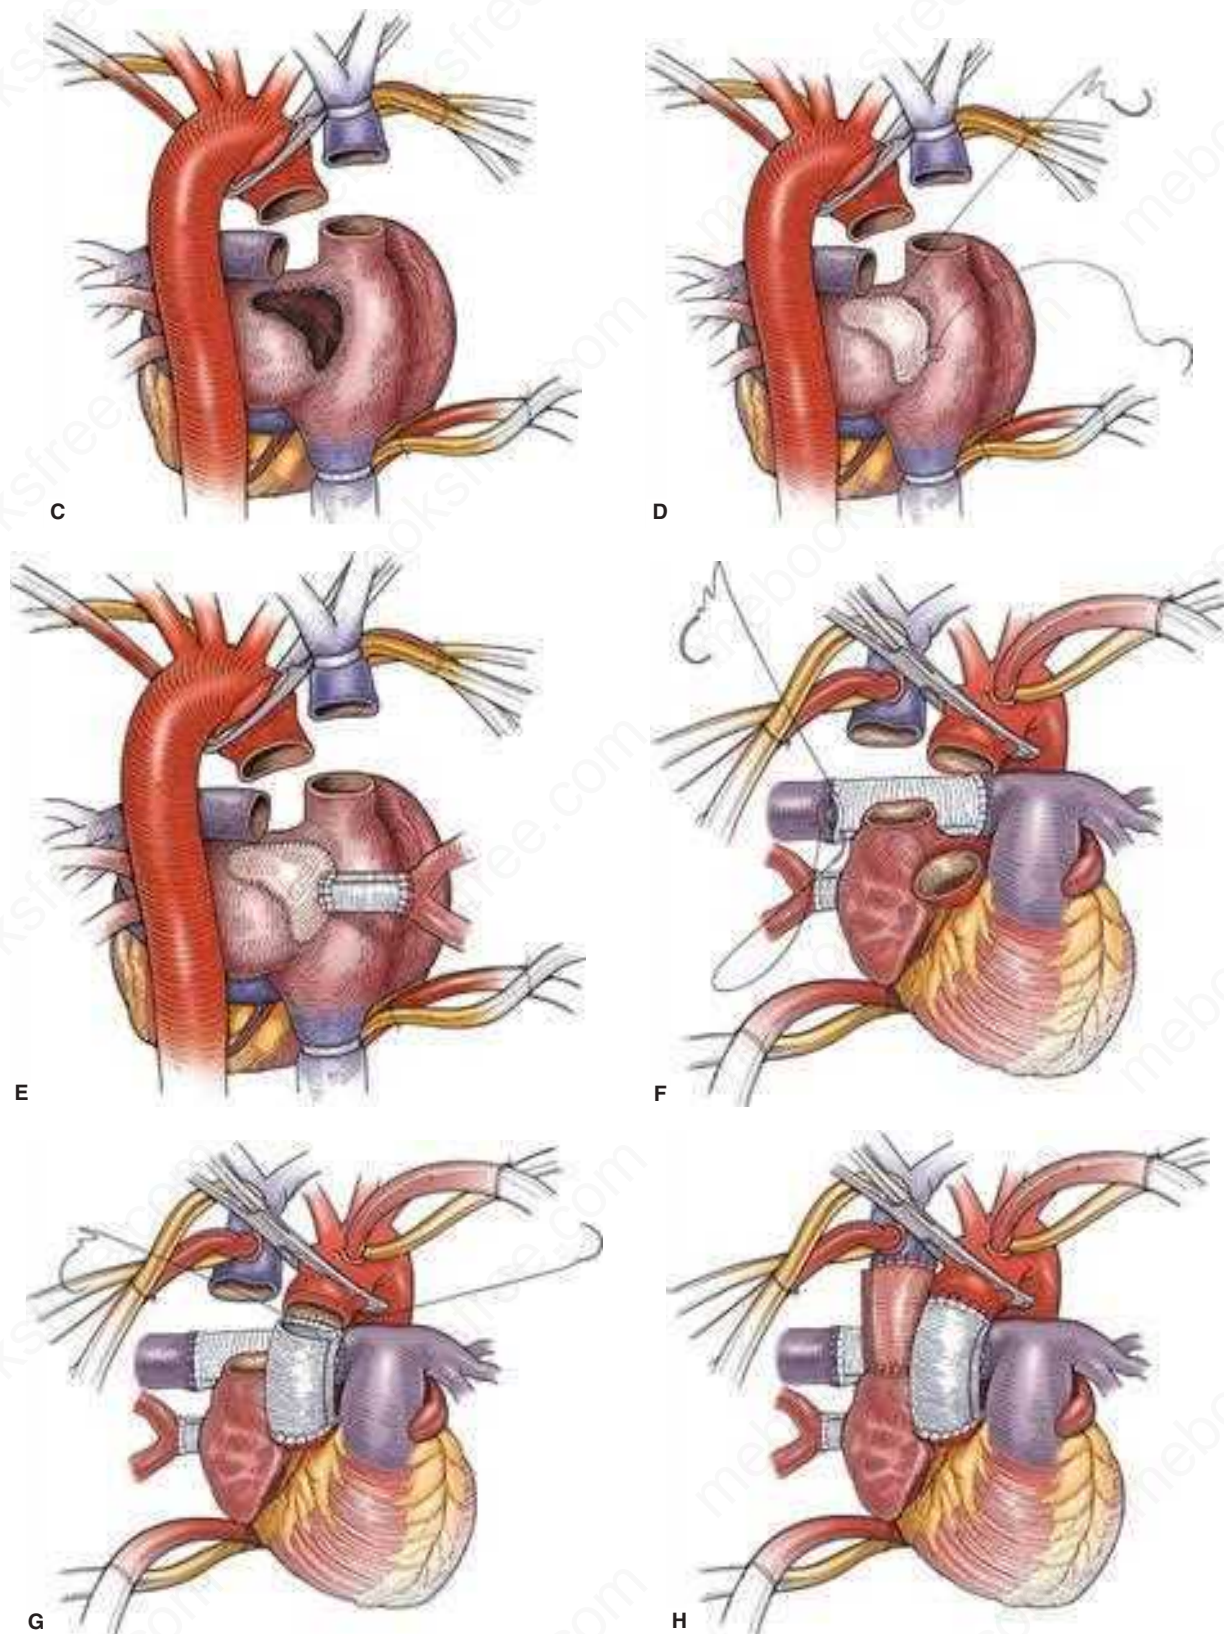

### Left-Sided Cardiac Sarcomas

Surgical resection is the most effective therapeutic option for patients with malignant left-sided cardiac tumors. Delay can result in death from obstruction to flow within the heart or

**FIGURE 58-26** (A) median sternotomy approach to a right heart sarcoma; (B) transection of the aorta, right main pulmonary artery, roof of the left atrium, and superior vena cava to rotate the right upper quadrant of the heart and allow adequate exposure for complete excision of a right heart sarcoma;

**FIGURE 58-26** (Continued) (C) posterior view of the heart to illustrate the incisions necessary for complete removal of a right-sided cardiac sarcoma that extended into the roof of the left atrium; (D) reconstruction of the roof of the left atrium; (E) reconstruction of the pulmonary veins using a Dacron graft; (F) reconstruction from an anterior view of the right main pulmonary artery; (G) reconstruction of the aorta using a Dacron graft and a running suture; (H) complete reconstruction of the heart after radical removal of a right heart sarcoma (note the superior vena cava reconstruction with bovine pericardium folded and stapled with an endo-GIA stapler).

embolization, which may occur in as many as 8% of patients awaiting operation. The clinical presentation of patients with primary left heart sarcoma depends on the anatomic location and extent of the tumor and is not influenced by histology. Most primary left heart sarcomas are reported to occur in the left atrium, a concept supported by the author's experience; 22/24 (92%) occurred in the left atrium and 2/24 (8%) occurred in the left ventricle. Most left atrial masses seen by cardiac surgeons are mistaken to be benign myxomas. Every left atrial sarcoma patient referred to our center previously underwent resection for a presumed myxoma that was later found to be a cardiac sarcoma. Each of these cases had rapid reappearance of the left atrial tumor at the site of resection likely representing regrowth of persistent incompletely resected sarcoma. Intracavitary left ventricular tumors are very uncommon and are rarely mistaken for a simple cardiac myxoma. Heart failure caused by obstruction of intracardiac blood flow is the most common and concerning presenting symptom. Heart block from local invasion, arrhythmia, pericardial effusion, distal embolus, fever, weight loss, and malaise are also seen. The mean age of presentation is reported to be 40 years of age.<sup>149</sup> Transthoracic echocardiography is the most common initial diagnostic test. TEE is specifically recommended for in all left-sided cardiac tumors because of increased resolution of left-sided structures. Cardiac MRI and PET/CT scans are also obtained in patients known or suspected to have sarcoma.

Once diagnosed, primary cardiac sarcoma patients have an often dismal prognosis. When medically treated, the survival at 12 months is less than 10%.<sup>160</sup> Most reports in the literature are either autopsy series or individual case reports or small case series. Operative mortality usually exceeds 20%, and the mean survival is typically around 12 months.<sup>161-163</sup> Many published series focus on primary cardiac sarcoma in general without regard to anatomic location. The Mayo Clinic reported 34 patients over 32 years with a median survival of 12 months.<sup>164</sup> A combined series from the Texas Heart Institute and the MD Anderson Cancer Center reported an actuarial survival of 14% at 2 years in 21 patients over a 26-year period.<sup>157</sup> The authors have previously reported a combined multimodality approach, and found a median survival of 23.5 months in 27 patients over 16 years with survival of 80.9% at one year and 61.9% at two years.<sup>147</sup> Subsequent analyses show that histologic type does not influence survival or treatment approach.<sup>165</sup> The major determinant of clinical presentation and surgical approach is anatomic location. Currently, these tumors are grouped based on location, such as PA sarcomas, right heart sarcomas, or left heart sarcomas.<sup>166</sup>

The high rate of local recurrence and secondary resections reported in the literature<sup>167</sup> indicate the left atrium and ventricle present unique anatomic exposure challenges. Complete resection and reconstruction is complicated because of the left heart proximity to vital structures. Often, a surgeon's inability to adequately visualize vital structures and reconstruct leads to an inadequate resection with rapid regrowth of tumor. Typically, left atrial tumors are approached

through the interatrial groove. The interatrial groove is often an adequate approach for benign tumors, but is limited for malignant tumors that are often larger and require a more generous margin of resection. We have considered complete cardiectomy and orthotopic cardiac transplantation for complete removal of these tumors. Although feasible, this approach requires the availability of a donor and postoperative immunosuppression; both of which present potential problems in cancer patients. Additionally series using orthotopic cardiac transplantation for this purpose have only shown a median survival of 12 months.<sup>168</sup> Left ventricular tumors can be approached through the aortic valve, the mitral valve, or through a ventriculotomy. A transaortic valve approach works nicely for benign tumors,<sup>82</sup> but is inadequate for malignant tumors because of their size and the amount of resection needed. A ventriculotomy through normal ventricular muscle is possible, but not ideal. The author's group adopted the approach of cardiac explantation, ex vivo tumor resection, cardiac reconstruction, and reimplantation of the heart (cardiac autotransplantation), which permits a radical tumor resection and accurate reconstruction.

#### CARDIAC AUTOTRANSPLANTATION

The technique of cardiac autotransplantation was introduced for cardiac tumors by Cooley in 1985 to deal with a large left atrial pheochromocytoma.<sup>128</sup> Although this case was not successful, it introduced the senior author (MJR) to the technique and its potential use for cardiac tumors. The author's group did the first successful cardiac autotransplant for cardiac sarcoma in 1998,<sup>154</sup> also reporting this for left atrial sarcoma and left ventricular sarcoma.<sup>169</sup> Working closely with the MD Anderson Cancer Center, the Methodist Hospital has now performed 34 cardiac auto transplants. Of the 34 patients, there were 26 primary cardiac sarcomas, 1 isolated malignant melanoma metastasis to the intracavitary left ventricle, and 7 benign cases. The benign group had no operative deaths and 100% 2-year survival. Overall 30-day, 1-year, and 2-year procedural survival was 85, 59, and 44%, respectively. For primary malignant tumors, survival at 1 and 2 years was 46 and 28%. Among patients with primary malignant tumors, 19 had isolated cardiac autotransplantation and 7 had autotransplantation plus pneumonectomy. Operative mortality (and median survival) for cardiac autotransplantation with and without pneumonectomy was 43% (55 days) and 11% (378 days), respectively. For primary sarcomas, microscopically positive or negative resection margins did not impact survival. A diagnostic algorithm for autotransplantation in cardiac tumors is included (Fig 58-37).

Cardiac autotransplantation has several fundamental differences from standard orthotopic heart transplantation.<sup>170</sup> In orthotopic heart transplantation, unless a domino procedure is being done, the explanted heart is not to be used and any damage to its structures is inconsequential. For a complete video of an autotransplant including replacement of the mitral valve, refer to the movie attached to this chapter. Therefore, the cardiectomy can be performed leaving a wide

margin of remaining tissue to use in tailoring the heart to be implanted without regard to cutting critical structures such as the CS. Similarly, the donor heart can usually be harvested with extra tissue at its margins to be used to help tailor the implantation unlike traditional orthotopic heart transplant surgery. The heart must be excised in cardiac autotransplantation in a manner that does not damage any structures that cannot be repaired, replaced, or are vital to cardiac function. Additionally, if the heart is simply excised and reimplanted, loss of workable tissue makes reimplantation more challenging than orthotopic heart transplantation. Cannulation techniques must take into consideration planned explantation. The aorta can be cannulated distally in the transverse arch. Venous cannulation must be directly into the SVC and IVC just below the right atrial junction. This requires greater exposure and mobilization of the SVC and IVC. After commencing CPB, further mobilization of the SVC and IVC is performed until each is completely free and surround with umbilical tapes on a tourniquet. Wide mobilization of the interatrial groove and circumferential mobilization of the ascending aorta and PA follows cannulation. This facilitates both accurate excision of the heart and reimplantation. The ascending aorta is cross-clamped and antegrade cold blood potassium cardioplegia is given (10 cc/kg) to achieve cardiac arrest. The left atrium is opened at the beginning of cardioplegia, and a sump drain is placed to decompress the heart. After cardioplegia and cardiac quiescence, the left atrium is opened to confirm pathology and appropriateness of autotransplantation. The SVC first divided beyond the right atrial junction. This is followed by IVC division which should be transected near the right atrial and SVC junction. For each transection, it is important to note the rim of tissue being left behind retracts substantially toward the venous cannulae and an extraordinarily wide rim must be left or reimplantation at the IVC can be exceedingly difficult. The ascending aorta is divided about 1 cm distal to the sinotubular junction and the PA is divided just proximal to its bifurcation. The left atrium transection is then completed, dividing the atrium just anterior to the pulmonary veins and on the left side equal distant between the pulmonary veins and the mitral valve and left atrial appendage. This allows complete removal of the heart which is placed into a basin of ice slush (Fig. 58-27). The posterior left atrium is then inspected, and any tumor is widely excised (Fig. 58-28). Bovine pericardium is used for reconstruction, and the pulmonary veins may be individually reimplanted into new orifices cut in the bovine pericardium or left as a cuff, if pathology permits. The anterior left atrium can be entirely removed, including the mitral valve, leaving only a mitral annulus.

Bovine pericardial reconstruction starts with cutting a hole to match the mitral annulus opening. Mitral valve replacement using pledgeted 2-0 ticon sutures begins with pledgets placed on the left ventricular side of the annulus, passing through the annulus, through the bovine pericardium, and then through the prosthetic mitral valve. When the sutures are tied, the neo atrial wall is sealed to the valve and annulus. The anterior and posterior bovine

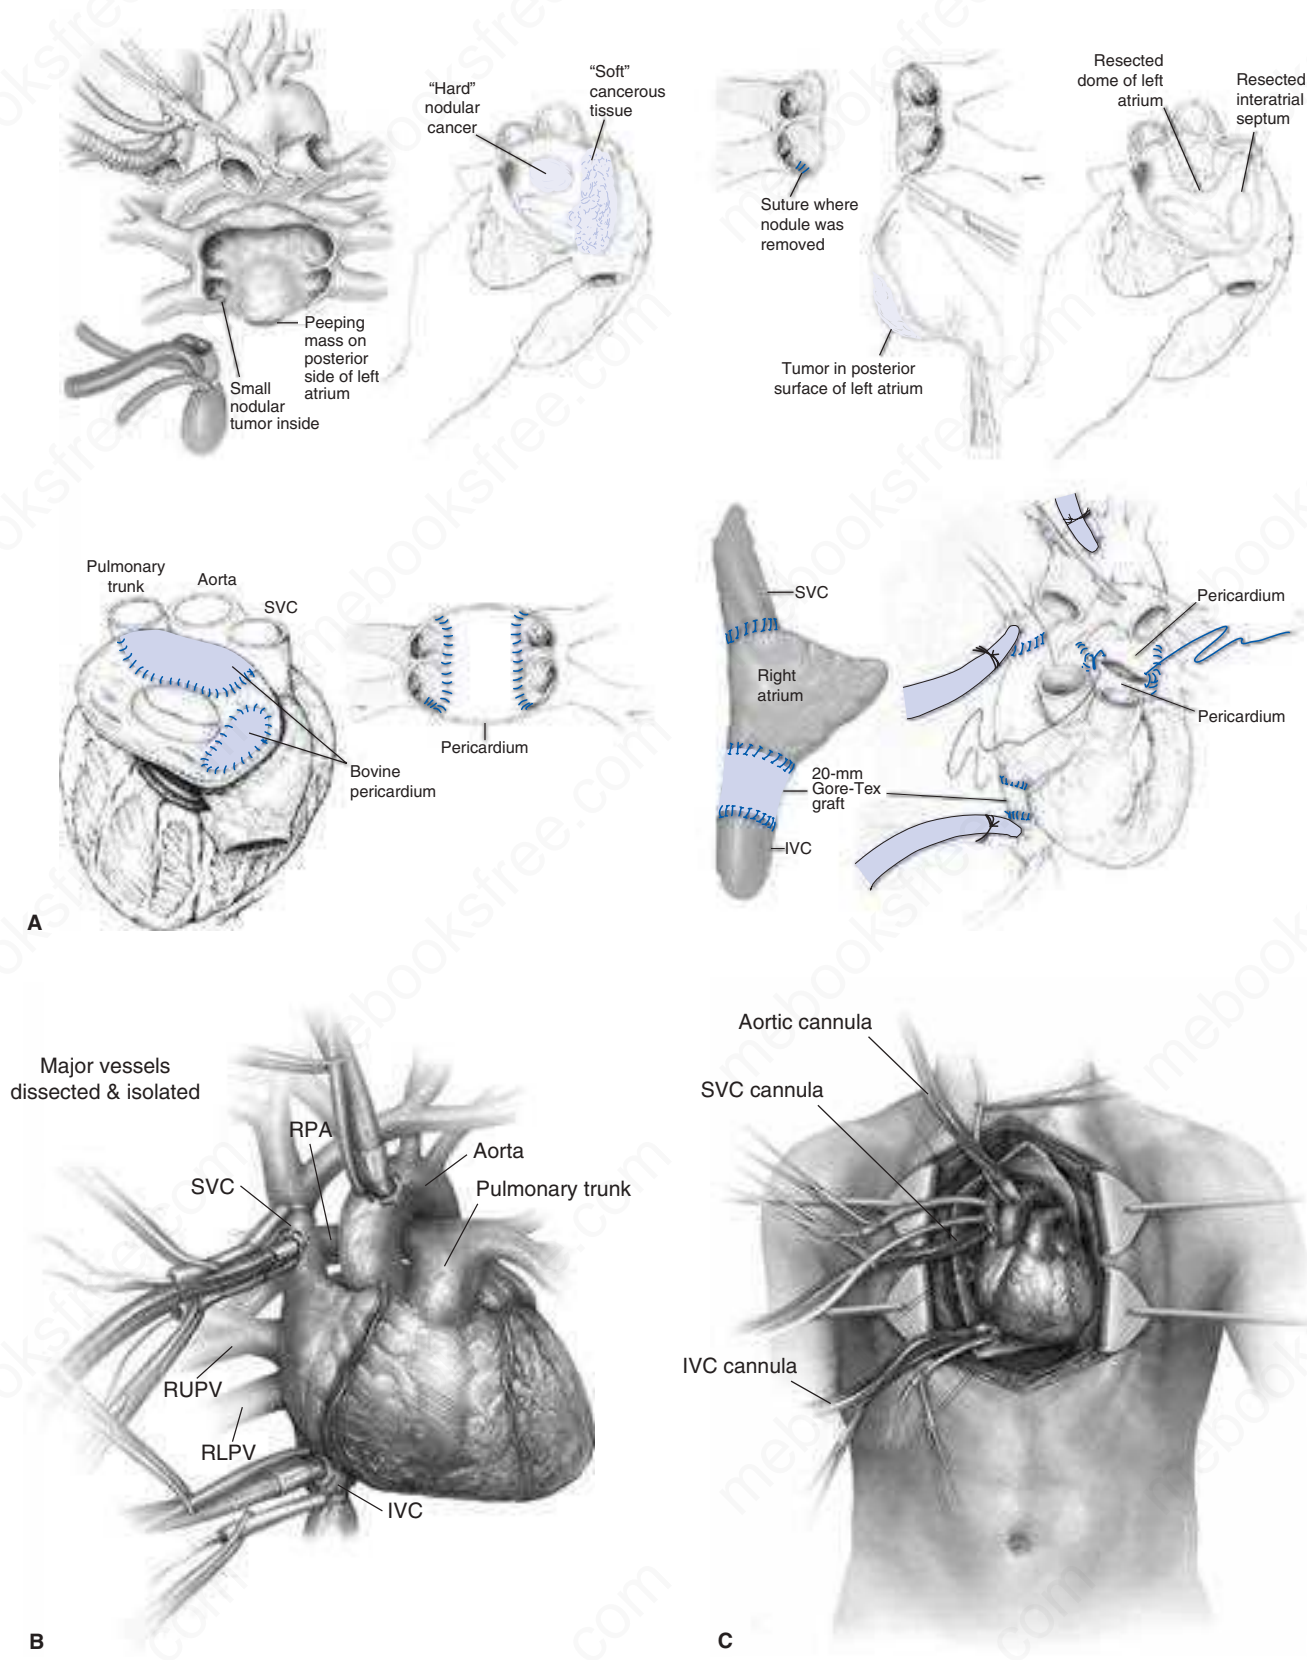

**FIGURE 58-27** Ex vivo heart showing large sarcoma arising from the anterior left atrial wall.

pericardium can then be tailored by cutting darts and sewing them together before reanastomosis. Reimplantation is similar to standard cardiac transplantation, beginning with the left atrium anastomosis. The right atrium is then attached to the IVC, and then the right atrium to the SVC. If either of these anastomoses appears to be under excess tension, an interposition graft of Gore-Tex, Dacron, or crafted pericardial tube graft can be used to bridge the defect successfully (Fig. 58-29). The PA and aorta are reanastomosed in a standard fashion using Prolene suture, warm-blood potassium cardioplegia is given antegrade, and the aortic cross-clamp is removed. The procedure for left ventricular tumors is similar, and occasionally requires mitral valve excision or partial excision of the interventricular septum (Fig. 58-30). The interventricular septum can be reconstructed with bovine pericardium and valve replacement is typically done with a tissue valve. Although these patients are young, a tissue valve is often chosen to avoid anticoagulation. Issues with structural valve deterioration are of less concern because survival is counted now in years rather than decades.

Because of poor survival, lesions requiring a pneumonectomy in addition to cardiac autotransplant should be considered a contraindication to surgery. This can usually be determined preoperatively with cardiac MRI to evaluate restriction of blood flow through the pulmonary veins.

### Lymphomas

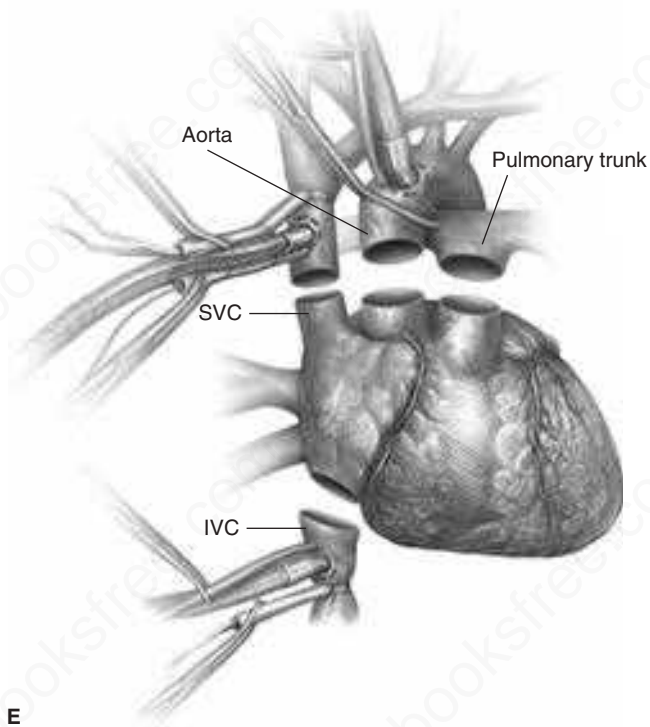

Lymphomas may arise from the heart, although this is rare.<sup>171</sup> Most of these tumors respond to radiation and chemotherapy, and surgical resection is rarely indicated.<sup>153</sup> Even when complete resection is not possible, incomplete resection has been performed to relieve obstructive systems and, when followed with radiation and chemotherapy, has allowed for extended survival in selected patients.

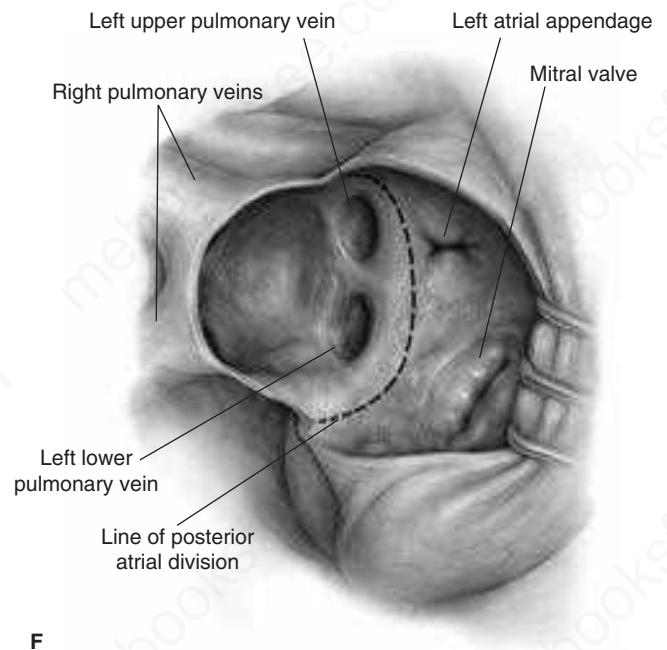

**FIGURE 58-28** (A) Explanation of the heart for exposure of extensive left atrial sarcoma. ### Pulmonary Artery Sarcomas

Most PA sarcomas are classified. The most frequent presenting symptom is shortness of breath and peripheral edema from concomitant right-sided heart failure.<sup>172</sup> The diagnostic modalities of choice for both the initial evaluation and monitoring for recurrence after resection for PA sarcomas are chest CT or MRI (Figs. 58-31, 58-32, and 58-33).

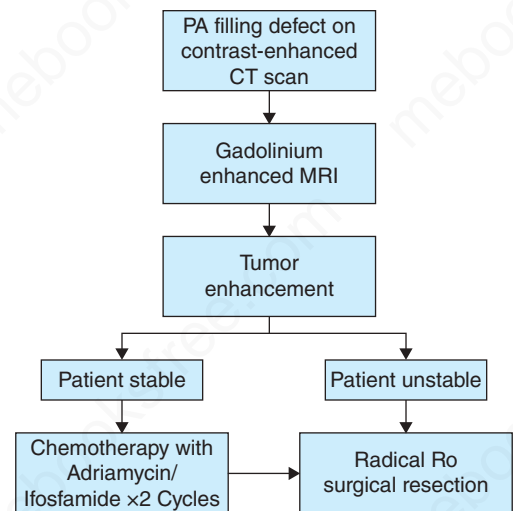

PA sarcomas are very rare tumors that are often confused with acute or chronic pulmonary embolus (PE). This confusion has led to both delay in diagnosis and many being treated with a tumor thromboendarterectomy approach rather than radical resection. These tumors usually are discovered after they have grown to considerable size (Fig. 58-34). PA sarcoma can present with cough, dyspnea, hemoptysis, and chest pain that may mimic PE. Constitutional symptoms often present include fever, anemia and, weight loss which are more consistent with malignancy than PE and these mass lesions will not decrease in size with anticoagulation. These tumors tend to arise from the dorsal surface of the main PA

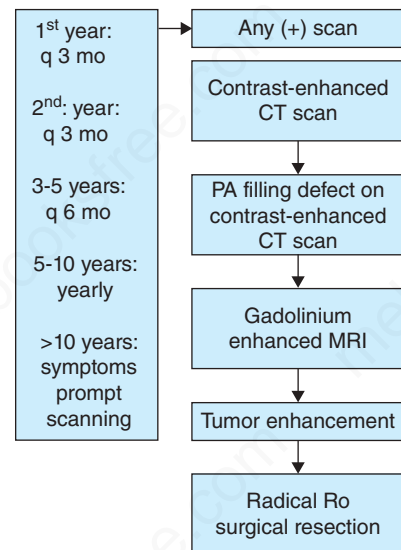

**FIGURE 58-30** Explanted heart undergoing anterior left atrial reconstruction with bovine pericardium.

**FIGURE 58-31** Pulmonary artery sarcoma as seen on a CT scan with the pathology specimen after radical removal (including pneumonectomy).

**FIGURE 58-32** Algorithm for initial evaluation of a pulmonary artery sarcoma.

**FIGURE 58-33** Postoperative evaluation algorithm for recurrent pulmonary artery sarcoma.

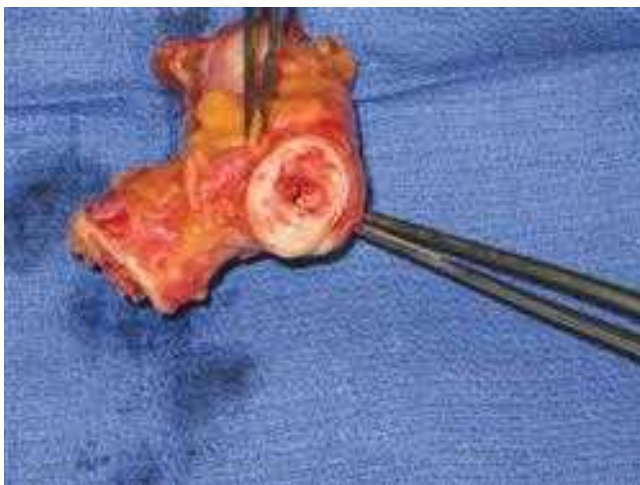

**FIGURE 58-34** Pulmonary artery angiosarcoma specimen showing involvement of the pulmonary valve.

just beyond the pulmonary valve.<sup>173</sup> They form from multipotential mesenchymal cells from the muscle remnant of the bulbus cordis<sup>174</sup> in the intimal and subintimal surfaces.<sup>165</sup> The tumor then tends to grow distally along the artery, rarely penetrating the actual wall of the artery but rather distending it (Fig. 58-35). This characteristic is important to note when planning surgical resection. Distal extension can go to the lung parenchyma itself as emboli, infarction, or metastasis.<sup>175</sup> Although survival difference based on cell histology is found in limited cases, that has not been our experience in cardiac sarcoma in general.<sup>172</sup> Surgical resection remains the primary method of treatment in patients with PA sarcoma and the only method shown to increase survival. A staging system has been developed to further classify these patients and determine who should be offered surgical therapy (Table 58-6).

Resection often requires replacement of a portion of the pulmonary root and branch PAs using a pulmonary homograft with or without artificial graft. Pneumonectomy may

**FIGURE 58-35** Pulmonary artery sarcoma demonstrating the extension of the tumor along the inside of the wall and no growth of tumor outside the arterial wall.

**TABLE 58-6: Staging System for Primary Pulmonary Artery Sarcomas**

Stage I	Tumor limited to the main pulmonary artery
Stage II	Tumor involving one lung plus a main pulmonary artery
Stage III	Bilateral lung involvement
Stage IV	Extrathoracic spread

be required to resect the tumor completely. Because exposure of the right main PA may require division of the aorta and possibly the SVC, we plan surgical cannulation for CPB by using dual venous cannulation with direct SVC cannulation and normal IVC cannulation via the right atrium. Arterial cannulation via the ascending aorta is routine. Both SVC and IVC are isolated with tourniquets to control blood flow into the right heart. Cardiopulmonary arrest is achieved with cold potassium blood cardioplegia. Fortunately, these tumors rarely penetrate the PA wall, allowing reasonable mobilization. The main PA has always been involved in our experience and the pulmonary valve is involved 30% of the time.<sup>172</sup> The main PAs can be resected out to their first branch points on each side from a median approach. In cases where one PA is relatively free and the other is involved deep into the lung, a pneumonectomy may be required. In this case, the pulmonary veins and main bronchus are dissected and divided before CPB is instituted to avoid bleeding while heparinized. The branch PAs and main PA are mobilized, CPB is instituted, and the involved main PA is divided. In such cases, the involved lung with little blood flow once resected may result in improved hemodynamics; especially after removal of tumor obstructing the contralateral PA. Once each PA has been divided or in the case of pneumonectomy the lung and main PA removed, the main PA trunk can be assessed for pulmonary valve involvement. If the pulmonary valve is involved, the entire PA trunk must be removed and replaced by a pulmonary allograft. Removal of the entire PA trunk and replacement by an allograft is similar to mobilization and replacement techniques for a Ross procedure.<sup>175</sup> If the resection of the right and/or left main PA is limited, then the allograft branches may be adequate to span the defect. When tumor extension is too distal for this, a Gore-Tex (ePTFE) graft can be used to interpose between the distal right PA resection point to distal left PA resection point and then implantation of the pulmonary allograft into the side of the ePTFE graft is performed. Despite the extensive nature of the resection, separation from CPB has not been difficult. The surgery relieves the patient of severe PA obstruction that is present preoperatively.

The authors have successfully resected PA sarcomas in 10 patients, three of whom required concomitant pneumonectomy. There were no in-hospital or 30-day deaths, and all patients were discharged home. Our longest survivor currently has lived more than 100 months and has no known disease. In most cases, adjuvant chemotherapy is used, even in the face of clear surgical margins. Radical PA resection is

both safe and appears to prolong survival compared to minimal or palliative resection. Resection in conjunction with chemotherapy also appears to prolong survival. Currently, recommendations to record such rare tumors in a national registry may allow better analysis of long-term outcomes.

## Heart Transplantation

Malignant primary cardiac tumors may grow to a large size before detection. Additionally, extensive myocardial involvement or location affecting the fibrous trigone of the heart may make complete resection impossible. Because complete resection yields better results than incomplete resection, orthotopic cardiac transplantation has been considered as a treatment option. Reports of transplantation for a number of cardiac tumors, including sarcoma,<sup>175-178</sup> pheochromocytoma,<sup>171</sup> lymphoma,<sup>172</sup> fibroma,<sup>134</sup> and myxoma have appeared. However, the long-term results are uncertain because some patients die from recurrent metastatic disease despite transplantation.<sup>171,172,174</sup> As of 2000, 28 patients had been reported involving orthotopic transplantation for primary cardiac tumors, and of these, 21 had malignant tumors.<sup>174</sup> The mean survival for patients with primary cardiac malignancy was 12 months. Although technically feasible in some cases, orthotopic transplantation is hindered by a scarcity of donor organs and coupled with an extensive recipient list of patients without cancer. In addition, the large size of the tumor when diagnosed often necessitates rapid intervention for progressive congestive heart failure. Finally, the effect of immunosuppression on any remaining malignancy is unknown. In most cases, orthotopic transplantation is reserved for unresectable benign tumors, such as cardiac fibroma.

## SECONDARY METASTATIC TUMORS

Approximately 10% of metastatic tumors eventually reach the heart or pericardium, and almost every type of malignant tumor has been known to do so.<sup>2,7</sup> Secondary neoplasms are 20 to 40 times more common than primary.<sup>4,175</sup> Up to 50% of patients with leukemia develop cardiac lesions. Other cancers that commonly involve the heart include breast cancer, lung cancer, lymphoma, melanoma, and various sarcomas.<sup>2,176,177</sup> Metastases involving the pericardium, epicardium, myocardium, and endocardium roughly follow that order of frequency<sup>2,7</sup> as well (Table 58-7).

The most common means of spread, particularly for melanoma, sarcoma, and bronchogenic carcinoma, is hematogenous and ultimately via coronary arteries. In addition, metastasis can reach the heart through lymphatic channels; through direct extension from adjacent lung, breast, esophageal, and thymic tumors; and from the subdiaphragmatic vena cava. The pericardium is involved most often by direct extension of thoracic cancer; the heart is the target of hematogenous and/or retrograde lymphatic metastasis.<sup>5</sup> Cardiac metastases rarely are solitary and nearly always produce multiple microscopic nests and discrete nodules of tumor cells<sup>2,7</sup> (Fig. 58-36). Cardiac metastases produce clinical symptoms in

**TABLE 58-7: Metastatic Cardiac Disease**

Tumor	Total (no.)	Cardiac (%)	Pericardial (%)
Leukemia	420	53.9	22.4
Melanoma	59	34.0	23.7
Lung ca	402	10.2	15.7
Sarcoma	207	9.2	9.2
Breast ca	289	8.3	11.8
Esophageal ca	65	7.7	7.7
Ovarian ca	115	5.7	7.0
Kidney ca	95	5.3	0.0
Gastric ca	3.8	3.6	3.2
Prostate ca	186	2.7	1.0
Colon ca	214	0.9	2.8
Lymphoma	75	—	14.6

Data from Kapoor AS: *Cancer and the Heart*. New York: Springer-Verlag Publishers; 1986.

only about 10% of afflicted patients.<sup>178,179</sup> The most common symptom is pericardial effusion or cardiac tamponade. Occasionally, patients develop refractory arrhythmias or congestive heart failure. Chest radiographs and electrocardiograms tend to show nonspecific changes, but echocardiography is particularly useful for diagnosis of pericardial effusion, irregular pericardial thickening, or intracavity masses interfering with blood flow.

Surgical therapy is limited to relief of recurrent pericardial effusions or, occasionally, cardiac tamponade. In most instances, these patients have widespread disease with limited life expectancies. Surgical therapy is directed at providing symptomatic palliation with minimal patient discomfort and hospital stay. This is most readily accomplished via sub-xiphoid pericardiotomy, which can be accomplished under local anesthesia if necessary with reliable relief of symptoms, a recurrence rate of about 3%, and little mortality.<sup>177</sup>

**FIGURE 58-36** Hematogenous metastases within the myocardium of a patient with renal cell cancer. (Reproduced with permission from Hurst JW et al: *Atlas of the Heart*. New York: McGraw-Hill; 1988.)

Alternatively, a large pericardial window in the left pleural space can be created using thoracoscopy, but we would recommend this only under unusual circumstances.<sup>180</sup> This can be accomplished with minimal patient discomfort but does require general anesthesia with single-lung ventilation and may be poorly tolerated by patients with hemodynamic deterioration secondary to large effusions.

## RIGHT ATRIAL EXTENSION OF SUBDIAPHRAGMATIC TUMORS

Abdominal and pelvic tumors on occasion may grow in a cephalad direction via the IVC to reach the right atrium. Subdiaphragmatic tumors are frequently renal carcinomas, although hepatic, adrenal, and uterine tumors occasionally have exhibited this behavior. Up to 10% of renal cell carcinomas invade the IVC, and nearly 40% of these reach the right atrium.<sup>181</sup> Radiation and chemotherapy are not effective in relieving the obstruction of blood flow. If the kidney can be fully removed, as well as the tail of the tumor thrombus, survival can approach 75% at 5 years.<sup>96,182</sup>

Renal cell tumors with atrial extension typically are resected with abdominal dissection to ensure resectability of the renal tumor. Initially, we performed a concomitant median sternotomy and often used CPB with hypothermic circulatory arrest when treating these patients. However, we have changed our approach and now work closely with our liver transplant surgeons who have extensive experience in the area of the retrohepatic vena cava. We have found that we can expose the vena cava up to the right atrium through an abdominal incision. With ligation of the arterial inflow, the tumor tail often shrinks below the diaphragm, and in almost all circumstances, this can be removed without the use of CPB. Occasionally venovenous bypass as used in hepatic transplantation is necessary to occlude inflow through the IVC, but this is unusual. If the tumor is too complex for this maneuver, then a median sternotomy is performed, and CPB with hypothermic circulatory arrest can be used to remove the tumor from the cardiac chambers down into the IVC. Perfusion can be restarted, followed by removal of the rest of the tumor. Although it leads to adequate exposure, significant problems with coagulopathy are often apparent after CPB and profound hypothermia.

A 5-year survival rate of 75% has been achieved following nephrectomy with resection of right atrial tumor extension.<sup>182,183</sup> Other subdiaphragmatic tumors with atrial extension that have been resected successfully include hepatic and adrenal carcinoma, as well gynecologic tumors.<sup>184-188</sup>

## MOLECULAR- AND BIOLOGIC-BASED DIAGNOSIS AND THERAPY FOR CARDIAC TUMORS

This is an exciting time for investigators involved in the search for novel therapies for tumors such as many of those discussed in this chapter. A “new biology” is being developed

in laboratories around the world working in these areas, and this is supplanted by the knowledge that is being obtained from the concerted Human Genome Project and the subsequent development of proteomics.<sup>146</sup> It is incumbent on the thoracic surgeon involved in the care of patients with cardiac tumors to have some degree of familiarity with the terms and promise of these advances because significant additional improvement in survival of many of these patients is unlikely to result from further advances in surgical technique.

Interestingly, many sarcomas demonstrate reproducible translocations that allow for the production of novel chimeric genes that may code for a variety of fusion proteins. Many of these proteins have been found to engender cellular phenotypic malignant changes, resistance to apoptosis, and unfettered growth.<sup>181</sup> Although not associated with cardiac involvement, the fusion proteins EWS-FL11 and EWS-ERG are noted in Ewing's sarcoma. When full-length antisense oligonucleotide constructs are used to target the mRNA of these proteins, protein expression is downregulated, and an eightfold increase in apoptosis sensitivity is noted.<sup>189</sup> These fusion proteins have been noted in some forms of rhabdomyosarcoma, and the most common is PAX3-FKHR. This oncoprotein combines components of two strong transcriptional activators and may increase the production of the downstream antiapoptotic protein BCL-XL. Antisense oligonucleotides directed at this oncoprotein mRNA have led to apoptosis in rhabdomyosarcoma cells.<sup>190,191</sup> A similar translocation and fusion protein have been noted in fibrosarcoma. This translocation [t(12;15)(p13q25)] brings together genes from chromosomes 12 and 15, which combines a transcription factor with a tyrosine kinase receptor. The resulting fusion protein is a tyrosine kinase that has oncogenic potential.<sup>192</sup> Reproducible translocations and fusion proteins with downstream effectors of malignant behavior have not been described for angiosarcoma, but they are actively being sought.<sup>188</sup> Antisense treatment has been maligned in the past owing to problems with both delivery and stability of therapeutic constructs. However, sophisticated biochemical alteration of these molecules has improved stability, and two recent solid tumor trials using antisense therapy for salvage have demonstrated positive results.<sup>193</sup> Additional methods of delivering antisense to tumor cells, including viral vector delivery, have been developed. Finally, in addition to antisense methods, small molecule inhibition of many of these fusion proteins should be possible.

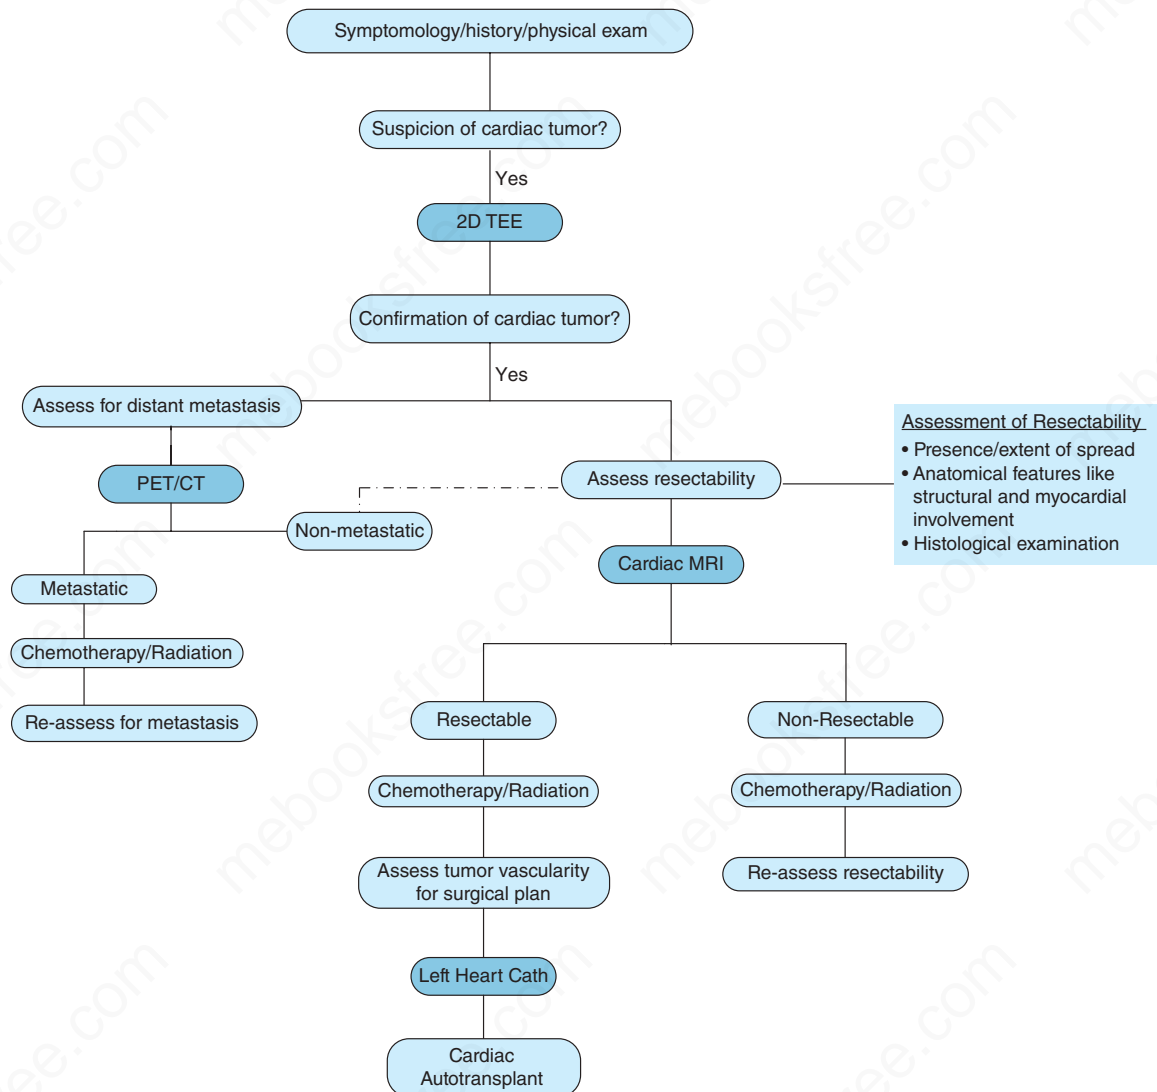

Angiosarcoma is an obvious target for therapies based on antiangiogenesis. The weak antiangiogenic properties of interferon-alpha are presumed to be the mechanism that accounts for responses to this agent in this tumor.<sup>194</sup> Multiple new antiangiogenic agents are being evaluated currently in phase I and II trials, and a number of noncardiac angiosarcoma patients have been treated at our institution on this basis. We have noted several to develop stabilized disease, but no definitive data are yet published. Certainly, the use of these agents in these vascular-origin tumors is theoretically attractive.

Viral vector-mediated gene therapy has been evaluated for various sarcomas in the preclinical setting. A number of

potential targets exist for these sorts of therapies. Although *p53* is not commonly mutated or absent, *mdm-2* is often overexpressed in many sarcomas, including angiosarcoma. This gene is a known oncogene that is able to directly induce cellular transformation. Importantly, when overexpressed, it binds to and inhibits *p53* activity, even though expression of *p53* may appear normal. Overexpression of *mdm-2* also has been associated with vascular endothelial growth factor (VEGF) overproduction and angiogenesis.<sup>194</sup> Preclinical studies of adenoviral *vector p53* transduction of sarcoma in severe combined immunodeficiency (SCID) mice have demonstrated growth delay, tumor regression, and decreases in VEGF expression.<sup>195</sup> Many other targets for this approach, including inhibition of nuclear factor-kappa B (NF- $\kappa$ B) expression using an adenoviral-dominant negative I $\kappa$ - $\beta$  $\alpha$  construct and prodrug-mediated gene therapy using a doxorubicin prodrug and adenoviral transfer of a metabolizing

enzyme in sarcoma cells, have been shown to be effective.<sup>184</sup> Unfortunately, the application of viral-mediated gene therapy paradigms to this tumor suffers the same problems of targeting, transgene expression durability, and immune response that are problematic for the field in general.

In regard to molecular diagnosis, there are no reproducible familial patterns for development of most malignant tumors. However, familial cardiac myxoma, rhabdomyoma, and fibroma may exhibit reproducible genetic abnormalities that lend themselves to the development of genetic testing to identify individuals at risk. Familial myxoma syndrome, or Carney complex, has been associated with mutations in the 17q24 gene *PRKAR1a* that codes for the R1 *a* regulatory subunit of cAMP-dependent protein kinase A (PKA).<sup>195</sup> Although not widely available, genetic diagnosis of this syndrome is now technically achievable.<sup>196</sup> Reproducible mutations in the *TSC-1* and *TSC-2* genes in patients with tuberous

**FIGURE 58-37** Proposed diagnostic algorithm for cardiac tumor patients.

sclerosis and cardiac rhabdomyoma, as well as mutations in the *PTC* gene of patients with the Gorlin syndrome and cardiac fibroma, have been noted.<sup>197-200</sup> It is hoped that in the near future we will be able to predict who is at particular risk for these and other cardiac tumors. This could allow for more intense surveillance, earlier detection, and a higher rate of surgical or multimodality cure for these patients.

## KEY POINTS

- Complete excision and radical resection is recommended to prevent local recurrence of cardiac tumors
- All benign cardiac tumors are potentially curable with current surgical techniques
- Multimodality therapy and multidisciplinary planning should be incorporated into the care of cardiac tumor patients (Fig. 58-37)
- Cardiac sarcomas are best classified by anatomic location rather than histologic subtype, and the former dictates their presentation, treatment, and prognosis
- Right heart sarcomas tend to be more bulky, infiltrative, metastasize earlier, and are usually amenable to neoadjuvant chemotherapy
- Left heart sarcomas tend to be more solid, less infiltrative, and metastasize later
- PA sarcomas usually present with obstruction, right heart failure, and tend to grow distally within the confinement of the PA
- Cardiac tumors located in the anterior left atrial wall may require autotransplantation for complete excision of the tumor, reconstruction, and reimplantation
- Cardiac autotransplant and concomitant pneumonectomy carries an unacceptable 50% mortality rate.

# Immunobiology of Heart and Lung Transplantation

Bartley P. Griffith • Agnes Azimzadeh

For over 40 years, cardiac and lung transplantation have achieved remarkable one-year patient survivals beyond 90% and conditional half-lives of 13 and 7.9 years, respectively.<sup>1</sup> While surgeons must acquire the technical expertise to perform these often demanding surgeries, long-term graft outcomes and the recipients' well-being benefit from a multidisciplinary team well versed in the basics of the immunology of transplantation. Comfort with treating patients who receive immunosuppressive therapies, both conventional and innovative, requires familiarity with the nonsurgical language of transplantation. The goal of this enhanced chapter is to squeeze the essentials into an understandable short text. The core features of the alloresponse are presented with some specific references unique to heart and lung allografts. These include (1) histocompatibility; (2) activation of alloresponse T lymphocytes; (3) T-cell-mediated rejection (TMR); (4) antibody-mediated rejection (AMR); (5) immunosuppressive therapy; (6) surveillance for rejection; (7) immune monitoring; and (8) emerging regulators of immunity.

## MAJOR HISTOCOMPATIBILITY COMPLEX

Major histocompatibility complex (MHC) molecules are a family of proteins that vary quite a lot between individuals (genetic polymorphism) and represent the molecular basis for how people's immune systems distinguish "self" from "nonself" with respect to infections and transplants. Human MHC molecules are known as human leukocyte antigens (HLA) because they are expressed at high levels on leukocytes and were first measured on peripheral blood lymphocytes. HLA are heterodimeric glycoproteins expressed on the surface of almost every cell in the human body. If recognized by an organ recipient, these proteins can trigger rejection. This is known as allorecognition.

HLA molecules on donor cells or HLA fragments, shed from thoracic organ transplants, are determined to be foreign by the immune system of the host. Intact HLA molecules expressed on the surface of cells serve two key functions in the context of transplantation. Fragments of foreign proteins, including fragments of HLA molecules, are presented in the

binding groove of HLA and are recognized by T-cell receptors (TCRs) of the recipient that happen to have high affinity for that protein fragment in the context of self HLA (indirect donor antigen presentation). In addition, recipient T-cells directly recognize donor HLA as "foreign" (direct donor antigen presentation).

The genes coding for these antigens are located on the short arm of chromosome 6. This region spans over 4 million base pairs in length and encodes for over 200 genes in three regions: Class I, Class II, and Class III (Fig. 59-1). HLA owns the most polymorphic title in man as more than 5000 types have been recognized.

Classic Class I HLA proteins/antigens are HLA-A, HLA-B, and more recently HLA-C. The  $\alpha$ -light chain is encoded in the MHC; however, the  $\beta$ -chain is  $\beta$ -2-microglobulin that is encoded on chromosome 15. When folded, the  $\alpha$ -heavy chain contains the peptide binding region which presents peptide antigen to the T-cell. Class I antigens are constitutively expressed on nearly all cells. Expression of Class I molecules (Fig. 59-2) is upregulated on the endothelium and parenchymal cells in association with inflammation, including after ischemia and reperfusion.

Classic Class II HLA proteins/antigens are HLA-DR, HLA-DRw, HLA-DQ, and more recently HLA-DP. These proteins consist of an  $\alpha$ -heavy chain and a  $\beta$ -light chain, both of which are encoded in the MHC. When folded, the  $\alpha$ -heavy chain and  $\beta$ -light chain come together with each contributing part of the peptide binding region (Fig. 59-2). Class II antigens are expressed mainly on B-cell lymphocytes, activated T-cells, monocytes/macrophages, and dendritic cells. Other cell types, such as endothelial cells, may express Class II antigen expression after activation.

Each person has two different HLA genes at each HLA locus (HLA-A, B, D, etc.) HLA antigens are co-dominantly expressed on the cell surface so that each cell has two different HLA proteins for each HLA locus. HLA "haplotype" (the sequence of A, B, D genes on one chromosome) is usually inherited as a group from each parent in a Mendelian fashion. Thus, two offspring of the same parents have a 50% chance of inheriting one identical haplotype, 25% chance of inheriting two identical haplotypes, and 25% chance of

**FIGURE 59-1** The major histocompatibility complex is divided into three regions or classes: Class I, Class II, and Class III.

**FIGURE 59-2** Class I and II HLA molecules are made up of polypeptidic chains with intrachain disulfide bonds. The  $\alpha_1$  and  $\alpha_2$  distal domains of Class I and the  $\alpha_1$  and  $\beta_1$  domains of Class II make up the peptide binding site for alloantigen. (Adapted with permission from Haber E: *Scientific American: Introduction To Molecular Cardiology*. Philadelphia; Elsevier Health Sciences; 1995.)

having no haplotypes in common. In addition, due to the distance between these genes in the MHC, there are “hot spots” of gene recombination. Recombination in offspring occurs approximately 1 to 2% between HLA-A and C, or between HLA-B and HLA-DR, and approximately 30% between HLA-DP and HLA-DQ. Recombination accounts for most of the occasional exceptions to faithful transmission of intact parental haplotypes to their children. HLA haplotypes are found in varying frequencies across the major population groups (White, Hispanic, Black, Asian, and American Indian).

In the early days of organ transplantation, hyperacute rejection occurred due to preexisting IgM alloantibodies. Best-known examples of these are the ABO blood group IgM antibodies. While still a barrier to xenotransplantation (cross-species transplantation), blood group typing has virtually eliminated this particular cause of immediate organ destruction in allotransplantation. Of interest is the success of blood group mismatched organs in neonatal recipients before they develop IgM antibodies to blood group antigens.<sup>2</sup> Antibodies against blood group antigens arise between 6 and 18 months postnatal due to the presence of related carbohydrate antigens on intestinal bacteria. Today, when hyperacute rejection is seen, it is normally caused by preexisting IgG antibodies usually directed against donor HLA proteins. These antibodies are often the result of previous blood-cell transfusions (most particularly multidonor platelets due to the high HLA load) or previous pregnancies or transplants. After wide adoption of the first crossmatch technique by Patel and Terasaki in 1969, hyperacute rejection based on preexisting HLA antibodies became rare.<sup>3</sup> Further improvements in screening for HLA antibodies have nearly eliminated it. Of interest in 1970, against early convention, Terasaki found that HLA-mismatched kidney recipients fared as well as those zero-mismatched recipients.<sup>4</sup> Starzl led the use of mismatched livers first, and soon, except for bone marrow, all followed in kidney, heart, and lung transplants.<sup>5</sup>

While HLA mismatches seem less predictive of outcomes, those recipients who present for transplant with preformed anti-HLA antibodies (prior pregnancies or blood transfusions) or developed antibodies in responses to the mismatches have more rejection. This has led to poor survival in heart and lung recipients.<sup>6-10</sup> There is some evidence that posttransplant removal of these donor-specific antibodies (DSA) can improve the function of kidneys and lungs.<sup>11,12</sup>

## ADAPTIVE IMMUNE RESPONSE: T LYMPHOCYTE

Success in heart and lung transplantation requires control over the immune response to donor HLA antigens expressed by the allograft. An adaptive response is initiated by T lymphocytes primed to donor antigens in the peripheral lymphoid tissues and are then recruited into the donor organ where those antigens are expressed. Alloreactive T lymphocytes are primed by alloantigens presented to them on donor (direct) and/or host (indirect) antigen-presenting cells

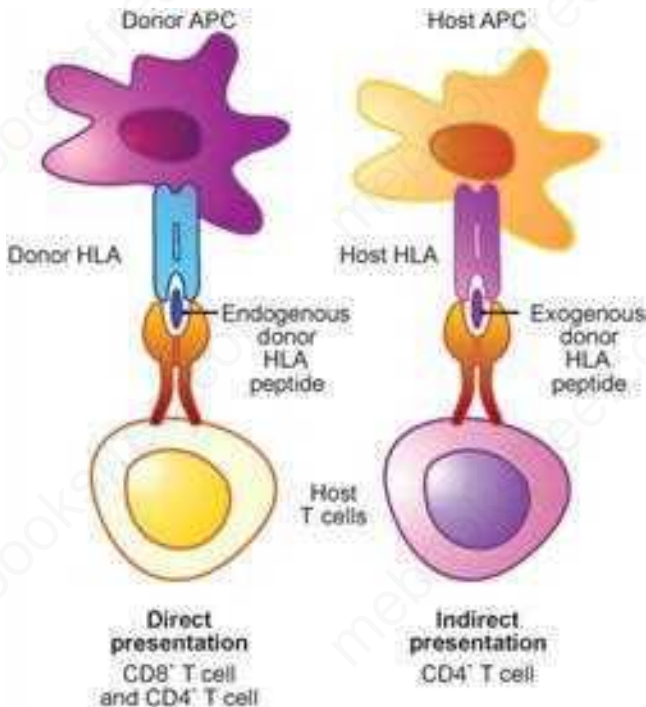

**FIGURE 59-3** Dendritic cell with its typical membrane extensions engaged with T lymphocyte. (Used with permission from Institute of Cellular Therapies, Noida, UP 201303, India. [www.dendriticcellresearch.com](http://www.dendriticcellresearch.com).)

(APCs) (Fig. 59-3). T-cells are the primary immune actors in the pathologic reaction to a transplanted organ. They participate in cytotoxicity and cytokine-mediated inflammation. B cells, antibodies, and macrophages contribute to the destruction of the graft via a variety of effector pathways. Ischemia/reperfusion injury of the allograft triggers innate immunity that can amplify T-cell alloresponse. Molecular modulators of innate immunity have recently been an expanding area of interest. These include cytokines, chemokines, complement, and more recently toll-like receptors (TLRs) and the inflammasome. While APCs are emphasized, B cells and natural killer (NK) cells exert influence on a host's decision to reject an allograft.<sup>13</sup>

## T-Lymphocyte Alloactivation

A T-cell can only become triggered to proliferate and differentiate if its TCR finds a fit with foreign peptides bound in the groove of HLA molecules presented on the surface of APCs.<sup>14</sup> “Professional” APCs differ from other HLA-expressing cells in that they also express “co-stimulatory” molecules that efficiently stimulate activation of both the APC and the responding T-cell. These include dendritic cells, B lymphocytes, and macrophages. The peptide HLA antigen complex may be presented by resident *donor* “passenger” APCs found in the transplanted heart or lung (direct presentation) or by the *host's* APCs (indirect presentation) (Fig. 59-4). HLA-peptide antigens become the specific key that fits into a T-cell's specific TCR receptor. In the thymus, T-cells learn to enable their TCR to recognize self-HLA complexes that present endogenous peptides (positive selection). Those cells that recognize self-peptides with a high affinity are deleted

**FIGURE 59-4** T cells are stimulated to proliferate when their TCR engages donor peptides processed and presented by an HLA molecule, expressed by donor or host antigen presenting cells (APCs).

(negative selection) so as to reduce the risk of their driving autoimmunity. T-cells that cannot bind self-protein HLA die from neglect. Positive selection occurs only for those T-cells whose affinity for self-protein HLA result in survival but not full proliferation. The T-cell repertoire emerging from the thymus can respond to proteins from various foreign origins (bacteria, viral, transplant). T-cells react against alloantigens because of the crossreactivity of the TCR with self and foreign HLA molecules. Host and passenger donor dendritic cells are thought to be the most efficient type of APCs for activating naive T-cells.

### Pathways of Antigen Presentation to Alloreactive T-cells (Signal 1)

*Donor passenger APCs* transplanted with the heart or lung *directly* process endogenous HLA-derived peptides from within themselves and present them in a groove on surface Class I HLA complexes on their surfaces (Fig. 59-5A). Class I protein MHC complexes presented on the *donor-derived* APCs (key) fit into the TCR (lock) expressed by recipient CD8<sup>+</sup> T-lymphocytes. This activation pathway, known as the *direct* pathway of peptide presentation, is responsible for the majority of initial T-cell activation reacting to alloantigens and thought to mediate most early events of acute cell-mediated cytotoxicity.<sup>15</sup>

Later alloresponses are focused on CD4<sup>+</sup> T-cells because they recognize donor-specific HLA peptides presented by Class II surface molecules expressed by *recipient* APCs. These

*recipient* APCs gradually replace donor APCs transplanted with the heart or lungs of the donor. Host APCs trafficking through the allograft phagocytose interstitial and cellular HLA protein antigens shed from the donor graft (Fig. 59-5B). This shedding is induced when the graft is stressed by ischemia (preservation), inflammation (bacterial and viral infection), and during rejection. Donor proteins undergo endosomal proteolysis and resulting peptides are combined with Class II HLA molecules. Donor peptide Class II HLA complexes are transported to the surface of the host APC and presented *indirectly* as the “key” to the TCR complex “lock” on CD4<sup>+</sup> T-cells. These T-cells then become activated by the *indirect* pathway. Because CD4<sup>+</sup> T-cells provide help to donor-specific B cells, later alloresponses tend to be associated with appearance of alloantibody.<sup>16</sup>

In addition to the direct and indirect pathways, a third pathway of antigen presentation involves the transfer of donor cell membrane components, including donor peptide-MHC complexes, to recipient APCs. Transfer can happen by direct cell-cell contact or through the release of very small particles (exosomes) by donor cells, which fuse with recipient APC cell membranes. This process known as the *semi-direct* pathway of antigen presentation pathway leads to presentation, by recipient APCs, of the same strongly crossreactive donor MHC/peptide that drive direct presentation.<sup>17</sup> Finally, it is helpful to distinguish the role of these pathways in the priming versus the effector phase of immune responses.<sup>18</sup>

Activated dendritic cells also provide co-stimulators to the naïve T-cells that are required for a full T-cell response. Macrophages present antigens to differentiated CD4<sup>+</sup> cells that activate the macrophage to promote cell-mediated immunity. B cells also serve an APC function by presenting antigens to helper T-cells. These then activate the B cell to become part of the effector humoral immune response through production of antibodies (Fig. 59-6).<sup>19</sup>

### Pathways of T-Cell Co-Stimulation: Signal 2

In addition to activation of the T-cell by engagement of its TCR with donor peptide/MHC complexes expressed by donor or recipient APCs (**Signal 1**), several other surface molecules participate in T-cell activation. Those that enhance TCR signaling (CD4 and CD8 molecules expressed by CD4<sup>+</sup> and CD8<sup>+</sup> T-cells, respectively) are called **co-receptors** because they bind to part of the same HLA molecule that engages the TCR. Another group of T-cell activating surface molecules is called **co-stimulatory receptors** (**Signal 2**) (Fig. 59-7). Blockade of co-stimulatory pathways provides important new possible therapy to prolong organ transplant survival and even reach a tolerant state. Co-stimulatory receptors or ligands on T-cells recognize respective cognitive ligands or receptors presented on APCs or the graft tissue itself. The best defined **co-stimulatory receptor** and ligand pair is the constitutively expressed CD28 T-cell co-stimulatory receptor and its APC ligands B7-1 (CD80) and B7-2 (CD86). This pathway is particularly important in activation of naïve

(nonmemory) T-cells. When engaged, these pairs deliver antiapoptotic signals and trigger the expression of cytokines and growth factors, including Interleukin-2 (IL-2) that encourage proliferation of alloantigen-specific CD4<sup>+</sup> or CD8<sup>+</sup> T-cells. If CD28 is blocked, T-cells may become anergic or apoptose. A second inducible co-stimulatory receptor for B7 molecules has been identified and termed CTLA-4 (CD152). Unlike the structurally homologous CD28, CTLA-4 appears on recently activated T-cells and is a negative regulator that promotes pathways that limit proliferation. It is efficient that the same co-stimulator (B7) can prompt initial proliferative signals via constitutive CD28 engagement and later, when CTLA-4 is induced, subsequently limit signals to the T-cell. Therapeutic targeting of this pathway with CD80 and CD86 blockade with CTLA-4-Ig-like molecules has been effective in primates and multiple clinical trials,<sup>20</sup> and was approved by the US Food and Drug Administration (FDA) for the prevention of acute rejection in adult kidney transplant patients in 2011. Inducible co-stimulator (ICOS) and programmed death-1 (PD-1) are more recent discoveries in the T-cell

CD28 family. When ICOS joins its ligand ICOS-L on an activated APC, it stimulates the T-cell effector response by promoting IL-4 and IL-10 production. PD-1 is the co-receptor for PD-ligands (PD-L1 and PD-L2) and, like CTLA-4, represses T-cell responses.<sup>21</sup>

A second family of co-stimulatory molecules belong to the tumor necrosis factor (TNF) super family.<sup>22</sup> The prototypic pathway is represented by the co-stimulatory receptor CD40 on APC binding to CD40 ligand (CD154) on T-cells. By reciprocal activation, CD154 on T-cells makes the APC “better” and is thought to “license” additional APCs to participate in the T-cell activation process. CD154 can also interact with CD40 expressed by CD8<sup>+</sup> T-cells thereby providing direct help from CD4<sup>+</sup> to CD8<sup>+</sup> T-cells.<sup>23</sup> Moreover, transplantation immunobiology is influenced by the innate immunity directors against substances from microbes, including bacteria, viruses, and fungi. These substances, often nucleic acids, are called pathogen-associated molecular patterns (PAMPs). PAMPs can bind to PAMP-receptors on APCs called TLRs. This engagement has the effect of strengthening the APC

**FIGURE 59-5A** Direct presentation of Class I HLA donor antigen by donor APCs. Donor-derived APCs (dendritic cells within the transplant) ubiquitinate an endogenous cytosolic (donor) protein and transport it through the proteasome where it is digested. Small proteins move with transporter associated with antigen processing (TAP) into the endoplasmic reticulum where it becomes associated with Class I HLA  $\alpha$ -chain. The protein HLA complex locates on the surface of the APC where CD8<sup>+</sup> T-cells with TCR “locks” specific for the protein-HLA complex “keys” can associate. The association prompts CD8<sup>+</sup> T-cell activation.

**FIGURE 59-5B** Indirect Class II HLA donor-antigen presentation by host APCs. Extracellular protein antigen shed from the heart or lung allograft is taken into a host APC by endocytosis. The protein is proteolyzed and transported into the Golgi. There it displaces the invariant chain held  $\alpha$  and  $\beta$ -chain Class II HLA molecule. The digested protein molecule finds its specific place within the HLA molecule and is moved to the APC surface where it can specifically adhere to a CD4<sup>+</sup> T-cell. The attached CD4<sup>+</sup> T-cell with donor-specific TCR is stimulated to proliferate and participate in the alloresponse.

**FIGURE 59-6** CD4<sup>+</sup> T lymphocytes are specifically activated by donor peptide proteins presented on APC peptide-HLA complexes. These T-cells in turn activate B lymphocytes expressing specific HLA Class II molecules and CD40. The B cells respond to growth factors by proliferation formation of germinal centers and production of specific alloantibody.

**FIGURE 59-7** The process of regulating T-cell ( $CD4^+$  and  $CD8^+$ ) activation involves engagement of the TCR/CD4 or CD8 with the foreign protein-HLA molecule and of several co-stimulators of the co-stimulatory pathway. The constitutively expressed CD28 co-receptor drives proliferation of naïve T-cells when engaged by its ligand B7-1. Inducible CTLA-4 (CD154) co-regulator acts to regulate this process negatively along with its APC-bound B7-2 ligand. Other CD28 family co-receptors include inducible ICOS that signals for proinflammatory IL-4 and IL-10 effector responses and PD-1 that has a negative regulatory effect on the T-cell. The APC is made “better” by a reciprocal activation between T-cells and APCs and the phenomena of “licensing” in which innate receptors (PAMP—Toll receptor) stimulate B7 expression. This has the effect also on the T-cell of inducing CD40 ligand (CD154). CD40 on the APC’s membrane drives additional B7 expression and elaboration of IL-12.

response, in part by increasing the expression of co-stimulatory molecules and proinflammatory cytokines, thereby strengthening signal 2.

Additional co-stimulatory molecules were recently discovered and alternative therapeutic approaches are being evaluated in experimental models.<sup>24,25</sup> In addition to promoting full T-cell activation, co-stimulatory signals are also crucially involved in cellular interactions between T and B cells, in which B cells receive *help* from T-cells to become fully activated and differentiate in memory B cells and antibody-producing plasma cells.

## MECHANISMS OF GRAFT REJECTION

### Cell-Mediated Rejection

Early cell-mediated rejection (CMR) begins with activation of  $CD8^+$  cells that bear TCR molecules which fit and engage donor-specific peptide-HLA Class I complexes on donor APCs. In the presence of help from  $CD4^+$  T-cells, they become cytolytic lymphocytes (CTLs) and directly attach to and kill graft endothelial and parenchymal cells bearing the identical donor peptide-HLA Class I complex presented to them by the APC “activators.” This is known as the *direct effector pathway* (distinct from direct presentation of HLA

by donor APC) since the  $CD8$  cell directly kills the allotarget. It is responsible for most acute CMR early (in the first few months) after transplant. In the presence of calcium, the protein perforin polymerizes onto the Class I bearing target cell and causes 16- to 20-nm pores to open in the cell membrane and allowing the CTL to release its granular content, including granzyme B and other cytotoxic molecules directly into the target cell, causing its apoptosis. Alternatively, apoptosis (programmed cell death) can also be stimulated in the target cell by interaction of the lymphocyte Fas ligand with the APO-1/Fas receptor of the target cell. Second messengers are elicited that activate endonucleases and proteases to cause fragmentation of DNA and thus organize the dissolution of the Class I bearing donor target cell (Fig. 59-8).

Unlike the  $CD8^+$  T-cells, the  $CD4^+$  T-cells primarily follow an *indirect effector pathway* (distinct from indirect presentation of HLA by recipient APC) by secreting various cytokines that drive inflammation and graft loss (Fig. 59-9). IL-2 increases the expression of its own receptors (IL-2R) on  $CD4^+$  T-cells, driving their proliferation and further differentiation. Activated  $CD4^+$  T-cells secrete additional lymphokines, including interferon- $\gamma$  ( $IFN\gamma$ ), which along with IL-2 stimulates  $CD8^+$  CTLs to bind to the allograft cells presenting donor MHC protein molecules.  $CD4^+$  T-cells are very heterogeneous. Four major categories are now recognized: Th1, Th2, Th17, and

**FIGURE 59-8** Complicated scheme of allograft rejection. CD8<sup>+</sup> lymphocytes become activated by donor-derived dendritic cells transplanted with the allograft. These cells enter a direct alloresponse pathway by proliferating into CTLs. The CTLs recognize and attach to Class I HLA donor peptide molecules on the surface of allograft cells. They directly kill the allotarget through cell-mediated cytotoxicity by injection of proteolytic granules, creating perforin-induced membrane pores and induction of apoptosis. CD4<sup>+</sup> T-cells are activated by host APCs that engulf donor protein shed from the allograft. The host APCs process the donor protein into surface-bound Class II HLA peptide molecules. The CD4 cells follow an indirect pathway in the alloresponse by proliferating and secreting growth factors plus proinflammatory cytokines. This indirect paracrine function augments CTL proliferation, attracts cellular mediators of inflammation-like macrophages and drives B cell central humoral immunity.

regulatory T-cells (Tregs). Th1 cells are the main mediators of CMR. They produce IFN $\gamma$  and favor IL-12 production by macrophages. Th2 cells make IL-4, 5, and 13 and promote humoral responses. Th17 produces IL-17, a cytokine recently discovered and involved in inflammation. In conditions where the immune response is partially inhibited, Tregs develop with the ability to inhibit immune responses.

### Broad Alloresponse

In severe rejection, B cells join the alloresponse when they receive help from CD4<sup>+</sup> T-cells (Fig. 59-6). CD4<sup>+</sup> T-cells are activated by APCs to express CD40L (CD154). Ligand B cells

expressing CD40 and MHC Class II receptors engage helper CD4<sup>+</sup> T-cells and proliferate. B cells participate in the rejection of allografts by efficiently providing APC function to helper CD4<sup>+</sup> T-cells and by elaboration of antibodies that (1) recognize and destroy the donor endothelial targets; (2) participate in antibody-dependent cytotoxicity (ADCC), or (3) stimulate the proliferation and migration of activated endothelial cells.<sup>26</sup> In the former, the endothelial antigen/antibody complexes activate the “classical” complement pathway, causing C3 and C5 to cleave, inciting inflammation (C5a) and formation of the membrane attack complex (MAC), which is comprised of C5b complexed with C6, 7, 8, and 9 (C5b-9). The MAC causes vascular cell death by inducing pores to form in the cell

**FIGURE 59-9** Histologic evidence of AMR-associated endothelial swelling, inflammation, and thrombosis accompanied by interstitial edema and hemorrhage (H&E staining). (Used with permission from SA Webber.)

membrane. When endothelial cells are activated or killed by complement, this in turn results in microvascular thrombosis and inflammation. ADCC describes the process by which antidonor IgG antibodies coating donor cells bind to the Fc $\gamma$  RIII receptor of NK lymphocytes (NK cell). Cells of the innate immune system such as NK cells are also present in allografts during rejection. These may react with alloantigens because they constitutively express inhibiting receptors specific for self-HLA Class I molecules or they may engage alloantibody-bound target (donor) cells through their Fc $\gamma$  receptor. NK cells can not only directly kill target cells by injecting proteolytic enzymes into their cytoplasm, but also modulate immunity by producing proinflammatory cytokines like IFN $\gamma$  (Fig. 59-8).

### Memory T-Cells

With improvement in immunosuppression that limits activation of naïve T-cells, donor-reactive memory cells have been recognized as a previously underappreciated risk to the allograft. This group of donor-reactive cells has an “effector memory” phenotype. This is defined by an immediate and strong recall that is less sensitive to co-stimulation blockade. Memory cells are thought to arise from heterologous immunity. This occurs when there is a resemblance between microbial antigens and donor HLA complex antigens. Some CD4<sup>+</sup> and CD8<sup>+</sup> cells exposed to Epstein Barr, Herpes Simplex, and cytomegalovirus (CMV) become primed to recognize allogenic HLA molecules. Memory T-cell numbers are proportionately increased following lymphoablative treatment with rabbit ATG or Alemtuzumab (anti-CD52 Ab). It is unclear

whether these memory cells are more resistant to depletion or whether they represent a conversion from naïve T-cells during repopulation. Memory CD4<sup>+</sup> cells provide help for the allo-response. They provide growth and proinflammatory factors that affect CD8<sup>+</sup> T-cells and B-cell antibody production. They can illicit the proinflammatory response from nodal-bearing tissue remote from the allograft. Memory CD4<sup>+</sup> cells recruit CD8<sup>+</sup> cells that infiltrate the allograft across the endothelium. The memory CD8<sup>+</sup> cells proliferate and recruit macrophages, neutrophils, and additional activated T effector cells into the donor organ.<sup>27</sup> To date, memory T-cells continue to evade efforts of therapeutic targeting. LFA-1 is one target that is under study for this purpose. Memory T cells are very heterogeneous and have multiple functions.

### Antibody-Mediated Rejection

AMR may be defined as a form of acute graft rejection phenotypically characterized by evidence of tissue damage mediated by anti-graft antibodies as effectors. The International Society for Heart and Lung Transplantation Working Group has codified specific criteria for cardiac AMR.<sup>28,29</sup> They include clinical evidence of DSA within the recipient, endomyocardial biopsy immunopathologic evidence of complement (specifically C4d and C3d) staining, and endothelial cell and macrophage activation (the latter assessed by CD68 staining). Similar features of AMR have been identified in the lung, although less consensus exists (Figs 59-9 and 59-10).<sup>30</sup>

Although B/plasma cell production of DSA is the essential pathophysiologic mechanism underlying AMR, T-cell

**FIGURE 59-10** Specific C4d deposition on a lung transplant allograft in a recipient with circulating HLA antibody is continuous and subendothelial in capillaries and small arterioles (left). Specific C4d has been seen on 31% of transbronchial biopsies in recipients with HLA-Ab. (Ionescu D.N., *Transplant Immunology* 15(2005) 63-68) (middle). In contrast, nonspecific staining of the interstitium and elastic layer is depicted (right). (Used with permission from K.R. McCurry, M.D.)

help directs and/or influences AMR,<sup>31,32</sup> consequently, AMR should not be thought of as T cell-independent. DSA may be “preformed,” that is, present prior to transplantation (see discussion of crossmatching and percent reactive antibody [PRA]), or develop *de novo* posttransplantation. It has been shown that DSA are identified temporally prior to pathological evidence of AMR<sup>33</sup> and the development of anticardiac myosin immune responses.<sup>34</sup>

Presensitization to HLA Class I or Class II antibodies predisposes to AMR.<sup>35</sup> Those recipients who develop presensitized antibodies, especially donor-specific, risk AMR.<sup>36</sup> In addition to anti-HLA antibodies, non-HLA antibodies, including those against self-antigens such as cardiac myosin, vimentin, and endothelial cells have been less often associated with AMR.<sup>37-39</sup> Cardiac AMR occurs early (weeks to months) after transplant and, if avoided early, rarely occurs later.<sup>40</sup> Classically, histological diagnosis of cardiac AMR has included evidence of endothelial swelling and activation macrophages in the graft plus confirming immunofluorescence or immunoperoxidase staining for immunoglobulin (IgG or IgM). While absence of immunofluorescence seems reasonable to rule out AMR, capillary swelling (63%) and macrophage vascular adherence (30%)<sup>41</sup> and complement (C3d and C4d) do not. Non-AMR causes of C4d staining include organ reperfusion injury, immunosuppression, treatment with monoclonal antibodies, and viral infections.<sup>42</sup> The distribution (diffuse vs localized) and intensity of the stains has not found a standardization for grading.

The incidence of AMR after heart or lung transplantation is uncertain due to a lack of universal screening in asymptomatic recipients. Symptomatic pure AMR without a component of acute cellular rejection occurs in 10 to 15% of cardiac transplant recipients, but AMR features have been reported in up to 40% of patients with acute cellular rejection (mixed rejection).<sup>43</sup> Clinical symptoms of cardiac AMR are those common in heart failure using echo. A >25% decrease

in ejection fraction and an increase in left ventricular mass distinguished AMR from CMR.<sup>44</sup> Reduced R-wave voltage-conduction abnormalities, including bundle branch block, are electrocardiographic associates.

## Desensitization Therapy

Once unacceptable antigens are determined from solid-phase assay (SPA), they can be entered into the United Network for Organ Sharing (UNOS) website ([www.unos.org/resources/frm\\_CPRA\\_calculator.ASP](http://www.unos.org/resources/frm_CPRA_calculator.ASP)). This will provide the calculated percent reactive antibody (cPRA). If the percentage chance that any donor is acceptable for transplantation is <50%, then it is reasonable to initiate a desensitization protocol. An optimal protocol has not been established. High-dose intravenous immunoglobulin (IVIg) (2 g/kg/over 2 days q 2-4 weeks), plasmapheresis (1.5 volume exchange × 5 days), monoclonal anti-CD20 B-cell therapy (rituximab 1 g IV weekly × 4), and in the past cyclophosphamide (1 mg/kg/day) have been used in various combinations.

At UCLA, plasmapheresis, IVIg, and rituximab reduced circulatory antibody levels from 70.5 to 30.2%. Heart transplantation of these candidates after negative complement-dependent cytotoxicity (CDC) resulted in similar five-year outcomes to control patients and untreated but high PRA patients (81.1, 75.7, and 71.4%). Of interest, the freedom from coronary allograft vasculopathy (CAV) was 74.3, 72.7, and 76.2%, respectively.<sup>45</sup>

It has been agreed that patients waiting for transplantation with circulating HLA antibodies should be studied every three months, and those desensitized every two weeks after therapy. Patients on ventricular assist devices or who receive blood transfusions or with infections should be closely monitored as well. After transplantation donor-specific antibody monitoring is recommended at regular intervals and when a humoral rejection event is suspected. Donor-specific titers should be

measured daily for 1 to 2 weeks and frequently thereafter in desensitized patients and those considered high risk for antibody response. This higher risk group of recipients is generally treated with thymoglobulin plus IVIG, plasmapheresis, and/or rituximab. Maintenance immunosuppressive therapy that has best controlled cellular and AMR includes tacrolimus, mycophenolate mofetil (MMF), and prednisone.<sup>46</sup>

Recent studies have demonstrated the utility of a multi-pronged approach to the treatment of DSA and AMR. The various components of this approach may suppress DSA production, deplete levels of already generated DSA, or modulate the functionality of DSA in vivo. Glucocorticoids induce B (and T) cell apoptosis,<sup>47</sup> while antiproliferative agents reduce B and T cell generation in the bone marrow. The anti-CD20 monoclonal Ab (mAb) rituximab depletes B cells from the circulation as well as secondary lymphoid organs; most institutional regimens for AMR treatment use rituximab.<sup>48</sup> Similarly, the anti-CD52 mAb alemtuzumab depletes both T and B cells, and has been used to treat AMR.<sup>49</sup> Although preclinical studies of anti-T cell co-stimulation agents such as belatacept (CTLA4-Ig) have shown efficacy in treating solid organ AMR,<sup>50</sup> little evidence is present with respect to thoracic organ AMR clinically.

The therapies above have been shown to reduce DSA and improve AMR. However, none has demonstrated consistent ability to deplete or impair plasma cells, which are generated from differentiated effector B cells are the primary source of antibody (and thus DSA) production. Recent studies have utilized the proteasome inhibitor bortezomib in the treatment of DSA/AMR,<sup>51</sup> with initial successes. Plasmapheresis reduces circulating general antibody and DSA levels, and is also part of most institutional regimens for the treatment of AMR.<sup>52</sup> Exogenous immunoglobulin (Ig) may compete with DSA for Fc receptor binding sites, impairing opsonization.<sup>53</sup> In addition, some amount of Ig may have anti-DSA idiotype specificity, thereby inhibiting DSA (and source B/plasma cell) activity. Finally, with respect to modulation of DSA functionality, novel complement-inhibiting drugs such as the anti-C5 mAb eculizumab have shown promise in kidney AMR, with one case report of usage for hyperacute lung allograft rejection.<sup>54</sup>

### Coronary Allograft Vasculopathy and Chronic Cardiac Allograft Dysfunction/Rejection

Although heart transplantation continues to be the therapeutic gold standard for the management of end-stage heart disease, in terms of patient survival outcomes, functional capacity, and cardiac function, its durability is principally limited by chronic cardiac allograft dysfunction. Chronic dysfunction of the transplanted heart is at least associated with and thought to be due to acquired coronary arteriopathy.<sup>55</sup>

Coronary allograft vasculopathy (CAV) and resultant ischemic cardiac allograft dysfunction constitute the leading cause of allograft loss and patient mortality in heart transplant recipients after one year.<sup>28</sup> CAV is characterized by coronary

arterial wall thickening with progressive lumen compromise, which is typically diffuse, both with respect to epicardial large vessel involvement and the presence of outflow/runoff small vessel disease.<sup>56</sup>

Similar to chronic lung allograft dysfunction (CLAD) in lung transplantation, a combination of allo-specific adaptive and innate immune stimuli and responses (see section on CLAD below) result in local vascular inflammation and damage of cardiac allografts. Both T and B cell responses have been implicated in the pathogenesis of CAV.<sup>57</sup> Endothelial cells may also function as professional Ag presenting cells and, consistent with this, inducibly express MHC Class II in the context of inflammation.<sup>58</sup> Thus with respect to direct alloantigen recognition, not only are antidonor HLA Class I-specific T-cells important in mediating CAV, but so too are antidonor HLA Class II-specific T-cells. In addition, antibodies directed against donor MHC and other endothelial antigens are known to be important to the development of CAV.<sup>59-61</sup>

Recently, it has been recognized that similarities between CAV and atherosclerotic coronary artery disease (CAD) have implications for the pathogenesis of CAV. Specifically, innate immune system-mediated vessel wall inflammation and damage is present in both settings, with resultant medial proliferation and even lipid deposition. Inflammatory signaling mediated by TLRs has been shown to facilitate CAV in experimental model systems.<sup>62</sup> Consistent with this, preclinical data suggest that antiproliferative agents may attenuate CAV. Sirolimus, which along with related mammalian target of rapamycin (mTOR) inhibitors are the majority of agents used in drug-eluting stents (DES), has exhibited promising results in preventing and treating CAV, either as systemic therapy<sup>63</sup> or in DES used for percutaneous coronary interventions (PCI) in instances of stenoses amenable to PCI.<sup>64</sup> In addition, the statin HMG-CoA reductase inhibitors and other drugs that regulate lipid metabolism have shown some promise in preclinical experimental studies.<sup>65</sup>

### Chronic Lung Allograft Dysfunction and Chronic Rejection

Lung transplantation is hampered by relatively poor, long-term recipient survival, which is principally due to progressive CLAD. CLAD is due to fibrous obliteration of small airways termed obliterative bronchiolitis and the recently included restrictive allograft syndrome.<sup>66</sup>

Both allo-specific and nonallo-specific injurious stimuli are capable of triggering immune responses and mediate allograft damage. Allo-specific stimuli with resultant allo-specific immune responses historically have been the primary focus of immunologic investigation, and thus are the best understood.

Nonallo-specific injury may also trigger allo-specific or nonallo-specific immune responses. Infection and aspiration of gastric contents clearly induce lung injury, and some experimental studies of gastric acid-induced lung allograft injury in a unilateral lung transplant model have demonstrated

disproportionate or exclusive damage to the allograft, suggestive of an allo-specific component to the immune response elicited against the generalized inflammatory stimulus. With respect to T-cell-mediated immunity, this may be due to enhanced exposure of donor MHC or MHC fragments, resulting in heightened TCR engagement and Signal 1 or inflammation-induced enhancement of expression and/or activity of co-stimulatory molecules on donor or recipient antigen-presenting cells, Signal 2. Finally, nonallo-specific injurious stimuli, such as ischemia/reperfusion injury, infection, and reflux-induced aspiration,<sup>67</sup> induce activation of the innate (nonadaptive) immune system. Ischemia/reperfusion injury is linked to subsequent development of CLAD, whereas the latter two mechanisms induce lung injury that is not restricted to the allograft.

## Immunologic Tolerance

Generally, the T-cell repertoire is edited during T-cell development in the thymus to delete clones that are self-reactive (*central tolerance*). Mechanisms responsible for tolerance to transplant-specific HLA antigens not present in the thymus occur in the periphery (*peripheral tolerance*). These include cell death of alloreactive T-cells by apoptosis (deletion), induction of functional unresponsiveness (anergy or ignorance), and active regulation of alloimmunity by either donor-antigen-specific or nondonor-antigen-specific mechanisms (regulation). Partial anergy has been induced by exposing CD4<sup>+</sup> T-cells to MHC antigen in the absence of co-stimulation,<sup>68</sup> although it influences naïve responses rather than those of memory. Much of the current interest has been in better understanding of a subset of CD4<sup>+</sup> T-cells called regulatory T-cells (Tregs) whose function is to suppress immune responses and to maintain tolerance of “self.”<sup>69,70</sup> Natural Tregs develop in the thymus in response to self-antigens and are important in autoimmunity. In addition, upon antigen exposure in the periphery, CD4<sup>+</sup> T-cells can convert to a regulatory phenotype forming a population of inducible (iTregs), recently renamed peripheral Tregs (pTregs).<sup>71</sup> TGF- $\beta$ , IL-2, and B7/CTLA-4 co-stimulation are required for nTreg production and survival. It remains to be fully elucidated how these molecules direct naïve T-cells to differentiate into effector, memory, or regulatory phenotypes under various clinically relevant circumstances. Most Tregs express the IL-2 receptor  $\alpha$  chain (CD25) and the transcription factor Foxp3. nTregs but not pTregs are thought to express the transcription factor Helios.<sup>70</sup> Foxp3 is a forkhead family transcription factor important for Treg-suppressive function but is also found in activated T-cells in man and thus is not specific to identify human Tregs. Additional markers are used to identify Tregs, such as CD127 (IL-7R $\alpha$ ) and CD45RA. Finally, analysis of spontaneously tolerant kidney recipients has demonstrated a subset of B-cell genes associated with an upregulation of CD20 mRNA.<sup>72</sup>

There has been limited success in translation of laboratory rodent-based tolerance protocols in clinical practice. Freedom from immunosuppression rarely is accomplished universally in strictly controlled large animal models. Management of

preexisting memory cells not inhibited by blockage of co-stimulation appears to be a major hurdle. Finally, redundant effector cell mechanisms, cytokines, and co-stimulatory pathways make single or even dual approaches seem underpowered to establish tolerance in the clinic. There has been a limited number of patients in whom tolerance was induced by a regimen, inducing a mixed allogeneic chimerism (co-existence of recipient and donor cells) for kidney allografts. However, work in the nonhuman primate model showed that even this highly tolerogenic regimen did not induce tolerance to cardiac allografts.<sup>73</sup> Heart and lung allografts are less easily amenable to tolerance than kidney, in other words, are more immunogenic.<sup>74</sup>

## HLA Antibody Analysis

### SEROLOGICAL TESTING

The serological lymphocytotoxic assay for antibody “screening” is based on mixing patient serum (unknown) with a panel of cells whose HLA typing is known and adding complement (or CDC assay). If antibodies are present in the patient serum that react with the cell’s HLA molecules, cell death occurs due to complement activation. This method is limited to detection of antibodies represented by the panel of antigens tested and by issues of sensitivity and accuracy. The specificity of the antigen to which the antibody is reacting (HLA or non-HLA antibody) is sometimes not clear due to the presence of other proteins in the patient serum, or to the antibody isotype (IgG or IgM, etc.; some antibody isotypes do not fix complement), and the titer (low, high) is not determined. Several enhancements of this assay were developed to address these issues: (1) heat or chemical treatment of the patient serum to inactivate IgM antibodies and identify IgG antibodies which were felt to be more important to outcomes; (2) additional washes of the target cells following incubation of the patient’s serum to “wash off” the nonspecific reactants, and (3) addition of anti-human globulin (AHG) to the reaction to increase the detection of low titer IgG antibody (CDC-AHG method). There are other subvariations of these serological enhancements.

The antibody-screening assay consists of a “panel” of known HLA-typed cells, with each cell representing a unique set of antigen targets for the serum to react. The assay generates the “panel reactive antibody (PRA)” titer, which is reported out as a percent of the prospective donor pool that would likely be killed by the patient’s serum. The result of this analysis is termed percent calculated PRA or %cPRA. The % cPRA gives a better indication of the patient’s likelihood of having a compatible offer of a UNOS deceased donor organ because it is based upon actual UNOS-typed donors. The panel may consist of any number of cells; however, minimally, cells from at least 30 carefully selected individuals are needed to cover the most common HLA antigen targets. In addition to the %PRA, the specificity of the antigen targets could be identified based upon the individual cell reactions. The more different HLA antigens to which the patient is sensitized, the higher the %PRA and the less likely the patient is to have a compatible donor identified. Using conventional

matching criteria, %PRA >10% and >25% have been associated with incrementally lower survival large registry reports.

Despite the use of enhancing techniques, serological antibody screening and methods of identification are not able to detect reliably low levels of HLA antibody, and are relatively poor for characterizing Class II antibody.

### SOLID PHASE FLOW CYTOMETRIC ANALYSIS

With the development of polymerase chain reaction (PCR) technique in the 1990s, testing with HLA antigen proteins testing could be performed. SPA were then developed in which a specific recombinant HLA protein antigen could be bound to the “solid” surface of a plate, well and now beads.

The development of solid-phase, “microbead”-based flow cytometry assays represent a monumental improvement from the initial solid-phase enzyme-linked immunosorbent assay antibody screening and techniques for identification. The use of fluorescent dyes is foremost as report molecules, allowing detection of the antigen-antibody reactions using a flow cytometer. Fluorescent dye light emissions are several-fold more sensitive than colorimetric dyes. The detection of the antibody-antigen reaction is made using beads coated with HLA molecules. Each HLA molecule-specific bead is identified by its unique mixture of two fluorescent dye colors incorporated into the bead. A secondary antihuman antibody is conjugated to a reporter molecule, in this case, to a fluorescent dye of another color. The higher the titer of the antibody in the patient’s serum, the more antibody is available to react to the antigen conjugated to the bead, and the more intense is binding of the secondary fluoresceinated antibody. The more reporter dye becomes bound to the bead complex, the more fluorescent emission is produced from the bead when analyzed by the flow cytometer. The fluorescent emission signal of each bead type is then averaged and the normalized value is reported as the “mean fluorescence intensity (MFI)” of the bead. For most laboratories, the MFI value  $\geq 1000$  is considered to be a positive reaction for the presence of the HLA antibody. This cutoff was derived as twice the MFI value for the negative control serum.

SPAs can now be used to classify heart and lung candidates as having no HLA antibodies, HLA antibodies without donor specificity or those with donor-specific HLA antibodies (DSA).

The HLA antigen is sourced from recombinant cell lines and is conjugated directly to the microbead, not simply captured. This allowed manufacturing of beads coated not only with the antigens of a single individual mimicking a cell (“multiantigen beads”), but also with a single HLA antigen (“single-antigen beads”). These single antigens can be further described to the exact HLA allele of that antigen. Since individuals become sensitized to the amino acid epitopes encoded by the antigen allele, microbead-based antibody analysis opened a completely new level of insight into characterizing antibodies contained in patient serum. This process is called “epitope mapping.” In combination with allele-level typing of patients and potential donors, epitope mapping of antibodies can better predict outcomes of transplants in highly

sensitized patients. The flow cytometer instrument may be either a larger instrument, which can acquire data from cells or beads, or a mini-flow cytometer, which only acquires data from beads, such as a Luminex instrument (Fig. 59-11).

The results of the serum antibody test and the donor crossmatch are interpreted together as a final assessment of recipient and donor compatibility. Composite MFI values of 4000 or greater are generally predictive of a positive flow crossmatch. This composite MFI value is derived from the “sum of MFI values” and the single-antigen antibody analysis for “each” donor target antigen present, either Class I or Class II. This is a rule of thumb, as cellular expression of these target antigens varies. Most centers will post unacceptable antigens in UNOS for those single antigens with MFI values of 4000 or greater, since these single antigens alone may result in a positive flow crossmatch with donors. Based upon these MFI values, a “virtual” or *in silico* crossmatch can be reliable in predicting the actual cellular crossmatch, especially with high MFI values.

## HLA Crossmatch

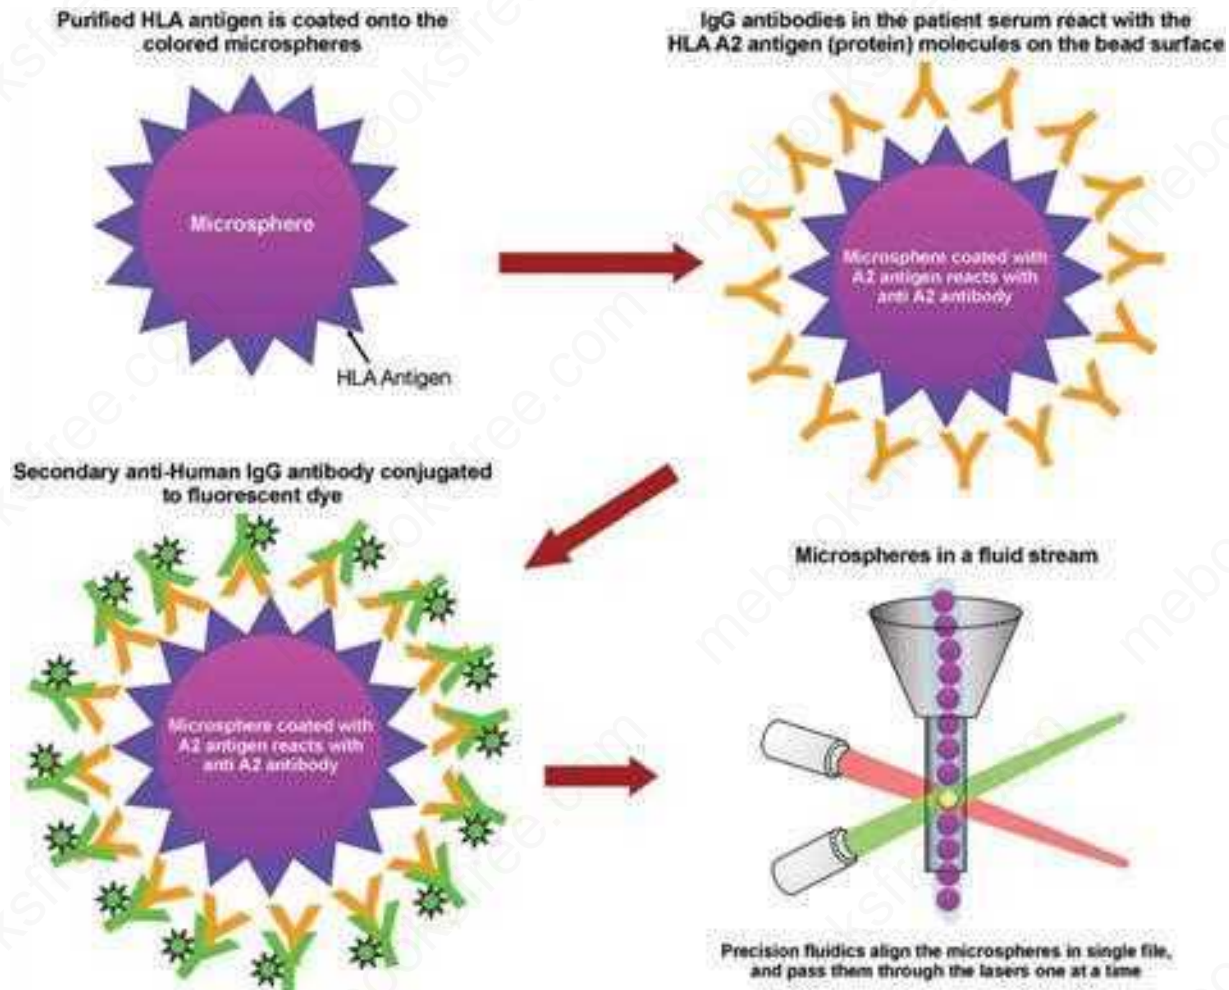

### VIRTUAL CROSSMATCH

Practical realities of matching sensitized candidates with nonlocal donors resulted in the acceptance of the virtual crossmatch (VXM).<sup>75,76</sup> The VXM is a comparison of the donor HLA genotype determined by organ procurement organizations to the gene families represented by beads that bound antibody from the sensitized candidate recipient. If gene families are shared between donor and the bead, the VXM is positive. For example, a candidate with antibodies against A1, A11, and B7 by Luminex single-antigen beads would be incompatible with a donor typed as A11, A25, B55, and B57.<sup>77</sup> The anti-A1 antibody determined by SPA corresponds to the donor-typed A1. While currently there is no method to determine the functional characteristics of the antibodies, recently it was estimated that the positive predictive value of an incompatible VXM compared with cytotoxic crossmatch was nearly 80%. UNOS has standardized HLA molecular data typing to include HLA A, B, C, DRB1 and DQB1. Most centers refuse nonlocal donors based on an incompatible VXM and insist on a prospective CDC-AHG crossmatch for sensitized patients when possible.

## Non-HLA Antibodies

It has become increasingly clear that non-HLA antibodies can cause injury in thoracic organ transplants.<sup>78,79</sup> About 16% of HLA antibody negative heart recipients may lose their graft to the mixed diagnosis of primary failure within 30 days of transplant.<sup>80</sup> SPA does not detect non-HLA antibodies, *but flow cytometry methods can detect MICA/B*. Antibodies-to-donor endothelial antigens are the largest poorly discussed group of clinically important non-HLA antibodies. These include endothelial, auto-antibodies and those to MHC Class I chain A (MICA) and B (MICB). Endothelial antigen targets may exist, constitutively or as induced auto-antigens

**FIGURE 59-11** Solid-phase microbead-based assays for HLA antibodies have improved sensitivity and specificity of detection. Single HLA antigens from recombinant cell lines are conjugated to a colored microsphere. The bead is reacted against candidate or recipient serum resulting in the specific adherence of circulating antibody to the selected HLA antigen. The microsphere HLA-serum antibody is reacted to an antihuman IgG antibody conjugated to a fluorescent dye. The microsphere complex is channeled through a flow cytometer and mean fluorescence intensity (MFI) for the combined emitting dye is measured. (Adapted with permission from Luminex Corporation, Austin, TX.)

due to activation of the endothelium. MICA and MICB are polymorphic antigens expressed on epithelial and, to an unknown extent, on endothelial cells. MICA antibodies may occur in up to 20% of candidates and have been associated with poorer survival but not increased rejection.<sup>80</sup>

“Auto-antibodies” against conserved (nonpolymorphic) proteins are frequently found in the blood of thoracic transplant recipients in association with chronic rejection. Vimentin (an intracellular cytoskeletal protein found in vessel walls and activated lymphocytes), cardiac proteins (cardiac myosin), and collagen type V (expressed mainly in the lung) are among the antigens against which auto-antibodies have been described. Antivimentin antibodies form earlier than anti-HLA after transplantation and are a response in up to 30% of heart recipients to exposure of antigens mounted on the surface of damaged and activated cells.<sup>81</sup> Antivimentin antibodies reflect tissue injury but might also activate platelets and neutrophils.<sup>82</sup> Antiheart antibodies exist preoperatively

in some patients due to their primary cardiac disease. At present, it is difficult to know their true significance. Finally, IgM non-HLA antibodies are cytotoxic and can react to all leukocytes, even the patient’s own. Antigen specificity is unknown as is the clinical relevance.

### Gene Expression Profiling: XDx Allomap

A DNA microarray-based real-time PCR-derived biosignature for cardiac rejection has been developed by XDx, the maker of Allomap molecular expression testing. Gene expression profiling (GEP) of circulatory leukocytes measures 11 informative genes associated with ACR and scores their expression detected by PCR technology.<sup>83</sup> Several pathways were identified that participate in regulation of effector cell activation, trafficking and morphology, platelet activation, plus corticosteroid sensitivity. These included PDCD1 and ITGA4 for T-cell activation and migration, IL1R2 steroid-responsive

gene, the decoy for IL-2, and WDR40A plus CMIR of the micro-RNA gene family. Peripheral blood samples are assigned a score with higher numbers associated with progressive risk of lack of immunological quiescence. This approach was recently randomized against surveillance endomyocardial biopsy in a multicenter trial in low-risk rejection cardiac recipients, 6 months to 5 years after transplantation.<sup>84</sup> The evaluation excluded recipients with a significant history of rejection, CAV, or allograft dysfunction. Results indicated 14.5% of patients profiled versus 15.3% of those surveilled by endomyocardial biopsy reached a composite endpoint of allograft loss/rejection with hemodynamic compromise, graft dysfunction due to other causes, death, or retransplantation. The low risk for rejection of the enrolled patients made interpretation to earlier and higher risk recipients problematic.<sup>85</sup> Other reports found that the profiled genes regulatory T-cell homeostasis and corticosteroid sensitivity can distinguish mild from moderate and severe rejection and are evident before histological, detectable rejection.<sup>86,87</sup> Currently, results of GEP by Allomap suggest surveillance endomyocardial biopsy in low-risk recipients may be avoided.<sup>28,85</sup>

### Functional Activity of Immune System

A long imagined goal of selective treatment based on a quantitative assessment of the net state of immunosuppression has been approached clinically with some success. An assay from peripheral blood has been developed (Cylex, ImmuKnow, Columbia, MD) to measure the intracellular concentration

of adenosine triphosphate (ATP) of activated lymphocytes. ImmuKnow measures T-cell responses by quantifying ATP activity<sup>88</sup> to phytohemagglutinin, a T-cell mitogen. In general, the collective studies suggest that ATP levels < 200 ng/mL correlate with an increased risk of infection.<sup>89</sup> In a study in 296 heart recipients spanning two weeks to 10 years post-transplant, infection in 39 recipients occurred with an average  $187 + 126$  ng/ATP/mL versus a steady state of  $280 + 126$  ng/ATP/mL. Rejection scores in eight recipients averaged 328 ng/ATP/mL and did not differ from baseline. However, three of eight with AMR scored 491 versus 280 ng/ATP/mL.<sup>89</sup> This assay opens the field to personalized immunosuppression that might help balance risks of infection and rejection.

### IMMUNOSUPPRESSION

Outcomes following heart and lung transplantation have followed the developments in renal and transplant trials of immunosuppressants (Fig. 59-12). Early reliance on high doses of prednisone and the antimetabolic azathioprine permitted enough success for the field to advance but limited the rates of patient survival to well below current standards of more than 10 years for heart and five years for lung. This early regimen was associated with morbid infection and rapidly progressive episodes of acute rejection. Earlier, it was easy to pick out our patients by their steroid-induced Cushingoid appearances, spine and hip fractures, cataracts, and persistent hyperglycemia. Bone marrow suppression was common, and it was always a battle to achieve adequate doses of

**FIGURE 59-12** Individual immunosuppressive drugs and sites of action in the “Three-Signal” T-cell activation model. (Reproduced with permission from Halloran PF: Immunosuppressive drugs for kidney transplantation, *N Engl J Med*. 2004 Dec 23;351(26):2715-2729.)

azathioprine. In the early 1980s, the situation changed for the patients, and the benefits of thoracic transplantation soared with the introduction of the calcineurin inhibitor cyclosporine by Starzl and Calne. Current approaches are attempting to more selectively inhibit alloresponse by including targets of the immune active **Signal 2** pathway.

### GLUCOCORTICOIDS

Prednisone is the chief oral glucocorticoid (GC) antiinflammatory. Effect is mediated by its intracellular block on nuclear factor (NF)- $\kappa$ B pathways.<sup>90</sup> This has the effect of reducing proinflammatory Th<sub>1</sub> cytokines with increase in the Th<sub>2</sub> suppressive secretome and of IL-10.<sup>90-92</sup> GC affects adaptive immunity by reducing the dendritic APC function, numbers of CD<sup>+</sup> cells and, at higher doses, production of anti-HLA antibody.<sup>93,94</sup>

Every transplant physician is aware of the heightened risk of increased infection from GC. While bacterial infections are commonly associated, GC also increases the risk of viral and protozoal-based complications. GC reduces innate immunity by effects on neutrophil adherence and trafficking, phagocytosis and expression of proinflammatory mediators.<sup>95</sup> Finally, GC adversely affects wound healing by reducing monocyte numbers and their entry to the wound as monocytes. Monocytes are important to healing due to their expression of growth factors and ability to phagocytose.<sup>96,97</sup> By limiting fibrocytes, GC further reduces wound healing.<sup>98</sup>

### PURINE ANALOGUES: AZATHIOPRINE AND MYCOPHENOLATE MOFETIL

Early efforts in solid organ transplantation were dependent on the purine analogue 6-mercaptopurine (6-MP) and its less toxic drug, azathioprine (Imuran). The metabolite of these days is 6-thioguanine nucleotide (6-TGN). It is incorporated in DNA and RNA and acts antagonistically to endogenous purines necessary for cell cycling.

MMF (Cellcept) and its active metabolite mycophenolic acid alter the purine synthesis by inhibiting inosine monophosphate dehydrogenase (IMPHD). This blocks inosine conversion to guanosine nucleotides. MMF is a more selective antimetabolic because lymphocytes are dependent on IMPHD for conversion while other cells have alternate pathways. MMF has generally come to be preferred as the rest of bone marrow and lungs are spared. The targeting of T&B lymphocytes has increased the risk of infection and particularly from CMV.<sup>99-102</sup> The most prominent adverse sites affected by MMF are a variety of gastrointestinal symptoms that can be severe enough to initiate a switch to azathioprine.

### CALCINEURIN INHIBITION: CYCLOSPORINE A AND FK506

Calcineurin inhibitors (CNIs) impede a critical intracellular signal pathway initiated with activation of the TCR. Usually, calcineurin binds calmodulin to dephosphorylate the nuclear factor of the activated T-cells (NFAT).<sup>103</sup> NFAT

can then translocate into the nucleus where it acts as a transcription factor for a number of immunologically important genes, including those coding for IL-2, -4, -5, TNF $\alpha$  and IFN $\gamma$ . CNIs affect B cells indirectly by their effect on reducing T-cell help. Cyclosporine (CsA) was the first CNI to be introduced and was followed by Tacrolimus (TAC) (FK506). Both affect NFAT but bind to different immunophilins. CsA binds cyclophilins and TAC to FK-binding-proteins (FK-BPs).

CNIs can cause acute and chronic kidney injury. They reduce both tubular and glomerular function via their adverse effect on the aquaporin gene and protein production.<sup>104</sup> Additionally, they are associated with upregulation of renal mesangial cells and of renal fibrosis.<sup>105,106</sup> CNIs are also diabetogenic: they reduce the production and release of insulin and are proapoptotic to islets.<sup>107,108</sup> Severe neurologic complications, ranging from tremor to seizure and coma, have been associated with the use of CNIs. The cause of the neurologic side effects is likely based on multiple known neurologic interactions.<sup>109</sup> Other specific complications include hyperlipidemia, cholestasis, and malignancies especially skin cancer and non-Hodgkin's lymphoma.<sup>110</sup>

## Proliferation Signal Inhibitors

### mTOR INHIBITORS: SIROLIMUS, EVEROLIMUS

mTORs are proliferation signal inhibitors (PSI) that inhibit serine/threonine protein kinase which is part of multiple pathways necessary for cell activation, proliferation, and vascular endothelial growth factor production.<sup>111,112</sup> Immune cells with higher metabolic needs depend on mTOR activation. mTOR has also been shown to increase the proinflammatory cytokine output and increase adaptive immune memory. The complex and perhaps contradictory action of mTOR inhibitors (mTORi) make this class of agents interesting. Rapamycin (sirolimus) and everolimus are the clinically available mTORi. Of note, mTORi reduce wound healing to the extent that perioperative use is limited due to concerns regarding healing of midline sternotomy of heart transplant and particularly of the bronchus following lung implant.<sup>113,114</sup> Unlike other immunosuppressants, mTORi decrease tumors associated with transplant, probably due to their global inhibition of angiogenesis and cellular proliferation. These drugs have found a more secondary role as replacement or addition to lowered doses of CNIs for nephrotoxicity, cancer, neurologic complications, and resistant rejection.

## Monoclonal Antibodies

### ANTI-IL-2R ANTIBODY: BASILIXIMAB

Basiliximab (Simulect) is a human-mouse antibody that targets the IL-2 $\alpha$  chain (anti-CD25). This limits the proliferation T-cell response. This agent can decrease CD25<sup>+</sup> T-cells for up to six weeks.<sup>115</sup> It may also affect Treg-suppressive roles as CD4<sup>+</sup>/CD25<sup>+</sup>/Foxp3<sup>+</sup> cells (Treg suppressive) decrease and CD4<sup>+</sup>/CD25<sup>-</sup>/Foxp3<sup>+</sup> cells increase.<sup>115</sup>

**ANTI-CD20 ANTIBODY: RITUXIMAB**

Rituximab depletes mature B cells by complement-mediated cytotoxicity and antibody-dependent cell toxicity. It seems also to have proapoptotic activity for B cells. This drug has been used to treat antibody-mediated allograft rejection, but its effect is at best limited. This is because it has little effect on plasma cells or mature antibody-secreting cells that do not express CD20. However, preemptive B-cell depletion at the time of transplant prevented CAV in a primate model<sup>116</sup> and is currently evaluated clinically (CTOT-11).

**BORTEZOMIB: VELCADE**

Velcade binds the catalytic site of the 26S proteasome in plasma cells. It is believed that this inhibition prevents degradation of preapoptotic factors.<sup>117</sup> Recently, Velcade has been approved for treatment of multiple myeloma and has been appropriated for persistent AMR of cardiac allografts. Complications include peripheral neuropathy, myelosuppression, and high incidence of varicella zoster infections. It has been successfully used with plasmapheresis to reduce cPRA in cardiac transplant candidates resistant to antibody-reducing treatment with rituximab and plasmapheresis.<sup>118</sup>

**ANTI-CD52 ANTIBODY: ALEMTUZUMAB**

Alemtuzumab (Campath) is active against CD52 which is a glycoprotein expressed by T and B lymphocytes, macrophages, monocytes, and NK cells.<sup>119</sup> Cell suppression can last for more than 12 months. This agent has been shown to reduce acute rejection episodes but may increase the risk of cancer.<sup>68</sup> It also has a tricky infection-associated profile due to its deeply and persistently suppressive effect.

**CTLA4-IG: BELATACEPT**

Belatacept (Nulojix) is the prototypic immunoglobulin-fusion protein. This recombinant protein is similar to the soluble form T-cell co-stimulatory receptor CTLA-4<sup>120</sup> and binds B7 ligands. This results in interference of Signal 2 for the CD28-B7 co-stimulation pathway. It is the only biologic used in transplantation to target specific alloimmune co-stimulation immune pathway. Signal 1 TCR activation in the absence of co-stimulation limits T-cell response and can induce T-cell anergy.<sup>121</sup> Belatacept succeeded Abatacept as a higher affinity construct for transplantation and was approved for acute kidney rejection in 2011.<sup>120</sup> This biologic was evaluated in a Phase III study of the Belatacept-based immunosuppression regimen versus cyclosporine in renal transplant recipients (BENEFIT). While renal function and blood pressure and lipid profiles were improved with Belatacept, acute rejection was more common (20% vs 7%) and worse histologically.<sup>122</sup> It has been proposed that memory T-cells are less controlled by co-stimulation blockade.

**Polyclonal Antibodies****ANTITHYMOCYTE GLOBULIN**

Antithymocyte globulin (ATG) is a polyclonal mixture of immunoglobulins (IgG) drawn from either rabbits (RATG

or thymoglobulin) or horses (eATG or ATGAM). These IgG predominant preparations are based on animal immunizations with human thymocytes. They recognize multiple targets principally on T lymphocytes. Depletion of cells follows complement-based lysis, ADCC, and apoptosis.<sup>123</sup> Beyond depletion of T-cells, ATG also increases Tregs and depletes and impairs NKs and reduces B cells.<sup>124</sup> Rounding out the broad effects is ATG's interference with the uptake of antigens by DC cells.

RATG is preferred for its effectiveness in reducing rejection.<sup>125</sup> It is associated with an increased risk of PTLD and CMV infection due to its broadly reacting immunosuppression<sup>126,127</sup>

**Intravenous Immunoglobulin**

IVIG is made from pooled human donor IgG. It has inherent problems with supply, cost, and batch-based variability. It has become part of the regimen for treatment of AMR as it was a proven treatment for autoimmune and diverse inflammatory conditions. Its effectiveness is believed due to presence of anti-idiotypic antibodies and its ability to block complement-binding target cells and molecules.<sup>128</sup> The Fab-mediated antigen binding effects of IgG appear to be joined by Fc-dependent immune modulation.<sup>129</sup>

**ACKNOWLEDGMENTS**

We thank Dr. Keshava Rajagopal, Department of Surgery, University of Texas, and Dr. Debra KuKuruga, Director, HLA Laboratory of Red Cross, University of Maryland Baltimore, for their significant contributions to this chapter.

# Heart Transplantation

Richard J. Shemin • Mario Deng

The number of patients with heart failure is growing. End-stage heart failure is associated with significant morbidity, need for recurrent hospitalizations, decrease in quality of life, and increased mortality. Cardiac transplantation has evolved as an effective therapy for many of these patients. Tremendous advancements in the fields of immunosuppression, rejection, and infection have transformed what was once considered an experimental intervention into a routine treatment available worldwide.

The innovative French surgeon Alexis Carrel performed the first heterotopic canine heart transplant with Charles Guthrie in 1905. Frank Mann at the Mayo Clinic further explored the idea of heterotopic heart transplantation in the 1930s. The neck became the preferred site of implantation in early experimental animal models because of the ease of monitoring the organ, the simplicity of access to major vessels, and because the recipient's native heart could serve as a built-in cardiac assist device for the transplanted organ. Mann also proposed the concept of cardiac allograft rejection, in which biological incompatibility between donor and recipient was manifested as a leukocytic infiltration of the rejecting myocardium. In 1946, after unsuccessful attempts in the inguinal region, Vladimir Demikhov of the Soviet Union successfully implanted the first intrathoracic heterotopic heart allograft. He later demonstrated that heart-lung and isolated lung transplantation also were technically feasible.

The use of moderate hypothermia, cardiopulmonary bypass, and an atrial cuff anastomotic technique permitted Norman Shumway (Fig. 60-1) and Richard Lower at Stanford University to further explore orthotopic heart transplantation using a canine model in 1960.

The first human cardiac transplant was a chimpanzee xenograft performed at the University of Mississippi by James Hardy in 1964. Although the procedure using Shumway's technique was technically satisfactory, the primate heart was unable to maintain the recipient's circulatory load and the patient succumbed several hours postoperatively.

Despite great skepticism that cardiac transplantation ever would be performed successfully in humans, South African

Christiaan Barnard surprised the world when he performed the first human-to-human heart transplant on December 3, 1967. Over the next several years, poor early clinical results led to a moratorium on heart transplantation, with only the most dedicated centers continuing experimental and clinical work in the field. The pioneering efforts of Shumway and colleagues at Stanford eventually paved the way for the reemergence of cardiac transplantation in the late 1970s.

The introduction of transvenous endomyocardial biopsy by Philip Caves in 1973 finally provided a reliable means for monitoring allograft rejection. Ultimately, however, it was the advent of the immunosuppressive agent cyclosporine that dramatically increased patient survival and marked the beginning of the modern era of successful cardiac transplantation in 1981.

Heart transplantation is now a widely accepted therapeutic option for end-stage cardiac failure; however, the annual number of transplants in the United States (approximately 2400 per year) has slowly increased since 2002, however, limited donor-organ availability remains a major limitation (from United Network for Organ Sharing [UNOS] data, through September 2012).

## THE CARDIAC TRANSPLANT RECIPIENT

### Recipient Selection

The evaluation of potential candidates for cardiac transplantation is performed by a multidisciplinary committee to ensure the equitable, objective, and medically justified allocation of donor organs to those patients most likely to achieve long-term benefit. It is very important to establish a mutual long-term working relationship among patient, social support system, and the entire team at the beginning of this process.

Indications and potential contraindications for cardiac transplantation are outlined in Table 60-1.<sup>1</sup> These inclusion and exclusion criteria can vary somewhat among transplantation centers.<sup>1-4</sup> The basic objective is to identify those

**FIGURE 60-1** Norman Shumway.

relatively healthy patients with end-stage cardiac disease, refractory to other appropriate medical and surgical therapies, who possess the potential to resume a normal active life and maintain compliance with a rigorous medical regimen after cardiac transplantation.

### ETIOLOGY OF END-STAGE CARDIAC FAILURE

Determination of the etiology and potential reversibility of end-stage heart failure is critical for the selection of transplant candidates. Overall, from 1982 to 2012, the indications for heart transplantation in adult recipients have been overwhelmingly ischemic heart failure and nonischemic cardiomyopathy (approximately 90%); with valvular (2-3%), adult congenital (2%), retransplantation (2%), and miscellaneous causes comprising the remainder.<sup>5</sup>

The perception of the irreversibility of advanced cardiac failure is changing with the growing efficacy of tailored medical therapy, high-risk revascularization procedures, and newer antiarrhythmic pharmacologic agents, as well as implantable defibrillators and biventricular pacing. Additionally, other surgical modalities, such as ventricular assist devices (VADs) and surgical ventricular restoration (SVR), have found increasing application.<sup>6,7</sup> Furthermore, it is

important to consider that prognosis may differ in patients with cardiomyopathy who have neither ischemic nor valvular heart disease. Caution should be exercised when judging prognosis in these patient subgroups, and a period of observation, intense pharmacologic therapy, and/or mechanical support should be undertaken before heart transplantation is considered.<sup>4</sup>

### EVALUATION OF THE POTENTIAL CARDIAC TRANSPLANT RECIPIENT

The complexity of the recipient evaluation mandates a team approach. The initial evaluation involves a comprehensive history and physical examination because this will help to determine etiology and contraindications. Table 60-2 summarizes the cardiac transplant evaluation tests.<sup>3</sup> Routine hematologic and biochemical analyses and pertinent tests as illustrated by organ system are performed.<sup>3</sup>

For the assessment of the heart itself, in addition to routine 12-lead electrocardiogram, Holter monitor, and echocardiography, all patients should undergo cardiopulmonary exercise testing to evaluate functional capacity if disease severity allows. Peak exercise oxygen consumption measured during maximal exercise testing  $\dot{V}O_{2,max}$  provides a measure of functional capacity and cardiovascular reserve, and an inverse relationship between  $\dot{V}O_{2,max}$  and mortality in heart failure patients has been demonstrated.<sup>8</sup> Documentation of adequate effort during exercise, as evidenced by attaining a respiratory exchange ratio greater than 1.0 or achievement of an anaerobic threshold at 50 to 60% of  $\dot{V}O_{2,max}$  is necessary to avoid underestimation of functional capacity.<sup>2</sup>

Right-sided heart catheterization should be performed at the transplanting center to evaluate the severity of heart failure (and hence the status level for transplant listing) and evaluate for the presence of pulmonary hypertension (PH). Right heart catheterization also can help guide therapy while awaiting transplantation. Coronary cineangiography should be reviewed to confirm the inoperability of coronary artery lesions in cases of ischemic cardiomyopathy. As well, either a positron emission tomographic (PET) scan, a thallium-201 redistribution study, or a cardiac magnetic resonance imaging (MRI) study should assess viability in selected patients who would be candidates for revascularization if sufficient viability is present.<sup>2,3</sup>

Endomyocardial biopsy should be performed on all patients in whom the etiology of heart failure is in question, especially those with nonischemic cardiomyopathies symptomatic for fewer than 6 months.<sup>3</sup> This can assist in therapeutic decision making and exclude diagnoses such as amyloidosis, which are considered relative contraindications to transplantation.

The neuropsychiatric assessment should be performed by persons experienced in evaluating cardiac patients to determine if organic brain dysfunction or psychiatric illness is present. An experienced social worker should assess for the presence of adequate social and financial support. At the time of listing, the transplant coordinator should ensure that the patient and family understand the peculiarities of the waiting

**TABLE 60-1: Recipient Selection for Heart Transplantation****Indications**

- I. Systolic heart failure (as defined by ejection fraction <35%)
  - A. Accepted etiology
    - 1. Ischemic
    - 2. Idiopathic
    - 3. Valvular
    - 4. Hypertensive
    - 5. Other
  - B. Controversial etiology
    - 1. HIV infection
    - 2. Cardiac sarcoma
- II. Intractable angina
  - A. Ineffective maximal tolerated medical therapy
  - B. Not a candidate for direct myocardial revascularization, percutaneous revascularization, or transmyocardial revascularization procedure
  - C. Unsuccessful myocardial revascularization
- III. Intractable arrhythmia
  - A. Uncontrolled with pacing cardioverter defibrillator
    - 1. Not amenable to electrophysiology-guided single or combination medical therapy
    - 2. Not a candidate for ablation therapy
- IV. Hypertrophic cardiomyopathy
  - A. Class IV symptoms persist despite interventional therapies
    - 1. Alcohol injection of septal artery
    - 2. Myotomy and myomectomy
    - 3. Mitral valve replacement
    - 4. Maximal medical therapy
    - 5. Pacemaker therapy
  - V. Congenital heart disease in which severe fixed pulmonary hypertension is not a complication
- VI. Cardiac tumor
  - A. Confined to the myocardium
  - B. No evidence of distant disease revealed by extensive metastatic workup
- VII. Restrictive cardiomyopathy
  - A. Class IV symptoms persist despite interventional therapies
  - B. Amyloid (if concomitant therapy such as chemotherapy/autologous stem cell transplant feasible)

**Absolute Contraindications**

- I. Age >65-75 years (may vary at different centers)
- II. Fixed pulmonary hypertension (unresponsive to pharmacologic intervention)
  - A. Pulmonary vascular resistance >4-6 Wood units
  - B. Transpulmonary gradient >12-18 mm Hg
- III. Systemic illness that will limit survival despite transplant
  - A. Neoplasm other than skin cancer (<2-5 years disease-free survival)
  - B. HIV/AIDS (CDC definition of CD4 count of <200 cells/mm<sup>3</sup>)
  - C. Systemic lupus erythematosus (SLE) or sarcoid that has multisystem involvement and is currently active
  - D. Any systemic process with a high probability of recurrence in the transplanted heart
  - E. Irreversible organ (eg, renal, hepatic, pulmonary) dysfunction

**Potential Relative Contraindications**

- I. Recent malignancy
- II. Chronic obstructive pulmonary disease
- III. Recent and unresolved pulmonary infarction and pulmonary embolism
- IV. Diabetes mellitus with end-organ damage (neuropathy, nephropathy, and retinopathy)
- V. Peripheral vascular or cerebrovascular disease
- VI. Active peptic ulcer disease
- VII. Current or recent diverticulitis
- VIII. Other systemic illness likely to limit survival or rehabilitation
- IX. Severe obesity or cachexia
- X. Severe osteoporosis
- XI. Active alcohol, nicotine or drug abuse
- XII. History of noncompliance or psychiatric illness likely to interfere with long-term compliance
- XIII. Absence of psychosocial support

 **TABLE 60-2: Cardiac Transplant Evaluation Tests**

Laboratory	Complete blood count with differential and platelet count, creatinine, blood urea nitrogen, electrolytes, liver panel, lipid panel, calcium, phosphorus, total protein, albumin, uric acid, thyroid panel, antinuclear antibodies, erythrocyte sedimentation rate (ESR), rapid plasma reagin (RPR), iron-binding tests, partial thromboplastin time, prothrombin time Blood type (incl. confirmatory test), IgG and IgM antibodies against cytomegalovirus, herpes simplex virus, HIV, varicella-zoster virus, hepatitis B surface antigen, hepatitis C antigen, toxoplasmosis, other titers when indicated Tuberculin skin test Prostate-specific antigen (male >50 years) Mammogram and Pap smear (female >40 years) Screening against a panel of donor antigens (panel reactive antibodies) and human leukocyte antigen phenotype 24-hour urine for creatinine clearance and total protein, urinalysis, urine culture 1 Baseline bacterial and fungal cultures, stool for ova and parasites if indicated
Cardiac	12-lead ECG, 24-hour Holter monitor Echocardiogram Thallium-201 imaging, positron-emission tomographic (PET) scan, or cardiac magnetic resonance imaging (MRI) to assess viability if indicated Exercise stress test and respiratory gas analysis with oxygen uptake measurements: peak exercise oxygen consumption $\dot{V}O_{2,max}$ Right- and left-sided heart catheterization Myocardial biopsy on selected patients in whom etiology of heart failure is in question and affects treatment choice
Vascular	Peripheral vascular studies Carotid Doppler and duplex ultrasound 55 years
Renal	Renal ultrasound and or intravenous pyelogram if indicated
Pulmonary	Chest x-ray Pulmonary function tests Chest CT scan to evaluate abnormal chest x-ray or thoracic aorta in older patients (usually >65 years)
Gastrointestinal	Upper endoscopy/colonoscopy if indicated Upper gastrointestinal series and/or barium enema if indicated Percutaneous liver biopsy if indicated
Metabolic	Bone densitometry
Neurologic	Screening evaluation
Psychiatric	Screening evaluation
Dental	Complete dental evaluation
Physical therapy	Evaluation
Social work	Patient attitude and family support, medical insurance, and general financial resources
Transplant coordinator	Education

time, preoperative period, long-term maintenance medications, and the rules of living with the new heart. It is also of paramount importance that providers discuss the patient's preferences with regard to life support (duration and type), in case of a deterioration in his or her condition while awaiting transplant.

### Indications for Cardiac Transplantation

Cardiac transplantation is reserved for a select group of patients with end-stage heart disease not amenable to optimal medical or surgical therapies. Prognosis for 1-year survival without transplantation should be less than 50%. Prediction of patient survival involves considerable subjective clinical judgment by the transplant committee because

no reliable objective prognostic criteria are available currently. Low ejection fraction (<20%), reduced  $\dot{V}O_{2,max}$  (<14 mL/kg/min), arrhythmias, high pulmonary capillary wedge pressure (>25 mm Hg), elevated plasma norepinephrine concentration (>600 pg/mL), reduced serum sodium concentration (<130 mEq/dL), and N-terminal probrain natriuretic peptide (>5000 pg/mL) all have been proposed as predictors of poor prognosis and potential indications for transplantation in patients receiving optimal medical therapy.<sup>8-11</sup> Reduced left ventricular ejection fraction and low  $\dot{V}O_{2,max}$  are widely identified as the strongest independent predictors of survival.

The indications for cardiac transplantation listing are continuously reviewed as new breakthroughs in the medical and surgical treatment of heart disease emerge.

## CONTRAINDICATIONS FOR CARDIAC TRANSPLANTATION

Table 60-1 lists the traditional absolute and relative contraindications. It should be acknowledged that strict guidelines can be problematic; therefore, each transplant program varies regarding absolute criteria based on clinical circumstances and experience. Furthermore, traditional contraindications for transplant listing are being questioned.

Age is one of the most controversial exclusionary criteria for transplantation. The upper age limit for recipients is center-specific, but emphasis should be placed on the patient's physiologic rather than chronologic age. The Official Adult Heart Transplant Report 2009 from the registry of the International Society for Heart and Lung Transplantation (ISHLT) noted that over the last 25 years, the percentage of recipients older than 60 years of age has increased steadily, approaching 25% of all heart transplants between 2002 and 2008 compared with just above 5% between 1982 and 1988.<sup>5</sup> Although the elderly have a greater potential for occult systemic disease that may complicate their postoperative course, some recent reports have suggested that morbidity and mortality in carefully selected older patients are comparable with those of younger recipients, and they have fewer rejection episodes than younger patients.<sup>12,13</sup>

Fixed PH, usually manifested as elevated pulmonary vascular resistance (PVR), is one of the few absolute contraindications to orthotopic cardiac transplantation. Fixed PH increases the risk of acute right ventricular failure when the right ventricle of the allograft is unable to adapt to significant PH in the immediate postoperative period.<sup>14</sup> Use of the transpulmonary gradient (TPG), which represents the pressure gradient across the pulmonary vascular bed independent of blood flow, may avoid erroneous estimations of PVR, such as those that may occur in patients with low cardiac output.<sup>4</sup> Some have advocated the use of PVR index (PVRI) unit, which corrects for body size.

$$\text{PVR (Wood units)} = \frac{\text{MPAP (mm Hg)} - \text{PCWP (mm Hg)}}{\text{CO (L/min)}}$$

$$\text{PVRI (units)} = \frac{\text{MPAP (mm Hg)} - \text{PCWP (mm Hg)}}{\text{CO (L/min)} \times \text{BSA}} = \frac{\text{PVR}}{\text{BSA}}$$

$$\text{TPG (mm Hg)} = \text{PAP (mm Hg)} - \text{PCWP (mm Hg)}$$

where MPAP is mean pulmonary arterial pressure, PCWP is pulmonary capillary wedge pressure, CO is cardiac output, CI is cardiac index, and BSA is body surface area.

A fixed PVR greater than 5 to 6 Wood units and a TPG greater than 15 mm Hg generally are accepted as absolute criteria for rejection of a candidate.<sup>1-4,11</sup> Over the years, several studies have found PH to have a significant effect on posttransplant mortality using various parameters, threshold values, and follow-up periods.<sup>15,16</sup> However, a lack of mortality difference after heart transplantation between patients with and without preoperative PH has also been reported.<sup>17</sup> Perhaps more significantly, measurable parameters of PH

have been shown to improve following heart transplantation. A study of 172 patients followed for up to 15.1 years, published in 2005 from the Johns Hopkins Hospital, showed that mild to moderate pretransplantation PH (PVR = 2.5 to 5.0 Wood units) was not associated with higher mortality rate, although there was increased risk of posttransplantation PH within the first 6 months.<sup>18</sup> However, when the continuous variable PVR was examined, each 1 Wood unit increase in preoperative PVR demonstrated a 15% or more increase in mortality, especially within the first year, but these associations did not reach statistical significance. Severe preoperative PH (PVR  $\geq$  5 Wood units) was associated with death within the first year after adjusting for potential cofounders but not with overall mortality or mortality beyond the first year.

In the preoperative evaluation of the transplant recipient, if PH is discovered, an assessment of its reversibility should be performed in the cardiac catheterization laboratory.<sup>16</sup> Sodium nitroprusside traditionally has been used at a starting dose of 0.5  $\mu\text{g/kg}$  per minute and titrated by 0.5  $\mu\text{g/kg}$  per minute until there is an acceptable decline in PVR, ideally 2.5 Wood units or at least by 50%, with maintenance of adequate systemic systolic blood pressure. If sodium nitroprusside fails to produce an adequate response, other vasodilators such as adenosine, prostaglandin E<sub>1</sub> (PGE<sub>1</sub>), milrinone, or inhaled nitric oxide or prostacyclin (eg, aerosolized Iloprost) may be used.<sup>2,19</sup> Some patients who do not respond acutely may respond to continuous intravenous inotropic therapy, and repeat catheterization can be performed after 48 to 72 hours. Intravenous B-type natriuretic peptide, eg, nesiritide (Natrecor), has shown some efficacy in refractory PH.<sup>20</sup> Recently, VADs are playing an important role in heart transplantation candidates with PH.<sup>21</sup> A period of left ventricular assist device (LVAD) support may allow for a decrease of pulmonary artery pressure secondary to unloading of the left ventricle. Patients with irreversible PH may be candidates for heterotopic heart transplantation, heart-lung transplantation, or LVAD destination therapy.<sup>22</sup> Use of modestly larger donor hearts for recipients with severe pretransplantation PH can provide additional right ventricular reserve.

Systemic diseases with poor prognosis and potential to recur in the transplanted heart or the potential to undergo exacerbation with immunosuppressive therapy are considered absolute contraindications for heart transplantation. Previously, any occurrence of neoplasm was a reason to exclude patients from transplantation. Currently available data do not appear to justify excluding some of these patients.<sup>23</sup> Most programs will consider patients who are free of disease for at least 5 years. A recent multicenter study investigated the influence of pretransplant malignancy on posttransplant recurrence and long-term survival in heart and lung transplant recipients. In this cohort, 111 recipients (lung: 37; heart: 74) with 113 pretransplant malignancies were identified. The cohort was divided into 3 groups by pretransplant cancer-free interval of <12 months,  $\geq$ 12 to 60 months, and  $\geq$ 60 months. Pretransplant cancer-free survival of  $\geq$ 5 years was associated with the lowest recurrence at a mean follow-up of 70  $\pm$  63 months

(6% at  $\geq 60$  months vs 26% at 12 to 60 months vs 63% at  $< 12$  months). Survival was significantly poorer in those cancer-free for  $< 12$  months, whereas there was no survival difference in the other 2 groups. Further study is warranted to determine the optimal malignancy-free period.<sup>24</sup> Heart transplantation for amyloid remains controversial because amyloid deposits recur in the transplanted heart. Although case reports of long-term survival can be found in the literature,<sup>25</sup> survival beyond 1 year tends to be reduced.<sup>23</sup>

Human immunodeficiency virus (HIV)-infected patients generally were excluded until a recent case series by the Columbia University Heart Transplant Group. With the newer antiretroviral drugs, the estimated 10-year survival after seroconversion exceeds 90%. In a retrospective single-center analysis of 1679 cardiac transplant patients, seven HIV-positive patients underwent heart transplantation. Five (4 men) were diagnosed with HIV before transplantation and 2 patients seroconverted after transplantation. Dilated cardiomyopathy was the indication for transplant in all patients. The 5 HIV recipients were aged  $42 \pm 8$  years, and time after HIV seroconversion averaged 9.5 years. All underwent cardiac transplantation as high-risk candidates. The CD4 count was  $554 \pm 169$  cells/microl, and viral load was undetectable in all patients at the time of transplantation. Two patients seroconverted to HIV-positive status at 1 and 7 years after transplant. No AIDS-defining illness was observed in any patient before or after transplant. Six patients received highly active antiretroviral therapy. Viral load remained low in the presence of immunosuppression. All patients were alive with a follow-up from transplant of  $57 \pm 78.9$  months.<sup>26,27</sup>

Irreversible renal dysfunction is a contraindication to heart transplantation. A creatinine clearance of less than 50 mL/min and a serum creatinine concentration of greater than 2 mg/dL are associated with increased risk of postoperative dialysis and decreased survival following heart transplantation.<sup>4,28</sup> The effect of chronic kidney dysfunction (CKD) on post-HTx outcomes was recently examined in 1732 recipients. In this population, 3% were CKD stage 4 and 5 at the time of transplant, increasing to 11% at 1 year and more than 15% at 6 years after transplantation. The risk of death was significantly higher in patients with CKD 4 and 5 (hazard CKD4:1.66; CKD5:8.54; dialysis:4.07). Multiorgan transplantation was not assessed in this cohort.<sup>29</sup> However, patients may be considered for combined heart and kidney transplantation.

Irreversible hepatic dysfunction has implications similar to renal dysfunction.<sup>4</sup> If transaminase levels are more than twice their normal value and associated with coagulation abnormalities, percutaneous liver biopsy should be performed to exclude primary liver disease. This should not be confused with chronic cardiac hepatopathy, which is characterized by elevated cholestatic parameters along with little or no changes in transaminases and is potentially reversible after heart transplantation.<sup>30</sup> The use of MELD and MELD-XI (excluding international normalized ratio) were shown to be predictive of survival after heart transplantation and VAD. Moreover, if the MELD-XI normalized during VAD support, post-transplant survival was similar to those without prior liver

dysfunction. In VAD patients with an elevated MELD-XI score, a decrease in score  $< 17$  may help identify optimal transplant candidates.<sup>31,32</sup>

Severe chronic bronchitis or obstructive pulmonary disease may predispose patients to pulmonary infections and may result in prolonged ventilatory support after heart transplantation. Patients who have a ratio of forced expiratory volume in 1 second to forced vital capacity ( $FEV_1/FVC$ ) of less than 40 to 50% of predicted or an  $FEV_1$  of less than 50% of predicted despite optimal medical therapy are considered poor candidates for transplantation.<sup>2,4</sup>

Transplantation in patients with diabetes mellitus is only contraindicated in the presence of significant end-organ damage (eg, diabetic nephropathy, retinopathy, or neuropathy).<sup>2,4</sup> Some centers have expanded their criteria successfully to include patients with mild to moderate end-organ damage.<sup>33</sup>

Active infection was a sound reason to delay transplantation before assist devices became more commonplace. Up to 48% of patients with implanted LVADs reportedly have evidence of infection. Interestingly, treatment for LVAD infection in these patients is to proceed with urgent transplantation.<sup>34</sup>

Other relative contraindications include severe noncardiac atherosclerotic disease, severe osteoporosis, and active peptic ulcer disease or diverticulitis, all of which may lead to increased morbidity.<sup>2,4</sup> Cachexia, defined as a body mass index (BMI) of less than 20 or less than 80% ideal body weight (IBW), and obesity, defined as BMI greater than 35 or greater than 140% of IBW, are associated with increased mortality after transplantation.<sup>35</sup> Poor nutritional status also may limit early postoperative rehabilitation. The effect of metabolic risk factors (hypertension, diabetes, obesity) was assessed in 15,960 recipients using an analysis of the UNOS Registry (1998-2008). Individually, these risk factors increased the risk of death posttransplant, with a hazard ratio of 1.10 for hypertension, 1.22 for diabetes, and 1.17 for obesity. Moreover, there was an exponential trend of increasing mortality with the addition of each risk factor, such that recipients with all 3 risk factors had a 63% increased mortality compared with recipients with none.<sup>36</sup>

The ultimate success of transplantation depends on the psychosocial stability and compliance of the recipient.<sup>37</sup> The rigorous postoperative regimen of multidrug therapy, frequent clinic visits, and routine endomyocardial biopsies demand commitment on the part of the patient. A history of psychiatric illness, substance abuse, or previous noncompliance (particularly with medical therapy for end-stage heart failure) may be sufficient cause to reject the candidacy of a patient. Lack of a supportive social system is an additional relative contraindication.

## Management of the Potential Cardiac Recipient

### PREFORMED ANTI-HLA ANTIBODIES

Patients with elevated levels of preformed panel reactive antibodies (PRAs) to human leukocyte antigens (HLAs) have higher rates of organ rejection and decreased survival than

do patients without such antibodies.<sup>38</sup> Consequently, before proceeding with transplantation, many medical centers do prospective cross-matching, ie, either by flow cytometry or enzyme-linked immunosorbent assay (ELISA), to determine whether donor-specific antibodies that threaten the allograft are present. The problem has been compounded by the increased frequency of preformed reactive antibodies in patients with VADs who are awaiting cardiac transplantation.<sup>39</sup> Furthermore, not all antibodies are complement fixing or dangerous. Performing a prospective cross-match can be time-consuming and often it is impossible because of the unstable condition of the organ donor or travel logistics, leading to increased costs for transplantation and longer waiting times for recipients. Recently, virtual cross-matching has been used to eliminate the need for prospective tissue cross-matching. Modern laboratory techniques allow for identification and titer of antibodies. Because all donor antigens are known at the time of allocation, an assessment can be made without an actual tissue/sera assay. However, a particular patient's antibody population is dynamic and may change from the time of the antibody screen. As a result, care must be taken in patients with particularly diverse and high antibody titers. Plasmapheresis, intravenous immunoglobulins (IVIGs), cyclophosphamide, mycophenolate mofetil (MMF), and rituximab all have been used to lower the PRA levels with variable results.<sup>2</sup>

### PHARMACOLOGIC BRIDGE TO TRANSPLANTATION

Critically compromised patients require admission to the intensive care unit for intravenous inotropic therapy. Dobutamine, a synthetic catecholamine, remains the prototype of this drug group. However, the phosphodiesterase III inhibitor milrinone is similarly effective.<sup>40</sup> The catecholamine dopamine is used often as a parenteral positive inotrope, but at moderate to high dose it evokes considerable systemic vasoconstriction. In candidates in whom an inotropic infusion has progressed to higher doses, combinations of dobutamine with milrinone are used. For transplant candidates dependent on inotropic infusions, eosinophilic myocarditis may develop as an allergic response to the dobutamine and may result in accelerated decline. VADs are being considered earlier, particularly as indices of nutrition decline.

### MECHANICAL BRIDGE TO TRANSPLANTATION

Placement of an intraaortic balloon pump (IABP) may be necessary in patients with heart failure who are refractory to initial pharmacologic measures. Ambulatory IABP through the axillary artery has been reported in few patients as a bridge to cardiac transplantation but is not commonly used today.<sup>41</sup>

The landmark Randomized Evaluation of Mechanical Assistance in Treatment of Chronic Heart Failure (REMATCH) trial provided evidence that LVAD support provided a statistically significant reduction in the risk of death from any cause when compared with optimal medical management. The survival rates for patients receiving LVADs ( $n = 68$ ) versus

patients receiving optimal medical management ( $n = 61$ ) were 52% versus 28% at 1 year and 29% versus 13% at 2 years ( $p = .008$ , log-rank test).<sup>6,42</sup> The extended follow-up confirmed the initial observation that LVAD therapy renders significant survival and quality-of-life benefits compared with optimal medical management for patients with end-stage heart failure. A recent systematic review of the published literature supported these findings. In the studies reviewed, implantation of an LVAD provided support for up to 390 days, with as many as 70% of patients surviving to transplantation.<sup>43</sup>

The total artificial heart (TAH) positioned orthotopically replaces both native cardiac ventricles and all cardiac valves. Potential advantages of this device include eliminating problems commonly seen in the bridge to transplantation with left ventricular and biventricular assist devices, such as right-sided heart failure, valvular regurgitation, cardiac arrhythmias, ventricular clots, intraventricular communications, and low blood flows. Copeland and colleagues reported that the TAH allowed for bridge to transplantation in 79% of their patients with 1- and 5-year survival rates after transplantation of 86 and 64%, respectively.<sup>44</sup>

Because these devices cannot be weaned, it is imperative that the patient's candidacy for transplantation be scrutinized before placement of the device. Trends toward better device durability and reduced complication rates likely will continue to improve through the development of newer, more innovative VADs, allowing destination therapy to be considered more frequently.

### LIFE-THREATENING VENTRICULAR ARRHYTHMIAS

Symptomatic ventricular tachycardia (VT) and a history of sudden cardiac death are indications for placement of an automatic implantable cardioverter-defibrillator (AICD), long-term antiarrhythmic therapy with amiodarone, or occasionally, radiofrequency catheter ablation, which have been shown to improve survival.<sup>45</sup> Biventricular VADS and the TAH can be considered in this subgroup.

## Recipient Prioritization for Transplantation

The prioritization of appropriate recipients for transplantation is based on survival and quality of life expected to be gained in comparison with maximal medical and surgical alternatives.<sup>3</sup> The United Network for Organ Sharing (UNOS) is a national organization that maintains organ transplantation waiting lists and allocates identified donor organs on the basis of recipients' priority status. This priority status is based on a recipient's status level (eg, IA, IB, or II), blood type, body size, and duration of time at a particular status level.<sup>2</sup> Geographic distance between donor and potential recipient is also taken into consideration. Highest priority is given to local status IA patients possessing the earliest listing dates. The recipient status criteria established by UNOS in 1999 are outlined in Table 60-3. In 1994, the percentage of patients awaiting transplantation for more than 2 years was 23%; this increased to 49% by 2003. From 1998 (with the

**TABLE 60-3: Current Recipient Status Criteria of the United Network for Organ Sharing (UNOS)\***
**Status IA**

- 
- A. Patients who require mechanical circulatory assistance with one or more of the following devices:
1. Total artificial heart
  2. Left and/or right ventricular assist device implanted for 30 days or less
  3. Intraaortic balloon pump
  4. Extracorporeal membrane oxygenator (ECMO)
- B. Mechanical circulatory support for more than 30 days with significant device-related complications
- C. Mechanical ventilation
- D. Continuous infusion of high-dose inotrope(s) in addition to continuous hemodynamic monitoring of left ventricular filling pressures
- E. Life expectancy without transplant <7 days

**Status IB**

- 
- A. A patient who has at least one of the following devices or therapies in place:
1. Left and/or right ventricular assist device implanted for >30 days
  2. Continuous infusion of intravenous inotropes

**Status II**

---

All other waiting patients who do not meet status Ia or Ib criteria

\*UNOS Executive Order, August 1999

---

institution of a new status system) to 2007, the distribution of patient status at transplant changed dramatically. In 1999, the distribution was 34% (1A), 36% (1B), and 26% (2). This shifted in 2007 to 50% (1A), 36% (1B), and 14% (2).<sup>46</sup>

Patients considered for transplantation should be examined at least every 3 months for reevaluation of recipient status. Yearly right-sided heart catheterization is indicated for all candidates on the waiting list and in selected cases for patients rejected because of PH. Presently, there is no established method to delist patients who have stabilized on medical therapy without loss of their previously accrued waiting time.

## THE CARDIAC DONOR

### Donor Availability

The US Uniform Anatomic Gift Act of 1968 states that all competent individuals over the age of 18 may donate all or part of their bodies and established the current voluntary basis of organ donation practiced in the United States. To accommodate the increasing demand for organs, the original stringent criteria for donor eligibility have been relaxed, and educational campaigns have increased awareness of the need for a larger donor pool. In 1986, the Required Request Law, which required hospitals to request permission from next of kin to recover organs, was passed to encourage physician compliance in the donor request process. Future reforms will be molded by the evolving public attitude to transplantation and likely will focus on continued public and physician education.

The availability of donor organs remains the major limiting factor to heart transplantation. In the early years of heart transplantation, the number of heart transplants performed

in the United States increased steadily to a peak in 1995 of 2363 and then reached a plateau in 1998. After 1998, there was a gradual decline in heart transplants per year to a nadir of 2015 in 2004, after which the number has steadily increased to 2207 in 2007.<sup>46</sup> A more risk-averse approach to donor use has been discussed as contributing factor for decreased organ use.<sup>47</sup> Conversely, successful use of hearts with donor cardiac arrest history < 8 minutes<sup>48</sup> and donor cardiopulmonary resuscitation<sup>49</sup> has recently been reported.

Interestingly, likely owing to improved preoperative care, the death rate for patients on the waiting list for a cardiac allograft has decreased steadily.<sup>46</sup>

### Allocation of Donor Organs

In an effort to increase organ donation and to coordinate an equitable allocation of allografts, Congress passed the National Organ Transplant Act in 1984. This act resulted in the drafting of the aforementioned Required Request Law, as well as the awarding of a federal contract to the UNOS for the development of a national organ procurement and allocation network. To facilitate transplantation, the United States is divided into 11 geographic regions.

Organs are offered to sick patients within the region in which they were donated before being offered to other parts of the country. This helps to reduce organ preservation time, improve organ quality and survival outcomes, reduce the costs incurred by the transplant patient, and increase access to transplantation.

The effect of the new UNOS broader regional algorithm for donor organ sharing that prioritizes donor heart allocation to higher-risk (status 1A and 1B) wait-listed patients was a significant reduction in waiting list mortality in status 1A

and 1B patients, with no change in the waiting list mortality for lower-priority patients (status 2). Importantly posttransplant outcomes were sustained despite the higher-risk nature of the recipients.<sup>50</sup>

## Donor Selection

Once a brain-dead individual has been identified as a potential cardiac donor, the patient undergoes a rigorous three-phase screening regimen. The primary screening is undertaken by the organ procurement agency. Information regarding the patient's age, height and weight, gender, ABO blood type, hospital course, cause of death, and routine laboratory data including cytomegalovirus (CMV), HIV, hepatitis B virus (HBV), and hepatitis C virus (HCV) serologies are collected. Cardiac surgeons and/or cardiologists perform the secondary screening, which involves further investigation in search of potential contraindications (Table 60-4), determination of the hemodynamic support necessary to sustain the donor, and review of the electrocardiogram, chest roentgenogram, arterial blood gas determination, and echocardiogram. Even when adverse donor criteria are reported, a team often is dispatched to the hospital to evaluate the donor on-site.

Although echocardiography is effective in screening for anatomical abnormalities of the heart, the use of a single echocardiogram to determine the physiologic suitability of a donor is not supported by evidence.<sup>51</sup> The Papworth Hospital transplant program in Great Britain increased its donor yield substantially by using a pulmonary artery catheter to guide the physiologic assessment and management of ventricular

dysfunction.<sup>52</sup> Coronary angiography is indicated in the presence of advanced donor age (traditionally for male donors >45 years of age and female donors >50 years of age). Angiography also should be performed if there is a history of cocaine use or the donor has three risk factors for coronary artery disease (CAD), such as hypertension, diabetes, smoking history, dyslipidemia, or family history of premature CAD.<sup>51</sup>

The final and often most important screening of the donor occurs intraoperatively at the time of organ procurement by the cardiac surgical team. Direct visualization of the heart is performed for evidence of right ventricular or valvular dysfunction, previous infarction, or myocardial contusion secondary to closed-chest compressions or blunt chest trauma. The coronary arterial tree is palpated for gross calcifications indicative of atheromatous disease. If direct examination of the heart is unremarkable, the recipient hospital is notified, and the procurement surgeons proceed with donor cardiectomy, usually in conjunction with multiorgan procurement.

## Expanded Donor Criteria and Alternate Listing

As the donor shortage has worsened and the number of patients waiting for transplants has increased, one of the areas of increasing interest is the use of marginal donors for marginal recipients. For this purpose, an alternate recipient list is being used by some centers to match certain recipients who might be excluded from a standard list with marginal donor hearts that otherwise would go unused. Expanded donor criteria include the use of donors substantially smaller than the recipients, donors with coronary artery disease that may require coronary artery bypass grafting (CABG), left ventricular dysfunction, or donors from older age groups.<sup>51</sup> Acceptable operative mortality has been reported, and the University of California, Los Angeles (UCLA) heart transplant group has shown that alternate listing did not independently predict early or late mortality.<sup>53</sup>

It also appears more beneficial in terms of patient survival to receive an allograft from a donor older than 40 years of age compared to remaining on the waiting list.<sup>54</sup> Other high-risk donors, such as HCV-positive or HBV (core IgM-negative)-positive donors, may be appropriate in selected higher-risk recipients.<sup>51</sup>

Also of special interest is the effect of donor alcohol and cocaine abuse on heart transplantation. A small single-center study showed unfavorable early outcome of patients receiving hearts from alcoholic donors (>2 oz of pure alcohol daily for 3 or more months), suggesting the presence of a subclinical preoperative alcoholic cardiomyopathy and poor tolerance of rejection episodes after transplantation.<sup>55</sup> Because of widespread cocaine abuse, donor guidelines have declared intravenous drug abuse a "relative" contraindication for donor selection. However, the dilemma of selecting donor hearts from nonintravenous drug abusers remains an open issue. A favorable outcome for patients who received transplanted hearts obtained from nonintravenous cocaine users has been reported.<sup>56</sup> However, judicious use of organs from donors

**TABLE 60-4: Donor Selection for Heart Transplantation**

- I. Suggested criteria for cardiac donor
  - A. Age <50-60
  - B. Absence of the following:
    1. Prolonged cardiac arrest
    2. Prolonged severe hypotension
    3. Preexisting cardiac disease
    4. Intracardiac drug injection
    5. Severe chest trauma with evidence of cardiac injury
    6. Septicemia
    7. Extracerebral malignancy and glioblastoma
    8. Positive serologies for human immunodeficiency virus, hepatitis B (active), or hepatitis C
    9. Hemodynamic stability without high-dose inotropic support (<20 µg/kg/min of dopamine)
- II. Suggested cardiac donor evaluation
  - A. Past medical history and physical examination
  - B. Electrocardiogram
  - C. Chest roentgenogram
  - D. Arterial blood gases
  - E. Laboratory tests (ABO, HIV, HBV, HCV)
  - F. Echocardiogram, pulmonary artery catheter evaluation, and in selected cases, coronary angiogram

with a history of cocaine use is strongly advised. Specific recommendations were made in a consensus report to improve the yield of donor hearts.<sup>51</sup>

## Management of the Cardiac Donor

Medical management of cardiac donors, an integral part of organ preservation, is complicated by the complex physiologic phenomenon of brain death and the need to coordinate procurement with other organ donor teams. Brain death is associated with an “autonomic and cytokine storm.” The release of noradrenaline (norepinephrine) leads to subendocardial ischemia. Subsequent cytokine release results in further myocardial depression. This is accompanied by pronounced vasodilatation and loss of temperature control.<sup>3</sup> Rapid afterload reduction may be achieved with sodium nitroprusside, whereas volatile anesthetics reduce the intensity of sympathetic bursts. The initial period of intense autonomic activity is followed by loss of sympathetic tone and a massive reduction in systemic vascular resistance. Overall, brain stem death results in severe hemodynamic instability, the degree of which appears to be directly related to the severity of the brain injury and may result from vasomotor autonomic dysfunction, hypovolemia, hypothermia, and dysrhythmias.<sup>57</sup>

Aggressive volume resuscitation sometimes is necessary, and the use of a Swan-Ganz catheter may be crucial to guide therapy.<sup>58</sup> Fluid overload should be avoided to prevent postoperative allograft dysfunction caused by chamber distention and myocardial edema. Inotropic support (eg, dopamine or dobutamine, epinephrine, or norepinephrine) to maintain a mean arterial blood pressure (MAP) of 60 mm Hg or more in the presence of a central venous pressure (CVP) of 6 to 10 mm Hg is recommended.<sup>51</sup> ATP is depleted rapidly by exogenous catecholamine administration, and this has an adverse effect on posttransplantation cardiac function.<sup>57</sup> Low-dose vasopressin is being used increasingly as first-line support because, in addition to treating diabetes insipidus, it independently improves arterial blood pressure and reduces exogenous inotrope requirements in brain stem dead donors.<sup>59</sup> Maintenance of normal temperature, electrolyte levels, osmolality, acid-base balance, and oxygenation is critical for optimal donor management. Central diabetes insipidus develops in more than 50% of donors because of pituitary dysfunction, and massive diuresis complicates fluid and electrolyte management.<sup>60</sup> The initial treatment of diabetes insipidus is aimed at correcting hypovolemia and returning the plasma sodium concentration to normal levels by fluid replacement with 5% dextrose or nasogastric water. In severe cases, intermittent treatment with the synthetic analogue 1-D-amino-8-D-arginine vasopressin (DDAVP) also may be required in addition to vasopressin infusion.<sup>57</sup>

Several studies have demonstrated beneficial effects of thyroid hormones and steroids on cardiac performance in brain stem dead-organ donors.<sup>52,59,61</sup> Recent guidelines advocate the addition of a standardized hormonal resuscitation package consisting of methylprednisolone (15 mg/kg bolus), triiodothyronine (4- $\mu$ g bolus followed by infusion of 3  $\mu$ g/h), and

arginine vasopressin (1-unit bolus followed by 0.5-4 units/h) to the standard donor management protocol.<sup>41</sup> Donors also receive insulin, titrated to keep blood glucose at 120 to 180 mg/dL. Other pertinent strategies include standard ventilator management with diligent endotracheal suctioning and a thermoregulation goal of 34 to 36°C using warming blankets and lights, warm intravenous fluids, and warm inspired air. Broad-spectrum antibiotic therapy with a cephalosporin is initiated following collection of blood, urine, and tracheal aspirate for culture. The approach for management of the cardiac donor recommended at the conference entitled, Maximizing Use of Organs Recovered from the Cadaver Donor: Cardiac Recommendations, is shown in Table 60-5 and summarized in Fig. 60-2.<sup>51</sup>

## Donor Heart Procurement

A median sternotomy is performed, and the pericardium is incised longitudinally. The heart is inspected and palpated for evidence of cardiac disease or injury. This visualization is communicated to the transplant team so the operation on the recipient can proceed timed with the expected arrival of the donor organ.

The superior and inferior venae cavae and the azygous vein are mobilized circumferentially and encircled with ties. The aorta is dissected from the pulmonary artery and isolated with umbilical tape. To facilitate access to the epigastrium by the liver procurement team, the cardiac team often then temporarily retires from the operating room table or assists with retraction. Once preparation for liver, pancreas, lung, and kidney explantation is completed, the patient is administered 30,000 units of heparin intravenously.

The azygous vein and superior vena cava (SVC) are doubly ligated (or stapled) and divided distal to the azygous vein, leaving a long segment of SVC (Fig. 60-3). The inferior vena cava (IVC) is incised and the left atrium vented either at the left atrial appendage or via a transected pulmonary vein. The aortic cross-clamp is applied at the takeoff of the innominate artery, and the heart is arrested with a single flush (1000 mL or 10-20 mL/kg) of cardioplegia solution infused proximal to the cross-clamp. Rapid cooling of the heart is achieved with copious amounts of cold saline and cold saline slush poured into the pericardial well.

After the delivery of cardioplegia, cardiectomy proceeds as the apex of the heart is elevated cephalad and any remaining intact pulmonary veins are divided.

This maneuver is modified appropriately to retain adequate left atrial cuffs for both lungs and the heart if the lungs also are being procured. While applying caudal traction to the heart with the nondominant hand, the ascending aorta is transected proximal to the innominate artery, and the pulmonary arteries are divided distal to the bifurcation (again, modification is necessary if the lungs are being procured).

More generous segments of the great vessels and SVC may be required for recipients with congenital heart disease. Alternatively, the SVC and IVC are transected, followed by the aorta and pulmonary artery. The left atrium is then divided

**TABLE 60-5: Management of the Cardiac Donor**

- I. Conventional management, before the initial echocardiogram
  - A. Adjust volume status (target central venous pressure 6-10 mm Hg)
  - B. Correct metabolic perturbations, including
    1. Acidosis (target pH 7.40-7.45)
    2. Hypoxemia (target PO<sub>2</sub> > 80 mm Hg, O<sub>2</sub> saturation > 95%)
    3. Hypercarbia (target PCO<sub>2</sub> 30-35 mm Hg)
  - C. Correct anemia (target hematocrit 30%, hemoglobin 10 g/dL)
  - D. Adjust inotropes to maintain mean arterial pressure at 60 mm Hg. Norepinephrine and epinephrine should be tapered off rapidly in favor of dopamine or dobutamine
  - E. Target = dopamine < 10 µg/kg/min or dobutamine < 10 µg/kg/min
- II. Obtain an initial echocardiogram
  - A. Rule out structural abnormalities (substantial left ventricular hypertrophy, that is, IVS/PW > 13 mm, valvular dysfunction, congenital lesions)
  - B. If left ventricular ejection fraction is 45%, proceed with recovery (consider aggressive management as shown below to optimize cardiac function before recovery) with final evaluation in the operating room
  - C. If left ventricular ejection fraction is <45%, aggressive management with placement of a pulmonary arterial catheter and hormonal resuscitation is strongly recommended
- III. Hormonal resuscitation
  - A. Triiodothyronine (T<sub>3</sub>): 4-µg bolus, then continuous infusion at 3 µg/h
  - B. Arginine vasopressin: 1-unit bolus, then continuous infusion at 0.5-4 units/h, titrated to a systemic vascular resistance of 800-1200 dyne/s/cm<sup>5</sup>
  - C. Methylprednisolone: 15 mg/kg bolus
  - D. Insulin: 1 unit/h minimum; titrate to maintain blood sugar at 120-180 mg/dL
- IV. Aggressive hemodynamic management
  - A. Initiated simultaneously with hormonal resuscitation
  - B. Placement of pulmonary artery catheter
  - C. Duration of therapy 2 hours
  - D. Adjustment of fluids, inotropes, and pressors every 15 minutes based on serial hemodynamic measurements to minimize use of beta-agonists and meet the following target (Papworth) criteria:
    1. Mean arterial pressure > 60 mm Hg
    2. Central venous pressure 4-12 mm Hg
    3. Pulmonary capillary wedge pressure 8-12 mm Hg
    4. Systemic vascular resistance 800-1200 dyne/s/cm<sup>5</sup>
    5. Cardiac index > 2.4 L/min/m<sup>2</sup>
    6. Dopamine < 10 µg/kg/min or dobutamine 10 µg/kg/min

Data from Zaroff JG, Rosengard BR, Armstrong WF, et al: Consensus conference report: maximizing use of organs recovered from the cadaver donor: cardiac recommendations, March 28-29, 2001, Crystal City, Va., *Circulation*. 2002 Aug 13;106(7):836-841.

as the last step. This allows for optimal division of the left atrium, particularly when lungs are recovered.

*It is critically important to avoid left ventricular distention and ensure thorough cooling with ice saline.*

Once the explantation is complete, the allograft is examined for evidence of a patent foramen ovale, which should be closed at that time. Any valvular anomalies are identified. The allograft then is placed in a sterile container and kept cold for transport to the recipient hospital.

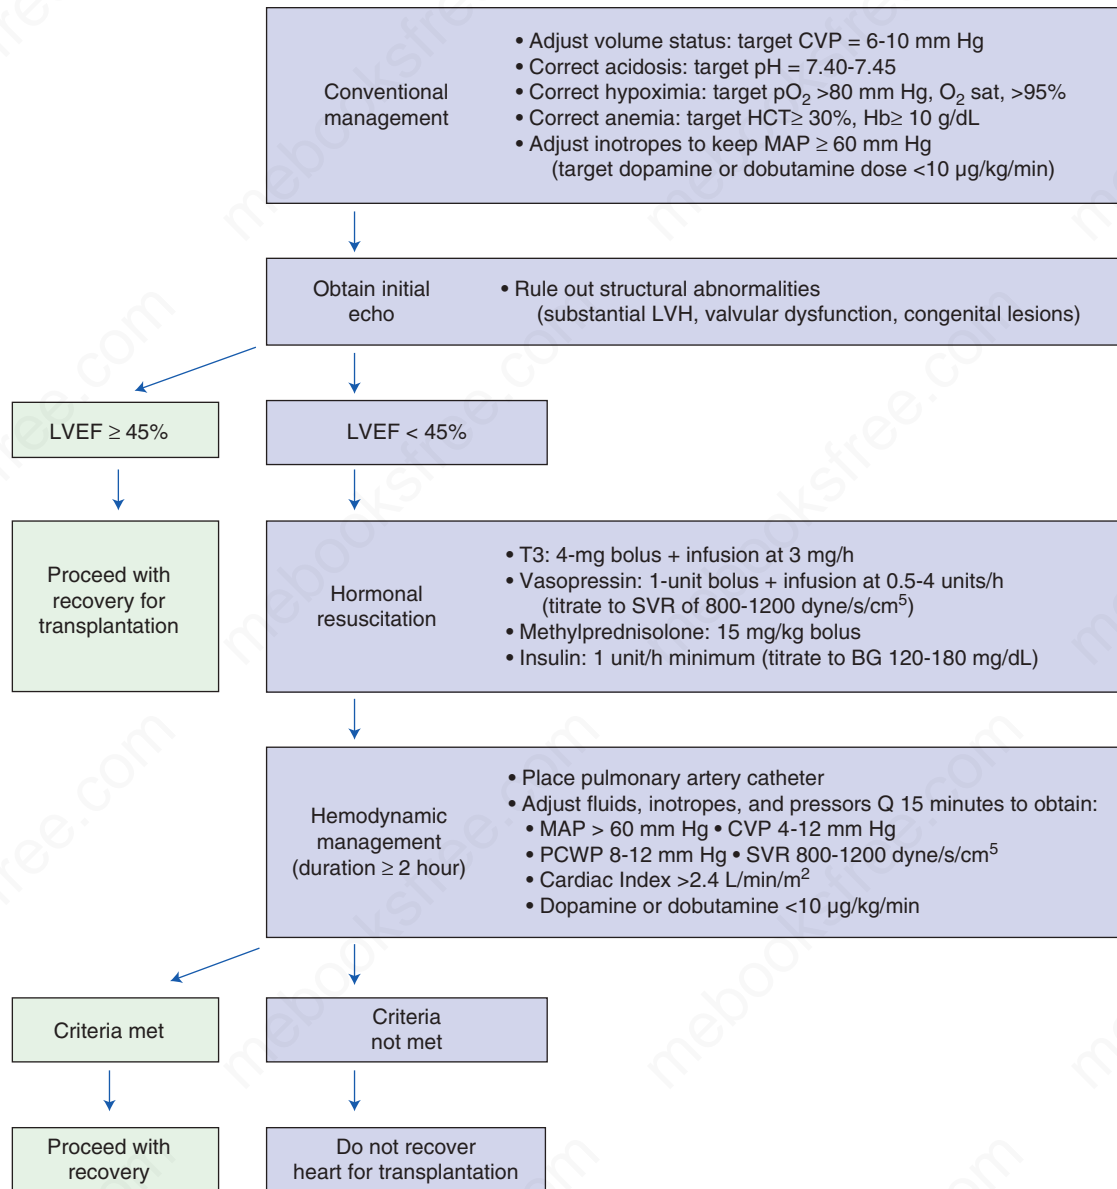

## Organ Preservation

Current clinical graft preservation techniques generally permit a safe ischemic period of 4 to 6 hours.<sup>62</sup> Factors contributing to the severity of postoperative myocardial dysfunction include insults associated with suboptimal donor management, hypothermia, ischemia-reperfusion injury, and depletion of energy stores.

A single flush of a cardioplegic or preservative solution followed by static hypothermic storage at 4 to 10°C is the preferred preservation method by most transplant centers. Crystalloid solutions of widely different compositions are available, and the debate over them speaks for the fact that no ideal solution currently exists. Depending on their ionic composition, solutions are classified as intracellular or extracellular.<sup>62</sup>

Intracellular solutions, characterized by moderate-to-high concentrations of potassium and low concentrations of sodium, purportedly reduce hypothermia-induced cellular edema by mimicking the intracellular milieu. Commonly used examples of these solutions include University of Wisconsin, Euro-Collins, and in Europe, Bretschneider (HTK) and intracellular Stanford solutions.

Extracellular solutions, characterized by low-to-moderate potassium and high sodium concentrations, avoid the theoretical potential for cellular damage and increased vascular resistance associated with hyperkalemic solutions. Hopkins,

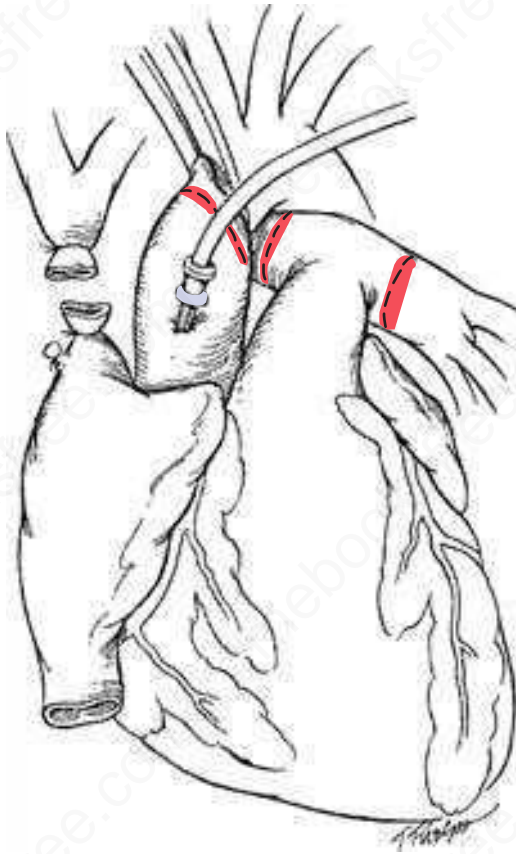

**FIGURE 60-2** Recommended heart donor management algorithm. (Reproduced with permission from Zaroff JG, Rosengard BR, Armstrong WF, et al: Consensus conference report: maximizing use of organs recovered from the cadaver donor: cardiac recommendations, March 28-29, 2001, Crystal City, Va., *Circulation*. 2002 Aug 13;106(7):836-841.)

Celsior, Krebs, and St. Thomas Hospital solutions are representative extracellular cardioplegic solutions. Several comparisons of the different types of intracellular and extracellular solutions have shown variable results.<sup>63,64</sup> Although a plethora of pharmacologic additives has been included in cardioplegic-storage solutions, the greatest potential for future routine use may lie with impermeants, substrates, and antioxidants.<sup>65</sup> A number of pharmacologic and mechanical strategies for leukocyte inhibition and depletion also have been explored.<sup>66</sup> Potential benefits of continuous hypothermic perfusion (CHP) preservation such as uniform myocardial cooling, continuous substrate supplementation, and metabolic by-product washout are currently overshadowed by exacerbation

of extracellular cardiac edema and logistical problems inherent to a complex perfusion apparatus. Newer portable perfusion circuits are being developed, and recent studies showed reduction in oxidative stress and attenuation of DNA damage in canine heart transplant models preserved by 24-hour CHP compared with 4 hours of static preservation.<sup>67</sup>

In a prospective, randomized, multi-center, international, non-inferiority trial led by the University of California, Los Angeles (UCLA), the investigators hypothesized that the clinical outcomes of patients undergoing heart transplantation with donor hearts preserved on Organ Care System (OCS) versus standard cold storage are similar. This study was designed to provide data that would allow in a follow-up

**FIGURE 60-3** Donor cardiectomy.

study to test if OCS can expand the donor heart pool (by testing/improving “non-standard/marginal” donor hearts). The OC is the only clinical platform (2014) for ex vivo human donor heart perfusion. It preserves the donor heart in a warm beating state during transport from the donor hospital to the recipient hospital. This study was conducted at 10 heart transplant centers in the United States and Europe. One hundred and twenty-eight patients were transplanted in the PROCEED II trial: 65 in the OCS group and 63 in the control group. With respect to the primary endpoint of 30-day patient and graft survival, the OCS group was found to be noninferior to the control group (OCS group: 94% [61/65] vs control group: 97% [61/63]). The results of secondary endpoints were similar for the two groups. Total preservation time was significantly longer in the OCS group versus control group, with a shorter cold ischemia time. Five donor hearts in the OCS group developed abnormal metabolic profile and were rejected for transplantation.<sup>68</sup> The clinical role of this system is yet to be determined. However, extended preservation times and better scheduling of a heart transplant are the real potential benefit of OCS preservation.

### Donor-Recipient Matching

Criteria for matching potential recipients with the appropriate donor are based primarily on ABO blood group

compatibility and patient size. ABO barriers should not be crossed in adult heart transplantation because incompatibility may result in fatal hyperacute rejection. Donor weight should be within 30% of recipient weight except in pediatric patients, in whom closer size matching is required. In cases of elevated PVR in the recipient (5-6 Wood units), a larger donor is preferred to reduce the risk of right ventricular failure in the early postoperative period. At UCLA we prefer a male donor for a male recipient when size and PH are an issue.

Although practices vary by transplant program, generally if the percent of PRA is greater than 10%, indicating recipient presensitization to alloantigen, a prospective negative T-cell cross-match between the recipient and donor sera is mandatory before transplantation.<sup>32,69</sup> A cross-match is always performed retrospectively, even if the PRA is absent or low. Retrospective studies also have demonstrated that better matching at the HLA-DR locus results in fewer episodes of rejection and infection with an overall improved survival.<sup>70</sup> Because of current allocation criteria and limits on ischemic time of the cardiac allograft, routine prospective HLA matching is not logistically possible.

## OPERATIVE TECHNIQUES IN HEART TRANSPLANTATION

### Orthotopic Heart Transplantation

#### OPERATIVE PREPARATION OF THE RECIPIENT

The original technique of orthotopic cardiac transplantation described by Shumway and Lower is still used commonly today. Following median sternotomy and vertical pericardiectomy, the patient is heparinized and prepared for cardiopulmonary bypass. Bicaval venous cannulation and distal ascending aortic cannulation just proximal to the origin of the innominate artery are optimal. Umbilical tape snares are passed around the superior and inferior venae cavae.

Bypass is initiated, the patient is cooled to 28°C, caval snares are tightened, and the ascending aorta is cross-clamped. The great vessels are transected above the semilunar commissures, whereas the atria are incised along the atrioventricular grooves, leaving cuffs for allograft implantation. Removal of the atrial appendages reduces the risk of postoperative thrombus formation.

Following cardiectomy, the proximal 1 to 2 cm of aorta and pulmonary artery are separated from one another with electrocautery, taking care to avoid injuring the right pulmonary artery. Continuous aspiration of pulmonary venous return from bronchial collaterals is achieved by insertion of a vent into the left atrial remnant either directly or via the right superior pulmonary vein.

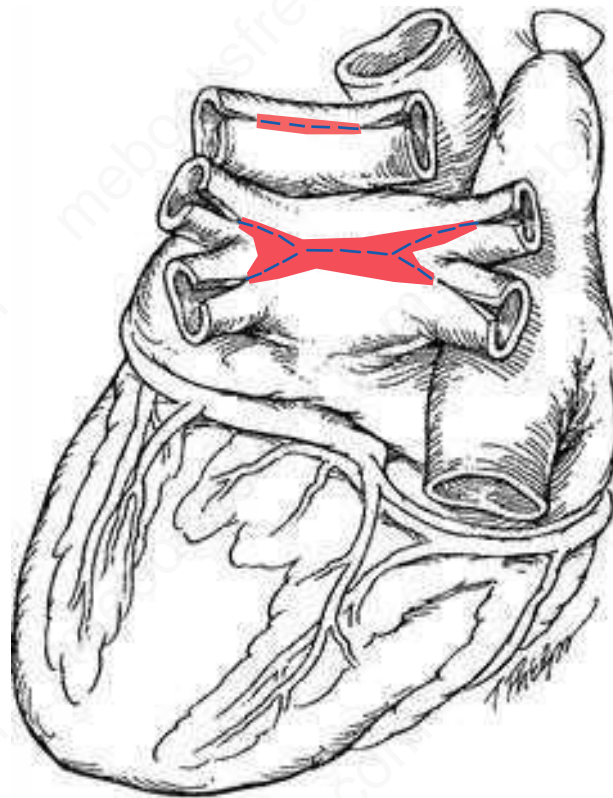

Timing of donor and recipient cardiectomies is critical to minimize allograft ischemic time and recipient bypass time. Frequent communication between the procurement and transplant teams permits optimal coordination of the procedures. Ideally, the recipient cardiectomy is completed just before arrival of the cardiac allograft.

No irrevocable surgical maneuvers should be performed before one is sure of the safe arrival of the donor organ. Redo sternotomy and removal of VADs or the TAH complicates this timing and should be carefully factored into the estimated donor organ ischemic time.

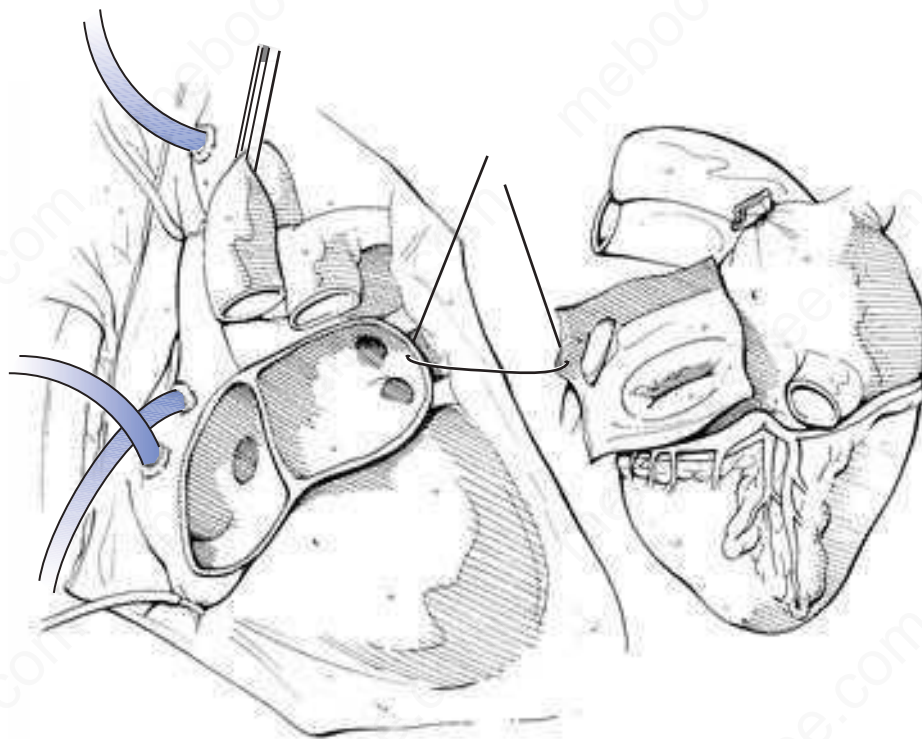

### IMPLANTATION

The donor heart is removed from the transport cooler and placed in a basin of cold saline. If not previously performed, preparation of the donor heart is accomplished. Electrocautery and sharp dissection are used to separate the aorta and the pulmonary artery. The left atrium is incised by connecting the pulmonary vein orifices, and excess atrial tissue is trimmed, forming a circular cuff tailored to the size of the recipient left atrial remnant (Fig. 60-4).

Implantation begins with placement of a double-armed 3-0 Prolene suture through the recipient left atrial cuff at the level of the left superior pulmonary vein and then through the donor left atrial cuff near the base of the atrial appendage (Fig. 60-5). The allograft is lowered into the recipient mediastinum atop a cold sponge to insulate it from direct thermal transfer from adjacent thoracic structures. An insulating pad is placed to protect the phrenic nerve. The suture is continued in a running fashion caudally and then medially to the inferior aspect of the interatrial septum (Fig. 60-6). The second arm of the suture is run along the roof of the left atrium and down the interatrial septum. It is important to continually assess size discrepancy between donor and recipient atria so that appropriate plication of excess tissue may be performed.

**FIGURE 60-4** Donor allograft preparation for orthotopic heart transplantation. Pulmonary vein orifices joined to form left atrial cuff.

**FIGURE 60-5** Implantation of allograft. First suture is placed at the level of the left superior pulmonary vein. (Reproduced with permission from Baumgartner WA, Kasper E, Reitz B, et al: *Heart and Lung Transplantation*. 2nd ed. New York: Saunders/Elsevier; 2002.)

**FIGURE 60-6** Implantation of allograft. Left atria anastomosis. (Reproduced with permission from Baumgartner WA, Kasper E, Reitz B, et al: *Heart and Lung Transplantation*. 2nd ed. New York: Saunders/Elsevier; 2002.)

The left atrium is continuously irrigated with cold saline while the RA, pulmonary artery and aortic anastomosis are completed with the LA vent off. Then the two arms of suture are tied together on the outside of the heart. Constant insufflation of carbon dioxide into the mediastinum to reduce the amount of intracardiac air should be standard.

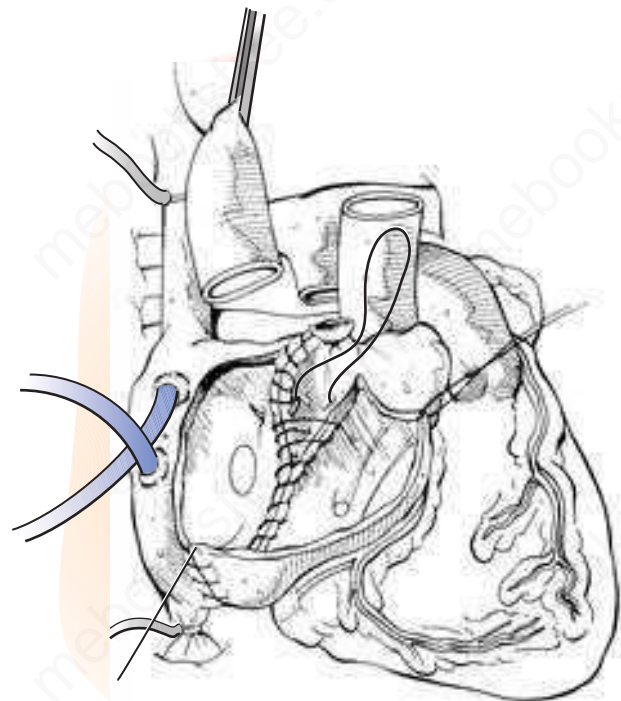

The traditional biatrial cuff technique starts with right atrial cuff anastomosis once the left atrial anastomosis is complete, a curvilinear incision is made from the inferior vena caval orifice toward the right atrial appendage of the allograft. This modification in the right atriotomy initially introduced by Barnard reduces the risk of injury to the sinoatrial (SA) node and accounts for the preservation of sinus rhythm observed in most recipients.

The tricuspid apparatus and interatrial septum are inspected. Recipients are predisposed to increased right-sided heart pressures in the early postoperative period owing to pre-existing PH and volume overload. The recovering right ventricle poorly tolerates both conditions.

To avoid refractory arterial desaturation associated with shunting, patent foramen ovale are closed. The right atrial anastomosis is performed in a running fashion similar to the left, with the initial anchor suture placed either at the most superior or inferior aspect of the interatrial septum so that the ends of the suture meet in the middle of the anterolateral wall (Fig. 60-7A,B).

A

B

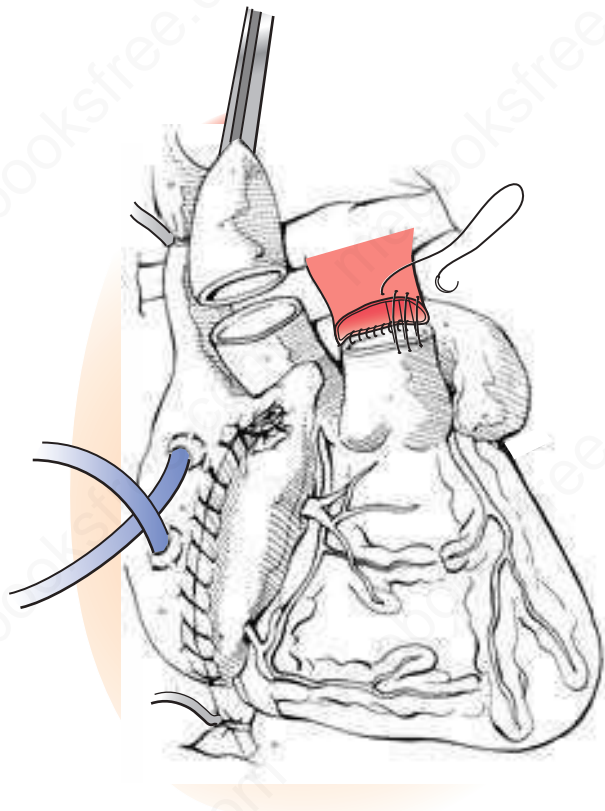

**FIGURE 60-7** Implantation of allograft. (A) Initiation of right atrial anastomosis. (B) Completion of right atrial anastomosis. (Reproduced with permission from Baumgartner WA, Kasper E, Reitz B, et al: *Heart and Lung Transplantation*. 2nd ed. New York: Saunders/Elsevier; 2002.)

The end-to-end pulmonary artery anastomosis is next performed using a 4 or 5-0 Prolene suture beginning with the posterior wall from inside of the vessel and then completing the anterior wall from the outside (Fig. 60-8). It is crucial that the pulmonary artery ends be trimmed to eliminate any redundancy in the vessel that might cause kinking.<sup>71</sup>

The aortic anastomosis is performed using a technique similar to that for the pulmonary artery, except that some redundancy is desirable in the aorta because it facilitates visualization of the posterior suture line if there is bleeding (Fig. 60-9).

Like and many other centers we now prefer direct end-to-end IVC and SVC anastomoses. This technique minimizes the risk of tricuspid regurgitation or SA node injury. Care to prevent twisting or narrowing of the cava is essential. Using this technique we perform the left atrial cuff, followed by the PA, aorta and then the IVC and SVC anastomoses.

Rewarming usually is begun after the aortic anastomosis, which is performed in a standard end-to-end fashion. Routine deairing techniques are then employed. Lidocaine (100-200 mg intravenously) and methylprednisone (500-1000 mg) are administered after the atrial anastomosis. Pressure-controlled (<50 mm Hg), leucocyte-depleted,

**FIGURE 60-8** Implantation of allograft. Pulmonary arterial anastomosis. (Reproduced with permission from Baumgartner WA, Kasper E, Reitz B, et al: *Heart and Lung Transplantation*. 2nd ed. New York: Saunders/Elsevier; 2002.)

**FIGURE 60-9** Implantation of allograft. Aortic anastomosis. (Reproduced with permission from Baumgartner WA, Kasper E, Reitz B, et al: *Heart and Lung Transplantation*. 2nd ed. New York: Saunders/Elsevier; 2002.)

substrate-enhanced aspartate and glutamate warm reperfusion is given for 3 minutes followed by warm leucocyte depleted blood for 7 minutes prior to releasing the aortic cross-clamp.

The aortic cross-clamp is removed. Half of patients require electrical defibrillation. A needle vent is inserted in the ascending aorta and maintained on suction for final deairing, with the patient in steep Trendelenburg position.

Suture lines are inspected carefully for hemostasis. Inotrope infusion is initiated, and temporary pacing may be required. The patient is weaned from cardiopulmonary bypass, and the cannulae are removed. Temporary epicardial atrial and ventricular bipolar pacing wires are placed in the donor right atrium and ventricle. Following insertion of mediastinal and pleural tubes, the median sternotomy is closed in the standard fashion.

Cold-blood cardioplegia is used in many centers. An initial dose often is given following removal from the cold storage solution before implantation. A second dose, or the initial dose as given by some centers, is administered after the right atrial anastomosis or IVC anastomosis, when a bicaval technique is used.

We generally do not redose cardioplegia after the heart is removed from cold storage. However, prior to releasing the cross-clamp a warm substrate enhanced (aspartate and glutamate) reperfusion solution is administered for 4 minutes with a mean pressure of 45 to 50 mm Hg. An additional leucocyte-depleted warm blood, pressure-controlled reperfusate, is given for an additional 5 to 7 minutes.

## ALTERNATIVE TECHNIQUES FOR ORTHOTOPIC HEART TRANSPLANTATION

The most commonly employed technique today is a bicaval anastomotic method. With this technique, the recipient right atrium is excised completely, leaving a left atrial cuff and a generous cuff of the IVC and SVC, respectively.

The left atrial cuff of the donor is anastomosed to the left atrial cuff of the recipient using the standard Shumway technique. The PA and aortic anastomosis are performed. Individual end-to-end anastomoses of the IVC and SVC are performed (Fig. 60-10).

Although these procedures are more technically difficult than standard orthotopic transplantation, published series using these techniques have reported shorter hospital stays, reduced postoperative dependence on diuretics, and lower incidences of atrial dysrhythmias, conduction disturbances, mitral and tricuspid valve incompetence, and right ventricular failure.<sup>72</sup> A single-center study comparing biatrial versus bicaval transplant showed an improved 12-month survival in the bicaval group.<sup>73</sup> However, an analysis of the UNOS database, including more than 11,000 patients, did not demonstrate a survival difference between patients in whom biatrial versus bicaval anastomotic techniques were used, although the bicaval technique was associated with decreased duration of hospital stay and postoperative pacemaker placement.<sup>74</sup>

**FIGURE 60-10** Bicaval heart transplantation.

Long-term outcomes and prospective, randomized studies evaluating these alternative techniques are still needed.

## Heterotopic Heart Transplantation

PH and right-sided heart failure have remained the leading causes of early mortality in cardiac transplantation. This has led to an interest in heterotopic heart transplantation. Currently, heterotopic heart transplants are performed rarely but may be indicated in patients with irreversible PH or significant donor-recipient size mismatch.<sup>22</sup>

## Heart Transplantation after VAD

Cardiac transplantation after VAD or TAH poses unique challenges. All patients should have a recent contrast chest computed tomography (CT) to identify location of cardiac structures to the sternum and the course of outflow grafts.

The femoral or axillary artery and femoral vein should be exposed for emergency cannulation before redo sternotomy. Sternal reentry should carefully dissect the heart from pleura to pleura to safely place a retractor. The initial focus is on dissection of the IVC, SVC, and aorta. Further dissection is ideal, but may require cardiopulmonary bypass. The apex and left atrium should not be manipulated before bypass as there is a risk of entraining air, particularly with axial-flow devices. Finally, before initiating bypass, the outflow graft should be clamped to prevent regurgitation through the device.

The sternotomy and lysis of adhesions can be difficult and time consuming. Timing of the dissection and the arrival of the donor heart is individualized based upon not taking any irreversible steps prior to arrival of the heart and not prolonging donor heart ischemic time for cardiectomy and device removal.

## POSTOPERATIVE MANAGEMENT

### Hemodynamic Management

#### HEART ALLOGRAFT PHYSIOLOGY

The intact heart is innervated by antagonistic sympathetic and parasympathetic fibers of the autonomic nervous system. Transplantation necessitates transection of these fibers, yielding a denervated heart with altered physiology. Devoid of autonomic input, the SA node of the transplanted allograft fires at its increased intrinsic resting rate of 90 to 110 beats per minute.<sup>75</sup> The allograft relies on distant noncardiac sites as its source for catecholamines; thus its response to stress (eg, hypovolemia, hypoxia, and anemia) is somewhat delayed until circulating catecholamines can exert their positive chronotropic effect on the heart. The absence of a normal reflex tachycardia in response to venous pooling accounts for the frequency of orthostatic hypotension in transplant patients.

Denervation alters the heart's response to therapeutic interventions that act directly through the cardiac autonomic nervous system.<sup>75</sup> Carotid sinus massage, Valsalva maneuver, and atropine have no effect on SA node firing or

atrioventricular conduction. Because of depletion of myocardial catecholamine stores associated with prolonged inotropic support of the donor, the allograft often requires high doses of catecholamines. The inotropic support is often necessary for several days. In patients with pre transplant VADs the vasoplegia requires support particularly in patients who have had axial flow pumps.

### ROUTINE HEMODYNAMIC MANAGEMENT

Donor myocardial performance is transiently depressed in the immediate postoperative period. Allograft injury associated with donor hemodynamic instability and the hypothermic, ischemic insult of preservation contribute to reduced ventricular compliance and contractility characteristics of the newly transplanted heart.<sup>76</sup>

Abnormal atrial dynamics owing to the midatrial anastomosis exacerbate the reduction in ventricular diastolic loading. An infusion of a variety of drugs such as epinephrine, norepinephrine, dobutamine and milrinone is initiated routinely in the operating room to provide temporary inotropic support.

Cardiac denervation brings in several consequences, which may include a chronotropic and inotropic supersensitivity to exogenous catecholamines.<sup>77</sup> Restoration of normal myocardial function usually permits the cautious weaning of inotropic support within 5 to 7 days.

Vasoplegia often requires vasopressin, norepinephrine, or neosynephrine.

RV dysfunction can be improved with inhaled nitric oxide.

### EARLY ALLOGRAFT FAILURE

Early cardiac failure still accounts for up to 20% of perioperative deaths of heart transplant recipients.<sup>78</sup> The cause of primary graft failure may be multifactorial. The most important etiologies are myocardial dysfunction owing to donor instability, PH, ischemic injury during preservation, and occasionally acute rejection. Mechanical support with an IABP, VAD, or ECMO can be used in patients refractory to pharmacologic interventions, although this measure, as well as retransplantation, has historically been associated with increased mortality.<sup>79,80</sup>

Chronic right ventricular failure frequently is associated with elevated PVR, and the unprepared donor right ventricle may be unable to overcome this increased afterload. Although recipients are screened to ensure that those with irreversible PH are not considered for transplantation, right-sided heart failure remains a leading cause of early mortality. Initial management involves employing pulmonary vasodilators such as inhaled nitric oxide, nitroglycerin, or sodium nitropruside. PH that is refractory to these vasodilators sometimes responds to PGE<sub>1</sub> or prostacyclin.<sup>14,81</sup> Intra-aortic balloon counterpulsation and right VADs (Centromag) also can be used in patients unresponsive to medical therapy.<sup>82</sup>

ECMO support for several days with an open chest has been successful to allow time for graft recovery in cases of inadequate biventricular function.

### ARRHYTHMIAS

Denervation of the transplanted heart leads to loss of autonomic nervous system modulation of the heart's electrophysiologic properties. Parasympathetic denervation causes loss of basal suppression of SA node automaticity, leading to a persistent increase in resting heart rate and a loss of normal, rapid heart rate modulation. This parasympathetic loss also causes elimination of the chronotropic effects of digoxin and atropine after heart transplantation. At the same time, sympathetic denervation causes a decrease and delay in exercise- or stress-induced augmentation of SA node automaticity, resulting in a decreased maximum heart rate with exercise.<sup>83</sup>

Sinus or junctional bradycardia occurs in up to half of transplant recipients. Risk factors for sinus node dysfunction include prolonged organ ischemia, angiographic nodal artery abnormalities, biatrial versus bicaval anastomosis, preoperative amiodarone use, and rejection.<sup>84</sup> Adequate heart rate is achieved with inotropic drug infusions and/or temporary epicardial pacing. Most bradyarrhythmias resolve over 1 to 2 weeks. Theophylline has been effective in patients with bradyarrhythmias and has decreased the need for permanent pacemakers in this patient population.<sup>85</sup>

Atrial fibrillation, atrial flutter, and other supraventricular arrhythmias have been reported in 5 to 30% of patients after heart transplantation.<sup>83</sup> Individual assessment of the risk: benefit ratio for anticoagulation therapy is necessary. Supraventricular tachycardia in transplant patients should be treated in the same manner as in nontransplant patients but with lower doses. Recurrent arrhythmias from reentry circuits or defined ectopic foci often can be cured by radiofrequency ablation.

Premature ventricular complexes are generally not considered ominous. Because of their rapidly terminal nature, sustained VT and ventricular fibrillation presumably are responsible for a significant portion of the 10% of sudden and unexplained deaths in heart transplant patients.<sup>86</sup>

Unique aspects of common antiarrhythmic drugs reflecting the differences in their therapeutic effects in heart transplant recipients compared with nontransplant patients are shown in Table 60-6.<sup>83</sup> Persistence of any form of arrhythmia should warrant further investigative efforts and an aggressive search for the presence of indicators of cardiac ischemia, rejection, pulmonary pathology, or infection. If arrhythmic episodes are frequent or underlying cardiac pathology is severe, retransplantation may be considered.

### SYSTEMIC HYPERTENSION

Systemic hypertension should be treated to prevent unnecessary afterload stress on the allograft. In the early postoperative period, intravenous sodium nitropruside or nitroglycerin usually is administered. Nitroglycerin is associated with less pulmonary shunting because of a relative preservation of the pulmonary hypoxic vasoconstrictor reflex. Nicardipine infusion has been reported to control postoperative hypertension more rapidly and was superior to sodium nitropruside in maintaining left ventricular performance immediately after

**TABLE 60-6: Differences in Therapeutic Agent Effects in Heart Transplant Recipients Compared with Nontransplant Patients**

Arrhythmia therapy	Differences in posttransplantation
<b>Drugs</b>	
AV nodal agents	
Digoxin	No effect on heart rate
$\beta$ -Adrenergic antagonists	Exacerbation of exercise intolerance
Calcium channel antagonists	Accentuated slowing of SA and AV nodes; may alter cyclosporine levels
Adenosine	Accentuated slowing of SA and AV nodes
Adrenergic agonists	
Norepinephrine	Unchanged peripheral effect, slightly more inotropic and chronotropic effect
Epinephrine	Unchanged peripheral effect, slightly more inotropic and chronotropic effect
Dopamine	Unchanged peripheral effect, less inotropic effect
Dobutamine	Unchanged
Ephedrine	Unchanged peripheral effect, less inotropic effect
Neo-synephrine	Unchanged peripheral effect, no reflex bradycardia
Isoproterenol	Unchanged
Antiarrhythmic agents	
Class Ia (quinidine, disopyramide, procainamide)	No cardiac vagolytic effect
Class Ib (lidocaine, mexiletine)	None reported
Class Ic (flecainide, encainide, moricizine, propafenone)	None reported
Class III (amiodarone, sotalol, ibutilide, dofetilide)	Possible exaggerated or atypical response
Anticoagulants	
Heparin	None reported
Warfarin	None reported
Miscellaneous	
Atropine	No effect on heart rate
Methylxanthines (theophylline, aminophylline)	Possibly more chronotropic effect
<b>Cardioversion</b>	None reported
<b>Radiofrequency catheter ablation</b>	Possible differences in pathway or chamber anatomy
<b>Electrical devices</b>	
Pacemaker	None reported
Intracardiac defibrillator	None reported

drug infusion.<sup>87</sup> If hypertension persists, an oral antihypertensive can be added, if possible, to permit weaning of the parenteral agents.

## Respiratory Management

The respiratory management of the cardiac transplant recipient uses the same protocols employed following routine cardiac surgery.

## Renal Function

Preoperative renal insufficiency owing to chronic heart failure and the nephrotoxic effects of calcineurin inhibitors such as FK506 and cyclosporine place the recipient at increased risk of renal insufficiency. Acute calcineurin inhibitor-induced renal insufficiency usually will resolve with a reduction in dose. Continuous intravenous infusion to eliminate the wide fluctuations in levels associated with oral dosing can

be attempted. Furthermore, concurrent administration of mannitol with calcineurin inhibitors may reduce their nephrotoxicity. Most centers administer a cytolytic agent in the immediate postoperative period and delay the initiation of calcineurin inhibitor therapy.

## Outpatient Follow-up

Before discharge, patients should receive comprehensive education about their medications, diet, exercise, and infection recognition. Close follow-up by an experienced transplant team is the cornerstone for successful long-term survival after cardiac transplantation. This comprehensive team facilitates the early detection of rejection, opportunistic infections, patient non-compliance, and adverse sequelae of immunosuppression. Clinic visits routinely are scheduled concurrently with endomyocardial biopsies and include physical examination, a variety of laboratory studies, chest roentgenogram, and electrocardiogram.

## ACUTE REJECTION

### Allo-Immunology

Cardiac allograft rejection is the normal host response to cells recognized as nonself. The vast majority of cases are mediated by the cellular limb of the immune response through an elegant cascade of events involving macrophages, cytokines, and T lymphocytes. Antibody-mediated rejection (AMR), also called *humoral rejection* or *vascular rejection*, seems less common but is also more challenging to diagnose. The highest risk factors are allografts from younger and female donors (irrespective of recipient sex). Although about 85% of episodes can be reversed with corticosteroid therapy alone,<sup>88</sup> rejection is still a major cause of morbidity in cardiac transplant recipients.<sup>5,89</sup> Therefore, key research priorities in heart transplantation over the next decade include individualized immunosuppressive therapy and investigation and management of long-term immune and nonimmune complications.<sup>90</sup>

### Hyperacute Rejection

Hyperacute rejection results from preformed donor-specific antibodies in the recipient. ABO blood group and PRA screening have made this condition a rare complication.

The onset of hyperacute rejection occurs within minutes to several hours after transplantation, and the results are catastrophic. Gross inspection reveals a mottled or dark red, flaccid allograft, and histologic examination confirms the characteristic global interstitial hemorrhage and edema without lymphocytic infiltrate. Immunofluorescence techniques reveal deposits of immunoglobulins and complement on the vascular endothelium. Immediate plasmapheresis, IVIG, and mechanical support are immediately instituted, and retransplantation may be the only successful strategy.

### Diagnosis of Acute Rejection

In the precyclosporine era, the classic clinical manifestations of acute rejection included low-grade fever, malaise, leukocytosis, pericardial friction rub, supraventricular arrhythmias, decreased voltage on ECG, low cardiac output, reduced exercise tolerance, and signs of congestive heart failure.

In the cyclosporine era, however, most episodes of rejection characteristically are insidious, and patients can remain asymptomatic even with late stages of rejection. Thus routine surveillance studies for early detection are crucial to minimize cumulative injury to the allograft.

Right ventricular endomyocardial biopsy remains the gold standard for the diagnosis of acute rejection. The most frequently used technique for orthotopic allografts is a percutaneous approach through the right internal jugular vein. Interventricular septal specimens are fixed in formalin for permanent section, although frozen sections are performed occasionally if urgent diagnosis is necessary.

Hemodynamic parameters may also be obtained with a pulmonary artery catheter. Complications are infrequent (1 to 2%) but include venous hematoma, carotid puncture,

pneumothorax, arrhythmias, heart block, and right ventricular perforation and injury to the tricuspid valve.

The exact schedule for endomyocardial biopsies varies among institutions but usually reflects the associated risk of increased rejection during the first 6 months after transplantation. Biopsies are performed initially every 7 to 10 days in the early postoperative period and eventually tapered to 3- to 6-month intervals after the first year. Suspicion of rejection warrants additional biopsies.

Evaluation of sample adequacy for the ISHLT grading scheme requires a minimum of four good endomyocardial tissue fragments, with less than 50% of each fragment being fibrous tissue, thrombus, or other noninterpretable tissues (eg, crush artifact or poorly processed fragments).<sup>91</sup> The pattern and density of lymphocyte infiltration, in addition to the presence or absence of myocyte necrosis in the endomyocardial biopsy, determine the severity grade of cellular rejection.<sup>92</sup>

Further elaboration of the pathologic features and identification of AMR have been addressed.<sup>93</sup> In 2004, the ISHLT Pathology Council proposed simplification of the 1990 diagnostic categories for cellular rejection to mild, moderate, and severe and identification of the histologic characteristics of AMR.<sup>94</sup> The new grading scale was developed to better address the challenges and inconsistencies in use of the old grading system. Tables 60-7 and 60-8 show the new 2004 ISHLT grading scale.<sup>94</sup>

Noninvasive studies for the diagnosis of acute rejection have been unreliable. Electrocardiographic voltage summation and E-rosette assay techniques were useful adjuncts in the early cardiac transplant experience<sup>95</sup>; however, they currently are of no value in patients receiving cyclosporine.<sup>96</sup> Attempts with signal-averaged electrocardiography,<sup>97</sup> echocardiography,<sup>98</sup> or in combination,<sup>99</sup> MRI,<sup>100</sup> technetium ventriculography,<sup>101</sup> and a variety of immunologic markers<sup>102</sup> have not provided sufficient sensitivity and specificity to warrant widespread use.<sup>103</sup>

**TABLE 60-7: ISHLT Standardized Cardiac Biopsy Grading: Acute Cellular Rejection, 2004\***

Grade 0 R <sup>†</sup>	No rejection
Grade 1 R (Mild)	Interstitial and/or perivascular infiltrate with up to 1 focus of myocyte damage
Grade 2 R	(Moderate) Two or more foci of infiltrate with associated myocyte damage
Grade 3 R	(Severe) Diffuse infiltrate with multifocal myocyte damage ± edema, ± hemorrhage ± vasculitis

\*The presence or absence of acute antibody-mediated rejection (AMR) may be recorded as AMR 0 or AMR 1, as required (see Table 64-8).

Peripheral blood gene expression profiling is an exciting new field.<sup>104</sup> The Allomap test has been FDA-cleared and widely implemented since 2006 to help rule out acute cardiac allograft rejection in stable heart transplant recipients and has led to a reduction in the use of protocol endomyocardial biopsy.<sup>105-108</sup>

## Prophylaxis and Treatment of Acute Rejection

Baseline immunosuppression has evolved considerably over the last four decades. Current trends suggest lower use of cyclosporine A compared with tacrolimus-based calcineurin inhibition. MMF has largely replaced imuram and remains the most commonly used adjunctive agent. Several centers are attempting to achieve a steroid-free dual immunosuppression regimen.<sup>109</sup>

Corticosteroids are the cornerstone for antirejection therapy. The treatment of choice for any rejection episode occurring during the first 1 to 3 postoperative months or for an episode considered to be severe is a short course (3 days) of intravenous methylprednisolone (1000 mg/day). Virtually all other episodes are treated initially with increased doses of oral prednisone (100 mg/day) followed by a taper to baseline over several weeks.<sup>110</sup> Although not yet universally accepted, many centers have reduced the doses of these corticosteroids successfully with reversal rates of rejection similar to traditional dosing.

Repeat endomyocardial biopsy should be performed 7 to 10 days after the cessation of antirejection therapy to assess adequacy of treatment. If the biopsy does not show significant improvement, a second trial of pulse-steroid therapy is recommended; if rejection has progressed (or if the patient becomes hemodynamically unstable), rescue therapy is indicated.

Substitution of tacrolimus for cyclosporine may obviate the need for admission in patients with steroid-refractory persistent rejection.<sup>111</sup> Alternatively, sirolimus may be substituted for mycophenolate or azathioprine.<sup>112</sup> The use of OKT3, antithymocyte globulin, and thymoglobulin generally is reserved for severe rejection with hemodynamic

compromise.<sup>113</sup> Methotrexate has been particularly successful in eradicating chronic low-grade rejection. Total lymphoid irradiation and photopheresis also have demonstrated success in some cases of refractory rejection.<sup>114</sup> Cardiac retransplantation is the ultimate therapeutic option for patients who do not respond to the aforementioned interventions. However, the results of retransplantation for rejection are dismal, and in most centers, it is no longer performed for this indication. Severe rejection with cardiogenic shock requires ECMO support during aggressive drug therapy.

Asymptomatic mild rejection (grade 1) usually is not treated but is monitored with repeat endomyocardial biopsies because only 20 to 40% of mild cases progress to moderate rejection.<sup>115</sup> On the other hand, the presence of myocyte necrosis (grades 3b and 4) represents a definite threat to allograft viability and is a universally accepted indication for therapy. Management of moderate rejection (grade 3a) is controversial and requires consideration of multiple variables.<sup>116</sup> Notably, Stoica and colleagues demonstrated that acute moderate-to-severe cellular rejection has a cumulative impact on cardiac allograft vasculopathy (CAV) onset.<sup>117</sup> Regardless of the biopsy results, allograft dysfunction is an indication for hospitalization, antirejection therapy, and if severe, invasive hemodynamic monitoring and inotropic support.

## Antibody-Mediated Rejection

AMR, previously termed vascular rejection and humoral rejection, is mediated by the humoral limb of the immune response. Unlike acute cellular rejection, hemodynamic instability requiring inotropic support is common in patients with vascular rejection.<sup>117</sup> The incidence of asymptomatic AMR is higher in the first year after heart transplantation with a high recurrence rate. The more severe AMR, the lower the chances of improvement.<sup>118</sup>

Diagnosis requires evidence of endothelial cell swelling on light microscopy and immunoglobulin-complement deposition by immunofluorescence techniques.<sup>119</sup> Aggressive treatment of patients with allograft dysfunction consists of plasmapheresis, high-dose corticosteroids, heparin, IgG, and cyclophosphamide.<sup>120</sup> Despite these interventions, symptomatic acute vascular rejection is associated with a high mortality.<sup>120,121</sup> Repeated episodes of acute vascular rejection or chronic low-grade vascular rejection are believed to play a dominant role in the development of allograft coronary artery disease.<sup>122</sup>

## INFECTIOUS COMPLICATIONS IN HEART TRANSPLANTATION

### Organisms and Timing of Infections

Infection is a leading cause of morbidity and mortality in the cardiac transplant population.<sup>5,123</sup> The introduction of new chemoprophylactic regimens with the resultant prevention of serious disease caused by CMV has resulted in significant reductions in the number of infectious episodes and a delay in presentation after heart transplantation.<sup>123</sup> Patients are at greatest risk of life-threatening infections in the first 3 months

**TABLE 60-9: Preliminary Nomenclature Scheme advised by ISHLT Antibody-Mediated Rejection Consensus Conference 2011**

Grade pAMR 0	Negative for pathologic AMR: both histologic and immunopathologic studies are negative
pAMR 1 (H+)	pAMR 1 (H+): Histopathologic AMR alone: histological findings present and immunopathological findings negative
pAMR1 (I+)	Immunopathologic AMR alone: histological findings negative and immunopathological findings positive
pAMR 2	Pathologic AMR: Both histologic and immunopathologic findings are present
pAMR 3	Severe pathologic AMR: This category recognizes the rare cases of severe AMR with histopathologic findings of interstitial hemorrhage, capillary fragmentation, mixed inflammatory infiltrates, endothelial cell pyknosis and/or karyorrhexis and marked edema. The reported experience of the group was that these cases are associated with profound allograft dysfunction and poor clinical outcomes

Data from Berry GJ, Angelini A, Burke MM, et al: the ISHLT working formulation for pathologic diagnosis of antibody-mediated rejection in heart transplantation: evolution and current status (2005-2011), *J Heart Lung Transplant*. 2011 Jun;30(6):601-611.

after transplantation and following increases in immunosuppression for acute rejection episodes or retransplantation.<sup>123</sup> Table 60-10 illustrates the most common organisms causing infections in the cardiac recipient.

## Preventive Measures and Prophylaxis Against Infection

Transmission of infections such as CMV, *Toxoplasma gondii*, HBV, HCV, and HIV after organ transplantation is well documented.<sup>124</sup> Prevention of postoperative infection begins with pretransplant screening of the donor and recipient.<sup>125</sup> Current suggested guidelines are outlined in Table 60-11. Perioperative and postoperative antimicrobial prophylaxes, as well as immunizations, are also outlined.

## Specific Organisms Causing Infection Following Heart Transplantation

### BACTERIA

Gram-negative bacilli are the most common cause of bacterial infectious complications following heart transplantation. Furthermore, *Escherichia coli* and *Pseudomonas aeruginosa* are the most prevalent organisms and usually cause urinary tract infections and pneumonias, respectively.<sup>123</sup> *Staphylococcus* species have been shown to cause the majority of Gram-positive-related infections.

### VIRUSES

CMV remains the single most important cause of infectious disease morbidity and mortality in the heart transplant patient.<sup>126</sup> CMV not only results in infectious disease syndromes but also is indirectly associated with acute rejection episodes, acceleration of CAV, and posttransplant lymphoproliferative disease.<sup>126</sup> Furthermore, the reduction in leukocytes associated with CMV infection predisposes the patient to super-infection with

other pathogens (eg, *Pneumocystis carinii* pneumonia). Infections develop secondary to donor transmission, reactivation of latent recipient infection, or reinfection of a CMV-seropositive patient with a different viral strain.<sup>126</sup> Variable regimens for CMV prophylaxis with ganciclovir are being used by different centers.<sup>127</sup> The standard of care for symptomatic CMV disease is 2 to 3 weeks of intravenous ganciclovir (at a dose of 5 mg/kg twice daily, with dosage adjustment for renal dysfunction). For tissue-invasive disease, particularly pneumonia, many centers add anti-CMV hyperimmune globulin to this regimen.<sup>128</sup> Preemptive treatment strategies employ periodic surveillance using techniques such as plasma polymerase chain reaction (PCR) and CMV antigenemia, a rapid diagnostic test that detects viral protein in peripheral blood leukocytes at a significant interval before clinical disease.<sup>129</sup> Valganciclovir (Valcyte) is an oral prodrug of ganciclovir with a 10-fold greater bioavailability than oral ganciclovir. It has been shown to be effective for prophylaxis and preemptive treatment of CMV and allows for more convenient use.<sup>130,131</sup>

Although not a cure for herpes simplex or zoster viruses, acyclovir can reduce recurrences and the discomfort associated with the vesicular lesions. Epstein-Barr virus (EBV) infection may be associated with posttransplant lymphoproliferative disorders in immunocompromised hosts.<sup>132</sup>

### FUNGI

Mucocutaneous candidiasis is common and usually can be treated with topical antifungal agents (nystatin or clotrimazole). Fluconazole is indicated for candidiasis refractory to this therapy or involving the esophagus. It is also useful for therapy of candidemia. One important caveat in the treatment of *Candida* infection with fluconazole is that certain species such as *Candida krusei* and *Candida glabrata* have a low susceptibility in vitro.<sup>123</sup>

Among patients undergoing heart transplantation, *Aspergillus* is the opportunistic pathogen with the highest

**TABLE 60-10: Infections in Cardiac Transplant Recipients**

**Early infections (first month)**

    - Varicella-zoster
  - B. Nodular or ulcerating lesions
    - Nocardia*
    - Candida* (disseminated)
    - Atypical *Mycobacterium* spp.
    - Cryptococcus*

\*Known donor-transmitted pathogens.

attributable mortality.<sup>132</sup> It causes a serious pneumonia in 5 to 10% of recipients during the first 3 months after transplantation. Dissemination of *Aspergillus* to the central nervous system is almost uniformly fatal.<sup>134</sup> Because aspergillosis is highly lethal in the immunocompromised host, even in the face of therapy, workup must be prompt and aggressive, and therapy may need to be initiated on suspicion of the diagnosis without definitive proof. Amphotericin B, itraconazole, and recently voriconazole are acceptable therapy.

**PROTOZOA**

In heart transplant recipients, the reported incidence of *P. carinii* pneumonia ranges from less than 1 to 10%.<sup>135</sup> Because the organism resides in the alveoli, bronchoalveolar lavage usually is necessary for diagnosis.<sup>136</sup> In the case of lung biopsy specimens, histopathologic examination is also helpful. *P. carinii* pneumonia is treated with high-dose trimethoprim-sulfamethoxazole or intravenous pentamidine.<sup>123</sup>

**TABLE 60-11: Guidelines for Routine Screening and Prophylaxis of Infections in Heart Transplantation**

- I. Preoperative screening
  - A. Donor
    1. Clinical assessment
    2. Serologic studies (HIV, HBV, HCV, CMV, *Toxoplasma gondii*)
  - B. Recipient
    1. History and physical examination
    2. Serologic studies (HIV, HBV, HCV, CMV, *T. gondii*, herpes simplex virus, varicella-zoster virus, Epstein-Barr virus, endemic fungi)
    3. PPD (tuberculin) skin test
    4. Urine culture
    5. Stool for ova and parasites (*Strongyloides stercoralis*; center-specific)
- II. Antimicrobial prophylaxis
  - A. Perioperative
    1. First-generation cephalosporin (or vancomycin)
  - B. Postoperative
    1. Trimethoprim-sulfamethoxazole or pentamidine (for *Pneumocystis carinii*)
    2. Nystatin or clotrimazole (for *Candida* spp.)
    3. Ganciclovir followed by acyclovir once discharged (for all patients except CMV-negative recipient and donor)
    4. Acyclovir (for herpes simplex and zoster; routine use is controversial)
    5. Standard endocarditis prophylaxis
  - C. Postoperative immunizations
    1. Pneumococcal (booster every 5-7 years)
    2. Influenza A (yearly; center-specific)
    3. Exposure to measles, varicella, tetanus, or hepatitis B by a nonimmunized recipient often warrants specific immunoglobulin therapy (eg, varicella-zoster immune globulin, VZIG)

Toxoplasmosis following heart transplantation usually is the result of reactivation of latent disease in the seropositive donor heart because of the predilection of the parasite to invade muscle tissue.<sup>137</sup> *T. gondii* infection may be acquired from under-cooked meat and cat feces. The diagnosis is made with certainty only by histologic demonstration of trophozoites with surrounding inflammation in biopsy tissue; PCR also has been used.<sup>138</sup> *T. gondii* usually causes central nervous system infections and is treated with pyrimethamine with sulfadiazine or clindamycin.<sup>123</sup>

## CHRONIC COMPLICATIONS FOLLOWING HEART TRANSPLANTATION

### Cardiac Allograft Vasculopathy

Cardiac allograft vasculopathy (CAV) is a unique, rapidly progressive form of atherosclerosis in transplant recipients that is characterized in its early stages by intimal proliferation and in its later stages by luminal stenosis of epicardial branches, occlusion of smaller arteries, and myocardial infarction. Long-term survival of cardiac transplant recipients is limited primarily by the development of CAV, the leading cause of death after the first posttransplant year.<sup>5</sup> Angiographically detectable CAV is reported in approximately 40 to 50% of patients by 5 years after transplantation.<sup>139</sup> Although CAV resembles atherosclerosis, there are some important differences that are illustrated in Fig. 60-11.<sup>140</sup> In particular, intimal proliferation is concentric rather than eccentric, and the lesions are diffuse, involving both distal and proximal portions of the coronary tree. Calcification is uncommon, and the elastic lamina remains intact.

The detailed pathogenesis of CAV is unknown, but there are strong indications that immunologic mechanisms that are regulated by nonimmunologic risk factors are the major causes of this phenomenon.<sup>141</sup> The immunologic mechanisms include acute rejection and anti-HLA antibodies, and some of the implicated risk factors relating to the transplant itself or the recipient are donor age, hypertension, hyperlipidemia, and preexisting diabetes. The side effects often associated with immunosuppression with calcineurin inhibitors or corticosteroids, for example, CMV infection, nephrotoxicity, and new-onset diabetes, after transplantation also play significant roles.<sup>142-144</sup>

It is generally believed that the initiating event of CAV is subclinical endothelial cell injury in the coronary artery of the allograft, which leads to a cascade of immunologic processes involving cytokines, inflammatory mediators, complement activation, and leukocyte adhesion molecules. These changes produce inflammation and, ultimately, thrombosis, smooth muscle cell proliferation, and vessel constriction. The initial endothelial injury may be the result of ischemia-reperfusion damage or the host-versus-graft immune response.<sup>143,144</sup>

CAV may begin within several weeks posttransplantation and progress insidiously at an accelerated rate to complete

obliteration of the coronary lumen with allograft failure secondary to ischemia. The clinical diagnosis of CAV is difficult and complicated by allograft denervation, resulting in silent myocardial ischemia. Ventricular arrhythmias, congestive heart failure, and sudden death are commonly the initial presentation of significant CAV.<sup>145</sup> An annual coronary angiogram usually is performed for CAV surveillance and remains the diagnostic standard of care. Based on the current ISHLT nomenclature recommendations,<sup>146</sup> moderate or severe CAV 1 year after heart transplantation is associated with subsequent major adverse cardiac events.<sup>147</sup> Intravascular ultrasound (IVUS) is better equipped to provide important quantitative information regarding vessel wall morphology and the degree of intimal thickening.<sup>148</sup>

Because angiography and IVUS are invasive tests, they pose increased risks for patients. Noninvasive tests (eg, thallium scintigraphy and dobutamine stress echocardiography),

**FIGURE 60-11** Schematic illustration of typical atherosclerosis and cardiac allograft vasculopathy.

however, have not been sensitive or specific enough to be a reliable screen for CAV.<sup>149</sup> Other possible modalities include pulse-wave tissue Doppler imaging, electron beam CT, fast CT scanning, and MRI. These modalities may replace invasive procedures in the future.

Currently, the only definitive treatment for advanced CAV is retransplantation, which has risks for the patient and poses problems associated with scarcity of donor organs.<sup>145</sup> Owing to the diffuse and distal nature of the disease, procedures such as stenting and angioplasty are inherently less effective than in nontransplant patients and result in a higher need for repeated procedures.<sup>150</sup> Therefore, prophylactic management is of paramount importance. Before transplantation, the focus should be on preventing endothelial injury at brain death, reducing cold ischemia time and improving myocardial preservation during storage and transportation.<sup>145</sup> Posttransplantation care focuses on empiric risk factor modification (eg, dietary and pharmacologic reduction in serum cholesterol, cessation of smoking, hypertension control, etc). Several studies have demonstrated a decrease in CAV in patients treated with a calcium channel blocker and angiotensin-converting enzyme and HMG-CoA reductase inhibitors.<sup>151,152</sup>

Newer immunosuppressive drugs, specifically the proliferation signal inhibitors (eg, everolimus and sirolimus), may be useful in reducing the incidence and severity of CAV and slowing disease progression.<sup>153-157</sup>

## Renal Dysfunction

The 2009 ISHLT registry reported a significant improvement in long-term renal dysfunction in the most recent cohort of heart transplant recipients (2001 to 2007) as compared to the previous cohort (1994 to 2000). Whereas only 60% of heart transplant recipients from 1994 to 2000 were free of severe renal dysfunction (defined as a creatinine concentration of more than 2.5 mg/dL and the need for dialysis or renal transplantation) by Kaplan-Meier estimates at 10 years, recipients transplanted from 2001 to 2007 had an 11% absolute decrease in severe renal dysfunction at 5 years compared with the previous cohort.<sup>5</sup> Notably, the risk of death after heart transplantation is markedly increased by the development of end-stage renal failure.<sup>158</sup>

Cyclosporine nephrotoxicity after heart transplantation is well recognized and well documented. The improved bioavailability of cyclosporine microemulsion (Neoral) compared with the conventional formulation has led to investigations into monitoring of cyclosporine levels 2 hours after dosing (C2).<sup>159</sup> Neoral C2 monitoring may be a better indicator of immunosuppression efficacy than trough levels and a better measure to avoid nephrotoxicity and other cyclosporine-associated side effects.<sup>160</sup> Lowering cyclosporine dose may be helpful in slowing the progression of renal disease, especially with concomitant use of newer immunosuppressive regimens such as MMF and sirolimus (rapamycin).<sup>161,162</sup> Calcineurin-free immunosuppression is also being implemented by some centers.<sup>163</sup>

## Hypertension

Moderate-to-severe systemic hypertension afflicts 50 to 90% of cardiac transplant recipients.<sup>5</sup> Peripheral vasoconstriction in combination with fluid retention seems to play the greatest role. Although the exact mechanisms are unclear, it likely involves a combination of cyclosporine-induced tubular nephrotoxicity and vasoconstriction of renal and systemic arterioles mediated by sympathetic neural activation.<sup>164</sup> Tacrolimus is associated with a lower incidence of hypertension than is cyclosporine.<sup>165</sup> No single class of antihypertensive agents has proven uniformly effective, and treatment of this refractory hypertension remains empirical and difficult. In a prospective, randomized trial, titrated monotherapy with either diltiazem or lisinopril controlled the condition in fewer than 50% of patients.<sup>166</sup> Diuretics should be used cautiously because the balance between edema/hypertension and volume depletion/hypotension can be tenuous in a subset of these patients. Overzealous diuresis can potentiate the apparent nephrotoxicity of cyclosporine by further reducing renal blood flow and altering cyclosporine pharmacokinetics.<sup>167</sup> Beta-blockers also should be used with caution because they may further blunt the heart rate response to exercise.

## Malignancy

Chronic immunosuppression is associated with an increased incidence of malignancy ranging from about 4 to 18%, which is 10- to 100-fold greater than in the general population.<sup>168</sup> Improved graft and patient survival, owing to pharmacologic advances in the area of immunosuppressive therapy, has led to an increase in the incidence of neoplasms.<sup>168</sup> Malignant neoplasias have become, along with graft vasculopathy, a significant limiting factor for the long-term survival of heart transplant recipients.<sup>5</sup> Lymphoproliferative disorders and carcinoma of the skin are the most common malignancies found in heart transplant recipients.<sup>168</sup> Loss of T-lymphocyte control over EBV-stimulated B-lymphocyte proliferation appears to be the primary mechanism for the development of lymphoproliferative disorders.<sup>169</sup> The risk of these malignancies is increased further following monoclonal and polyclonal antibody therapy.<sup>170,171</sup>

Treatment options in transplantation include a reduction in immunosuppression and initiation of high-dose acyclovir (to attenuate EBV replication), in addition to conventional therapies for carcinoma (eg, chemotherapy, radiation therapy, and surgical resection), which are associated with very high risk and limited success. The role of statins and the risk of cancer were explored in a retrospective study of 255 patients who received transplants at a single center (1985-2007). The cumulative incidence of malignancy 8 years after transplantation was decreased in patients who received statins (34 vs 13%). In addition, statin use was associated with improved cancer-free and overall survival. A prospective study seems warranted,

and although it was not possible for the study investigators to adjust for all confounders, these data are suggestive of improved cancer-free and overall survival in those recipients receiving statin.<sup>172</sup>

## Other Chronic Complications

Hyperlipidemia eventually develops in the majority of recipients and is managed with dietary restrictions, exercise, and lipid-lowering agents.<sup>173</sup> Other complications that commonly contribute to posttransplant morbidity include osteoporosis, obesity, cachexia, and gastrointestinal complications, notably cholelithiasis.<sup>174,175</sup>

## CARDIAC RETRANSPLANTATION

Retransplantation accounts for fewer than 3% of the cardiac transplants currently performed.<sup>5</sup> Primary indications for retransplantation are early graft failure, allograft coronary artery disease, and refractory acute rejection.<sup>176,177</sup>

The operative technique and immunosuppressive regimen are similar to those employed for the initial transplantation. Despite reduced mortality in the cyclosporine era, actuarial survival remains markedly reduced. Analysis of the ISHLT registry for retransplantations performed between 1987 and 1998 reveals survival to be 65, 59, and 55% for 1, 2, and 3 years, respectively. Intertransplant interval of 6 months or less was associated with a dismal 1-year survival of 50% in this analysis.

Conversely, when the interval between primary and retransplantation was more than 2 years, 1-year survival after retransplantation approached that of primary transplantation.<sup>177</sup> The 2009 ISHLT registry report indicates that the 5-year survival of retransplanted patients has increased by 15-17% with each successive decade (1982-1991, 1992-2001, 2002-2007). As well, in the most recent cohort (2002-2008), patients undergoing retransplantation at greater than 5 years from initial transplant had the same 1-year survival rate as primary transplants from the same era (86%).<sup>5</sup> Advanced donor age also was a predictor of increased mortality among these recipients.<sup>177</sup>

A recent UNOS Registry study examined risk factors associated with high risk of graft failure after retransplantation (n = 671). Older age, increasing serum creatinine, and preoperative mechanical ventilation were associated with 1-year graft failure by multivariate analysis. Each decade increase in recipient age was associated with a 20% increase in the odds of 1-year graft failure. In addition, each 1 mg/dL increase in serum creatinine increased the likelihood of graft failure by 58%.<sup>178</sup>

Another UNOS Registry project studied the effectiveness of bridging patients to retransplant with mechanical circulatory support. According to the UNOS Registry, 149 of 1690 retransplants were bridged with mechanical support, consisting of extracorporeal membrane oxygenation (ECMO) in 54 and a VAD in 90. Those bridged to retransplant did poorly overall, with the ECMO sub-group faring the worst. Survival

in patients who were bridged on VAD and received an allograft at least 1 year after the primary transplant was similar to those retransplant recipients who did not require VAD. However, survival was significantly worse in the bridged population who underwent retransplant within a year of the primary transplant.<sup>179</sup>

These data suggest that although cardiac retransplantation is associated with significant morbidity and mortality, careful selection of patients, especially those who are younger and with longer intertransplant intervals, may be associated with more favorable outcome. Nonetheless, the disparity between the demand and supply for donor hearts continues to make cardiac retransplantation an ethical dilemma.<sup>180</sup>

## RESULTS OF HEART TRANSPLANTATION

Although no direct comparative trials have been or are likely to be performed, survival following heart transplantation remains favorable if compared with both the medical and device arms of the REMATCH trial.<sup>2,6</sup> The superiority of heart transplantation is more clearly evident in medium- and high-risk patients with end-stage heart failure.<sup>181</sup> The overall results actually are improving despite increasing risk profiles.<sup>5,78</sup>

The reported operative (ie, 30-day) mortality for cardiac transplantation ranges from 5 to 10%.<sup>182</sup> Overall 1-year survival is up to 86%.<sup>5,78</sup> After the steep fall in survival during the first 6 months, survival decreases at a linear rate (approximately 3.5% per year), even well beyond 15 years posttransplantation.<sup>5</sup> Graft failure (primary and nonspecific), multisystem organ failure, and infection account for most deaths within the first 30 days. Infection, graft failure, and acute rejection are the leading causes of death during the first year; thereafter, CAV and malignancy are the major causes of death.<sup>5,78</sup>

While many subgroups including patients with arrhythmic right ventricular cardiomyopathy, hypertrophic cardiomyopathy, restrictive cardiomyopathy (except for patients with amyloid or chemotherapy/radiation therapy), and adult congenital heart disease had comparable outcomes, post-transplant outcomes in 485 women with peripartum cardiomyopathy (PPCM) were inferior. Outcomes were examined using the UNOS Registry (1987-2010; n = 42,406). The PPCM patients were younger with a higher degree of sensitization, required higher intensity pretransplant cardiovascular support, suffered an increased graft failure and death, which may be secondary to the higher pretransplant acuity, increased rejection seen, and greater degree of sensitization.<sup>183</sup>

Studies examining the health-related quality of life in patients after cardiac transplantation demonstrate marked improvement, particularly in the absence of complications, and approach the general population by 10 years after transplantation.<sup>184</sup>

Factors affecting long-term survival were examined in several studies. In an analysis of the UNOS Registry (1987-1999), recipients surviving a minimum of 10 years (n = 9404)

were identified and compared with recipients who died within 10 years ( $n = 10,373$ ). Predictors of long-term survival in a multivariate model included recipient age at transplant  $< 55$  years, shorter ischemic time, younger donor age, white race, and annual center volume  $> 9$ . Mechanical ventilation and the presence of diabetes diminished the likelihood of long-term survival.<sup>185</sup>

A recent study examined the influence of insurance and education on long-term survival. Medicare and Medicaid patients had lower 10-year survival (8.6 and 10.0%, respectively) than private insurance/self-pay patients. College-educated patients had 7.0% higher 10-year survival. These survival differences increased over time. Multivariable analysis demonstrated that college education decreased mortality risk by 11%, whereas Medicare and Medicaid increased the mortality risk by 18 and 33%, respectively.<sup>186</sup>

A recent systematic review saw a relationship between low center volume and increased mortality. The minimal acceptable transplant volume was unable to be determined; however, 10 to 12 transplants per year corresponded to the upper limit of low-volume categories that have relatively high mortality. The effect of reorganizing centers to ensure minimal target volumes was unable to be determined.<sup>187</sup>

The relationship between recipient risk and institutional volume on short-term mortality was studied using the UNOS Registry (2000-2010) using a previously validated recipient risk index. Institutional volume per year, defined as low ( $<7$ ), medium (7-15), and high ( $>15$ ) acted as a modifier on association between risk and mortality, such that high-risk recipients had improved 1-year survival when their transplants occurred at high-volume centers.<sup>188</sup>

Another UNOS Registry study, using mixed-effect logistic regression models, demonstrated that although 1-year mortality increases with decreasing center volume, this accounted for only 16.7% of the variability in mortality between centers. This suggests that although institutional volume may be an important predictor of outcome, other factors contribute to mortality risk that may not be encompassed by the data currently collected in the registry.<sup>189</sup>

### Additional Insights from the United Network for Organ Sharing Database

As noted in the above sections, the recent literature on heart transplantation has seen a notable increase in clinical studies analyzing the multi-institutional UNOS open transplant cohort. This database is publically accessible and includes all heart transplants performed in the United States from October 1987 onward. The database also includes patients on the waitlist, donor information, and outcomes. As with all large administrative datasets, it is limited by potential errors in coding as well as incompletely populated variables. However, questions that had previously only been addressed using single or limited multiinstitutional data can now be investigated using this cohort of over 20,000 patients. Among those issues addressed have been the impact of

various recipient factors, on short- and long-term survival after heart transplantation. Russo and coworkers reported that uncomplicated diabetes mellitus should not preclude listing for heart transplantation due to equivalent survival with nondiabetics.<sup>190</sup> However, severe diabetics did have poorer survival and should be considered for destination LVAD therapy or high-risk listing. Zaidi and coworkers reported better short and intermediate survival after heart transplantation in patients with sarcoidosis compared to recipients with other diagnoses, and concluded that a diagnosis of sarcoidosis should not preclude heart transplantation.<sup>191</sup> Kpodonu and coworkers demonstrated that 1-year survival after heart transplant for amyloid cardiomyopathy was significantly decreased in female recipients, whereas it was comparable with other diagnoses for male recipients.<sup>192</sup> Nwakanma and coworkers confirmed increasing risk of rejection in the year after transplantation and decreased survival with increasing PRA levels.<sup>193</sup> Weiss and coworkers reported that advanced age ( $>60$  years) was associated with acceptable long-term outcomes ( $>70\%$  5-year survival).<sup>194</sup> Although elderly recipients did have slightly higher rates of infection and acute renal failure, as well as a 2-day longer hospital length of stay, the survival benefit of transplantation in elderly CHF patients was compelling. Another study by Weiss and coworkers identified a potential provider bias in the listing of obese patients as potential heart transplant recipients.<sup>195</sup> Specifically, that obese individuals wait longer and have a lower likelihood of receiving a donor heart after listing, despite similar short-term survival.

Insights into the impact of operative technique and the use of LVADs on posttransplant survival have also been gained from the UNOS database. As noted, Weiss and coworkers reported equivalent survival after heart transplantation using biatrial versus bicaval anastomotic techniques.<sup>74</sup> However, they did identify that the bicaval technique was associated with a shortened hospital length of stay and decreased rates of permanent pacemaker placement. Pal and coworkers investigated status 1 patients bridged to transplant using LVADs and IV inotropes, and found that patients bridged to transplant using LVADs were, by in large, those who failed bridging with IV inotropes.<sup>196</sup> In contrast with International Society of Heart and Lung Transplantation data, no increase in posttransplant morbidity or mortality was found in LVAD-bridged patients compared with nonbridged status 1 patients. Shuhaiber and coworkers compared patients bridged with transplant with Novacor versus HeartMate LVADs and found no difference in 1-year survival, rates of rejection, or rates of infection.<sup>197</sup> However, patients bridged with Novacor LVADs demonstrated lower 5-year survival posttransplant.

Weiss and coworkers also investigated the effect of transplant center volume on long-term outcomes after heart transplantation, and reported that annual center volume is an independent predictor of short-term mortality in OHT.<sup>198</sup> Although the current Centers for Medicare and Medicaid Services mandate is that heart transplant centers perform 10 per year to qualify for funding, this study found that a higher cutoff resulted in better outcomes;

centers performing greater than 40 per year have a 30-day mortality less than 5%.

## THE FUTURE

As a result of a series of unprecedented advances over the past decade, the clinical outcome of heart transplantation has improved dramatically. Although cardiac replacement remains the best therapeutic option for patients with end-stage heart failure, a number of challenges await future investigators to further improve survival and reduce transplant-related morbidity. A major factor limiting long-term survival of recipients is allograft rejection and the untoward effects of immunosuppression. Development of reliable, noninvasive diagnostic studies will permit more frequent evaluations for the early detection of rejection and for monitoring the effectiveness of therapy. Ultimately, this will allow more precise control of immunosuppression and, in turn, a reduction in cumulative allograft injury and infectious complications. Molecular tests and gene expression profiling could be available soon and may provide the best noninvasive option.<sup>105,108</sup>

Immunosuppressive strategists will continue their efforts to establish specific unresponsiveness to antigens of transplanted organs in hopes of preserving much of the recipient's immune responses. Proliferative signal inhibitors such as sirolimus and everolimus are showing promising results. Alternatively, donor organs may be made less susceptible to immunologic attack through genetic engineering techniques by altering the expression of cell membrane-bound molecules. This approach is being used currently in the pursuit of clinically applicable xenotransplant sources. Xenografts eventually may be an additional source of donor organs, although extended xenograft survival remains an elusive goal. Complicating this alternative are unresolved ethical issues concerning transgenic experimentation and the potential for transmission of veterinary pathogens to an immunosuppressed recipient.

Future improvements in organ preservation permitting extension of the storage interval will have several benefits. In addition to a modest increase in the donor pool, extension of storage times would permit better allocation of organs with respect to donor-recipient immunologic matching. Assist devices are being used currently both as a bridge to transplantation and as a destination therapy. It appears that as the technology of assist devices continues to improve, it is only a matter of time before they become a long-term solution for patients with severe congestive heart failure.

The concept of regenerating the failing heart using cardiomyocytes of different sources, autologous smooth muscle cells, and dermal fibroblasts is in the experimental stage. Lineage-negative bone marrow cells or bone marrow-derived endothelial precursor cells are also being studied to induce new blood vessel formation after experimental myocardial infarction.<sup>199</sup> Cardiac transplantation remains a remarkable achievement of the twentieth century and has revolutionized therapy for end-stage heart failure. Further investigations are needed to overcome the current obstacles to long-term graft function and patient survival.

# Lung Transplantation and Heart-lung Transplantation

Hari R. Mallidi • Jatin Anand • Robert C. Robbins

Human lung transplantation, performed as a single lung, double lung, or heart-lung bloc, has emerged as a life-saving procedure for patients with end-stage pulmonary disease. With improvement of operative techniques, organ preservation, and immunosuppressive regimens, combined heart-lung and isolated lung transplantation have become common treatments for patients with a variety of end-stage disease entities. To date, 3703 combined heart-lung transplants and 43,428 lung transplants have been reported worldwide.<sup>1</sup> Although the number of heart-lung transplants performed annually has declined in recent years, the number of single-lung transplantation (SLT) procedures remains stable, accompanied by a steady increase in bilateral lung transplant procedures (Fig. 61-1). Clinical progress in thoracic organ transplantation has been considerable, yet significant barriers that limit the scope of these procedures still remain. These include donor organ shortage, limited preservation techniques, graft rejection, and infectious complications. This chapter summarizes the state of the art in combined heart-lung and isolated lung transplantation.

## LUNG TRANSPLANTATION

### History of Lung Transplantation

In 1949, Henry Metras described many of the important technical concepts for lung transplantation, including preservation of the left atrial cuff for the pulmonary venous anastomoses and reimplantation of an aortic patch containing the origin of the bronchial arteries to prevent bronchial dehiscence.<sup>2</sup> Airway dehiscence was a major obstacle in experimental lung transplantation, and he proposed that preservation of the bronchial arterial supply was critical to airway healing. Unfortunately, this technique was technically cumbersome and never gained widespread popularity. In the 1960s, Blumenstock and Khan advocated transection of the transplant bronchus close to the lung parenchyma to prevent ischemic bronchial necrosis.<sup>3</sup> Additional surgical modifications were developed to prevent bronchial anastomotic complications, including telescoping of the bronchial anastomosis, described by Veith in 1970,<sup>4</sup> and coverage of the anastomosis with an omental pedicle flap, described by

the Toronto group in 1982.<sup>5</sup> Corticosteroids were found to be another contributor to poor bronchial healing,<sup>6</sup> a problem ameliorated by the introduction of cyclosporine immunosuppression. Thus, by the 1970s, the stage was set for successful lung transplantation in the human.

The first human lung transplant was described in 1963 by Hardy and colleagues at the University of Mississippi.<sup>7</sup> The patient, a 58-year-old man with lung cancer, survived 18 days postoperatively. Over the next two decades, nearly 40 lung transplants were performed without long-term success. In 1986, the Toronto Lung Transplant Group reported the first successful series of single-lung transplants with long-term survival.<sup>8</sup> Improved immunosuppression, along with careful recipient and donor selection, was pivotal to their success. For patients with bilateral lung disease, en bloc double lung replacement was introduced by Patterson in 1988 as an alternative to heart-lung transplantation with a domino procedure in which the explanted heart was offered to a second recipient with end-stage heart disease.<sup>9</sup> This technique was later replaced by sequential bilateral lung transplantation, described by Pasque and colleagues in 1990.<sup>10</sup> More recent operative innovations include living lobar transplantation, performed for the first time by Vaughn Starnes at Stanford in 1992.<sup>11</sup>

Lung transplantation has seen a steady growth over the past decade, with over 3800 procedures reported to the International Society for Heart and Lung Transplantation (ISHLT) registry in 2013.<sup>1</sup> Currently there are 153 centers reporting lung transplant data, with more than half of these performing more than 10 transplants per year. Although the number of single-lung transplants performed has been relatively stable since the mid-1990s, bilateral lung transplant procedures have shown a consistent growth in volume.<sup>1</sup>

### Indications for Lung Transplantation

#### GENERAL GUIDELINES

Organ allocation for lung transplantation underwent a major change in 2005 that has significantly affected the process of recipient selection. Historically, lung allocation was determined strictly by the amount of time a patient spent on the

**FIGURE 61-1** UNOS data representing the number of lung transplant procedures reported by year and procedure type, collected from data reported to the International Society of Heart and Lung Transplantation Registry. This figure may underestimate the total number of procedures worldwide. (Reproduced with permission from Yusen RD1, Edwards LB1, Kucheryavaya AY, et al: The registry of the International Society for Heart and Lung Transplantation: thirty-first adult lung and heart-lung transplant report—2014, *J Heart Lung Transplant*. 2014 Oct;33(10):1009-1024.)

waiting list (matching for size and blood group). Consequently, the limited supply of donor organs resulted in an increasing number of patients on the waiting list with progressively longer wait times (Fig. 61-2).<sup>12</sup> To address these shortcomings, the organ allocation system was revised in 2005 to prioritize medical urgency and expected outcome after transplantation. Under this system, prioritization is based on a lung allocation score (LAS) that is calculated based on the following clinical criteria: age, height, weight, lung diagnosis code, functional status, diabetes, assisted ventilation, supplemental O<sub>2</sub> requirement, percent predicted forced vital capacity (FVC), pulmonary artery systemic pressure, mean pulmonary artery pressure, pulmonary capillary wedge pressure, current PCO<sub>2</sub>, highest PCO<sub>2</sub>, lowest PCO<sub>2</sub>, change in PCO<sub>2</sub>, 6-minute walk distance, and serum creatinine. These values can be entered into an online calculator to derive the LAS (<https://optn.transplant.hrsa.gov/resources/allocation-calculators/las-calculator/>). Based on these criteria, the waitlist urgency measure (defined as the expected number of

days during the next year on the waiting list without a transplant) is subtracted from the posttransplant survival measure (defined as the expected number of days lived during the first year after transplantation) to determine the net transplant benefit. This raw allocation score is then normalized to a scale of 0 to 100 to calculate the LAS. In this scoring system, post-transplant survival is limited to 1 year because the predictive variables are only relevant in the early postoperative period.<sup>13</sup>

The rationale for approaching recipient selection from the perspective of transplant benefit is based on the premise that patient selection for lung transplantation must balance the anticipated survival after transplantation (currently at a median of 5 years) with projected life expectancy on the waiting list. Although waiting times have historically averaged 432 days, the institution of the LAS has reduced this period to an average of 262 days.<sup>14</sup> Nevertheless, mortality while on the waiting list remains at nearly 20%, so it is imperative to identify recipients as early as possible within the “transplant window.”<sup>15</sup> Ideally, recipient evaluation should select individuals with progressively disabling pulmonary disease who still possess the capacity for full rehabilitation after transplantation. Much of the current success in lung transplantation stems from improvement in recipient selection, because early attempts were thwarted by selection of patients with prohibitive operative risk factors. Candidates should have a less than 50% 2- to 3-year predicted survival despite appropriate medical or alternative surgical strategies. Disabling symptoms prompting consideration for transplantation typically include dyspnea, cyanosis, syncope, and hemoptysis. Potential recipients are identified by their local primary physicians and referred to transplantation centers for further evaluation.

Tests required for transplant listing are reviewed in Table 61-1. Diagnostic studies that are particularly useful in evaluating potential recipients include full pulmonary function tests, an exercise performance test, electrocardiogram,

**FIGURE 61-2** Between 1994 and 2003, the availability of donor organs held relatively constant, with an increasing number of patients placed on the waiting list. (Reproduced with permission from 2004 OPIN/SRTR Annual Report.)

**TABLE 61-1: Typical Laboratory Tests and Studies Obtained During Recipient Evaluation for Heart-lung and Lung Transplantation**

### Suitability for Transplantation (Phase I)

#### Required Laboratory Tests and Studies

- CBC with differential, platelet, and reticulocyte count
- Blood type and antibody screen (ABO, Rh)
- Prothrombin and activated partial thromboplastin time (PT, aPTT)
- Bleeding time
- Immunology panel (FANA, RF)
- Electrolytes, including Mg<sup>2+</sup>
- CK with isoenzymes
- Serum protein electrophoresis
- Urinalysis
- Viral serologies
  - Compromised host panel (cytomegalovirus, adenovirus, Varicella-Zoster, herpes simplex, Epstein-Barr virus)
  - Hepatitis A, B, and C antibodies, Hepatitis B surface antigen (HBsAg)
  - Cytomegalovirus (quantitative antibodies and IgM)
  - Human immunodeficiency virus
- Electrocardiogram
- Chest x-ray

#### Studies Obtained as Indicated

- Echocardiogram with bubble study
- MUGA for right and left ventricular ejection fraction
- Cardiac catheterization with coronary angiogram
- Thoracic CT scan
- Quantitative ventilation-perfusion scans
- Carotid duplex
- Mammogram
- Colonoscopy
- Sputum for Gram stain, AFB smear, KOH, and routine bacterial, mycobacterial, and fungal cultures

### Required For Listing (Phase II)

- HLA and DR typing
- Transplant antibody
- Quantitative immunoglobulins
- Histoplasma*, *Coccidioides*, and *Toxoplasma* titers
- PPD
- Pulmonary function tests with arterial blood gases
- 12-Hour urine collection for creatinine clearance and total protein
- Urine viral culture

echocardiogram, 24-hour creatinine clearance, and liver function tests. Former smokers must undergo screening to exclude smoking-related illnesses, such as peripheral vascular disease and malignancy. A negative sputum cytology, thoracic computed tomographic (CT) scan, bronchoscopy, otolaryngologic evaluation, and carotid duplex scan are required. In addition, left heart catheterization and coronary angiography should be performed in recipient candidates who have a history of smoking.

Patients deemed suitable for transplantation during the initial evaluation are subjected to a final phase of testing (see Table 61-1). If accepted by the transplant review committee, they are listed on the national transplant registry based on LAS. Listed candidates should be seen every 3 to 6 months at the transplant center and regularly by their primary physicians, to maintain optimal medical condition. If appropriate, a period of exercise rehabilitation and nutritional modification may be initiated. Most transplant centers require patients to reside within several hours of the center by automobile or air charter.

ABO compatibilities are strictly adhered to, because isolated cases of hyperacute rejection have been reported in transplants performed across ABO barriers.<sup>16</sup> Donor-to-recipient lung volume matching is an important consideration. According to the 27th-30th ISHLT registry reports, taller donor heights have been shown to correlate with a lower risk for 1-year posttransplant mortality.<sup>1,17</sup> A range of acceptable donor heights is mandated at the time of patient listing. However, the best parameter for size matching remains controversial.

Height alone is an important predictor of lung size, yet gender affects lung size independently of height.<sup>18</sup> Therefore, another parameter commonly reported is the predicted total lung capacity (pTLC), which is calculated from a regression equation based on both gender and height. The pTLC of a 170-cm male is 6.5 L while that of a 170-cm female is 5.4 L, illustrating the importance of gender considerations and the utility of the pTLC.

Current ISHLT Guidelines recommend that donor pTLC should be matched to within 75 to 125% of the recipients pTLC.<sup>19</sup> Eberlein and colleagues evaluated a pTLC donor-to-recipient ratio (pTLC donor/pTLC recipient) in a retrospective registry study of over 10,000 patients and found an association between a high pTLC ratio (suggesting an oversized allograft) and improved survival after lung transplant.<sup>20</sup> The authors concluded that the pTLC ratio is an independent predictor of death in the first year after lung transplant and should therefore be carefully considered.

Preoperative comparison of donor and recipient chest tomography typically involves matching the vertical (apex to diaphragm along the midclavicular line) and transverse (level of diaphragmatic dome) radiologic dimensions. Donor lung dimensions should not be greater than 4 cm over those of the recipient. If needed, donor lungs may be downsized by lobectomy or wedge resection. As high-resolution three-dimensional CT imaging and advanced software becomes more readily available, lung-size-matching using newer technologies continues to emerge.<sup>21</sup>

In contrast to renal transplantation, HLA matching is not a criterion for thoracic organ allocation. Because only short ischemic times are tolerated by lung and heart-lung blocs, it is not possible to perform this tissue typing preoperatively.<sup>22</sup> However, several retrospective studies have been performed evaluating the influence of HLA matching on long-term graft survival and development of obliterative bronchiolitis (OB).

Wisser and colleagues examined the relationship between HLA matching and long-term survival in 78 lung transplant recipients, finding improved graft survival with matching at the HLA-B locus.<sup>23</sup> In a retrospective study of 74 lung transplant patients, Iwaki and coworkers also correlated matching at the HLA-B and HLA-DR loci with improved graft survival.<sup>24</sup> These studies suggest a relationship between HLA matching and long-term graft function.

Once an appropriate donor-recipient pairing is made, the recipient is screened for preformed antibodies against a panel of random donors. A percent reactive antibody (PRA) level greater than 25 prompts a prospective-specific crossmatch between the donor and recipient. A positive crossmatch indicates the presence of antidonor circulating antibodies in the recipient, which would likely lead to hyperacute rejection. In the event of a positive crossmatch, the donor organ cannot be accepted for that recipient.

### DISEASE-SPECIFIC GUIDELINES

Common indications for lung transplantation are listed in Table 61-2, with listing criteria given in Table 61-3.

Chronic obstructive pulmonary disease (COPD) represents the most common indication for lung transplantation, accounting for 36% of lung transplants performed each year.<sup>25</sup> Decision making with respect to referral for transplantation and listing is based on worsening clinical deterioration as quantified by the BODE index. This predictive tool takes into account body mass index (B), degree of airflow obstruction (O), dyspnea (D, measured by the modified Medical Research Council MMRC dyspnea scale), and exercise capacity (E, measured by a 6-minute walk test).<sup>26</sup>

The BODE index score ranges from 0 to 10, and patients are considered for transplant with a score of 7 to 10, because median survival in this cohort is only 3 years.<sup>26</sup> In patients with COPD who have apically predominant emphysema, lung volume reduction surgery (LVRS) may represent an alternative strategy to postpone or eliminate the need for transplantation. Patients who have undergone pleurodesis or who have advanced disease ( $FEV_1$  and  $DLCO < 20\%$  or significant pulmonary hypertension) are not eligible for LVRS.<sup>27</sup> Based on the National Emphysema Treatment Trial, which studied the benefit of LVRS, a cohort of transplant-eligible high-risk patients (median survival of 3 years with medical therapy) was identified in which  $FEV_1$  was less than 20% and either  $DLCO$  less than 20% or homogeneously distributed emphysema was present.<sup>27</sup> The decision to perform single-versus double-lung transplantation (DLT) in a patient with COPD must take into account the patient's ability to tolerate single-lung ventilation, cardiopulmonary bypass, and the risk of ventilation-perfusion mismatch in single-lung transplant when compressive atelectasis and restriction occurs in the donor lung. Interestingly, a statistical model derived from United Network for Organ Sharing (UNOS) data between 1987 and 2004 estimated that 45% of COPD patients would gain a survival benefit of 1 year after double-lung transplant, compared with only 22% of patients who underwent single-lung transplant.<sup>28</sup>

Idiopathic pulmonary fibrosis (IPF) represents the second most common indication for lung transplantation worldwide, accounting for just over 20% of all lung transplants.<sup>17</sup> Median survival from the time of diagnosis is only 2.5 to 3.5 years, suggesting that transplant referral should be made as soon as histologic or radiographic evidence of the disease

**TABLE 61-2: Indications for Lung Transplantation from January 1995 Through June 2013**

Diagnosis	SLT (n = 15,321) No. (%)	BLT (n = 26,579) No. (%)	Total (n = 41,900) No. (%)
COPD/emphysema	6594 (43.0)	7078 (26.6)	13,672 (32.6)
IPF	5354 (34.9)	4825 (18.2)	10,179 (24.3)
Cystic fibrosis	234 (1.5)	6628 (24.9)	6862 (16.4)
AAT	771 (5.0)	1572 (5.9)	2343 (5.6)
IPAH	92 (0.6)	1158 (4.4)	1250 (3.0)
Sarcoidosis	280 (1.8)	776 (2.9)	1056 (2.5)
Bronchiectasis	62 (0.4)	1069 (4.0)	1131 (2.7)
LAM	138 (0.9)	302 (1.1)	440 (1.1)

UNOS data from January 1995 through June 2013. AAT, A1 anti-trypsin deficiency; COPD, chronic obstructive pulmonary disease; IPAH, idiopathic pulmonary arterial hypertension; IPF, idiopathic pulmonary fibrosis; OB, obliterative bronchiolitis. Reproduced with permission from Yusen RD, Edwards LB, Kucheryavaya AY, et al: The registry of the International Society for Heart and Lung Transplantation: thirty-first adult lung and heart-lung transplant report—2014. *J Heart Lung Transplant*. 2014 Oct;33(10):1009-1024.

**TABLE 61-3: Listing Criteria Specific to the Disease Entities Commonly Evaluated for Lung Transplantation**

#### Chronic Obstructive Pulmonary Disease

- BODE index of 7 to 10 or at least one of the following:
  - History of hospitalization for exacerbation associated with acute hypercapnia (PCO<sub>2</sub> exceeding 50 mm Hg)
  - Pulmonary hypertension or cor pulmonale, or both, despite oxygen therapy
  - FEV<sub>1</sub> < 20% and either DL<sub>CO</sub> < 20% or homogenous distribution of emphysema

#### Idiopathic Pulmonary Fibrosis

- Histologic or radiographic evidence of UIP and any of the following:
  - A DL<sub>CO</sub> < 39% predicted
  - A 10% or greater decrement in FVC during 6 months of follow-up
  - A decrease in pulse oximetry < 88% during a 6-minute walk test
  - Honeycombing on HRCT (fibrosis score > 2)

#### Cystic Fibrosis

- FEV<sub>1</sub> < 30% of predicted, or rapidly declining lung function if FEV<sub>1</sub> > 30% (females and patients < 18 years of age have a poorer prognosis; consider earlier listing) and/or any of the following:
  - Increasing oxygen requirements
  - Hypercapnia
  - Pulmonary hypertension

#### Idiopathic Pulmonary Arterial Hypertension

- Persistent NYHA Class III or IV on maximal medical therapy
  - Low (350 m) or declining 6-minute walk test
  - Failing therapy with intravenous epoprostenol, or equivalent
  - Cardiac index of < 2 L/min/m<sup>2</sup>
  - Right atrial pressure > 15 mm Hg

#### Sarcoidosis

- NYHA functional Class III or IV and any of the following:
  - Hypoxemia at rest
  - Pulmonary hypertension
  - Elevated right atrial pressure > 15 mm Hg

BODE, body mass index, airflow obstruction, dyspnea, and exercise capacity; HRCT, high-resolution computed tomography; NYHA, New York Heart Association; UIP = usual interstitial pneumonitis.  
Data from Kreider M, Kotloff RM: Selection of candidates for lung transplantation, *Proc Am Thorac Soc*. 2009 Jan 15;6(1):20-27.

is present. Listing a patient with IPF must take into account the fact that many patients have an indolent form of the disease, and numerous studies have identified the following risk factors for rapid decline in patients with histologic or radiographic evidence of IPF:<sup>29</sup>

- DLCO less than 39% of predicted
- 10% or greater decrement in FVC during a 6-month period
- Oxygen saturation less than 88% during a 6-minute walk test
- Honeycombing on CT scan

Traditionally, IPF patients have been considered for either SLT or DLT. However, recent data suggest that there may

be a survival advantage for double-lung over single-lung transplant—particularly among high-risk patients (defined as LAS > 52).<sup>30</sup>

Cystic fibrosis (CF) is the third most common indication for lung transplant, accounting for 16% of the total number of transplants performed.<sup>25</sup> In these patients, bilateral sepsis mandates removal of both native lungs. In a landmark study from the Hospital for Sick Children in Toronto, Kerem and colleagues established that CF patients with an FEV<sub>1</sub> of less than 30% of predicted experienced a 2-year mortality rate of 50%.<sup>31</sup> However, subsequent risk stratification models have challenged these findings and presented conflicting data on the question of life expectancy in CF. Therefore, the current ISHLT guidelines state that an FEV<sub>1</sub> less than 30% should prompt a referral to a transplant center with the decision to proceed with listing dependent on other indicators of disease severity such as oxygen-dependent respiratory failure, hypercapnia, and pulmonary hypertension.<sup>32</sup> CF recipients should have an otolaryngologic evaluation before being placed on an active waiting list. Most of these patients require endoscopic maxillary anastomies for sinus access and monthly antibiotic irrigation to decrease the bacterial load of the upper respiratory tract. This measure has decreased the incidence of serious posttransplant bacterial infections.<sup>33</sup>

Idiopathic pulmonary arterial hypertension represents 3.3% of the total lung transplantation volume worldwide.<sup>25</sup> Survival with this condition has improved dramatically with the institution of vasodilator therapy, with 5-year survival of 55% on epoprostenol compared with 28% among historical controls.<sup>34</sup> Listing for transplantation is indicated when a patient remains in NYHA Class III or IV after 3 months of therapy (often seen in the setting of declining 6-minute walk test, cardiac index of < 2 L/min/m<sup>2</sup>, or right atrial pressure > 15 mm Hg).<sup>29</sup>

Sarcoidosis accounts for 2.6% of all lung transplants.<sup>25</sup> The natural course of this disease can be highly variable, but in general patients should be referred for transplant if they develop NYHA class III or IV symptoms. Impairment of exercise tolerance and hypoxemia at rest, pulmonary hypertension, or right atrial pressure greater than 15 mm Hg serve as general guidelines for listing.<sup>32</sup>

Less than 2% of all single- and bilateral-lung transplants are retransplantations.<sup>25</sup> Overall, survival is poor compared with first-time transplantation, although certain subsets of patients perform better than others. In fact, the Pulmonary Retransplant Registry has collected data from 230 patients at over 40 centers and found that 1-year survival of ambulatory, nonventilated patients undergoing retransplantation after 1991 is comparable with first-time transplants.<sup>35</sup>

## Impact of the Lung Allocation Score

Since the introduction of the LAS in 2005, there has been a decrease in waitlist time and waitlist mortality with a concurrent increase in the number of transplants performed per year (Fig. 61-3). Although early data have suggested that the 1-year survival since introduction of the LAS has not changed, more recent data indicate that the posttransplant survival

**FIGURE 61-3** Since the introduction of the lung allocation score (LAS) in 2005, there has been a rise in the number of lung transplants performed each year with a concurrent decrease in the number of waiting list deaths. (Data from U.S. Department of Health and Human Services. Organ Procurement and Transplantation Network.)

beyond 1 year may be lower.<sup>36</sup> This is in accordance with the fact that sicker patients are being prioritized, including more that are bridged to transplantation with extracorporeal membrane oxygenation (ECMO) (Fig. 61-4). Furthermore, the most common diagnoses are also changing, with more

**FIGURE 61-4** Percentage of patients on ECMO at the time of transplant by year. Only patients with no prior transplants were included. Figure created using the United Network for Organ Sharing (UNOS) database, based on Organ Procurement and Transplant Network (OPTN) data as of June 17, 2016. ECMO, extracorporeal membrane oxygenation.)

IPF and less COPD patients being selected for transplantation (Fig. 61-5)<sup>1</sup> Long-term data revealing the impact of the LAS are only recently becoming available and remain under intense investigation.

Previously, ISHLT and UNOS registries have demonstrated that DLT in COPD patients is associated with improved outcomes. Furthermore, SLT and DLT have shown similar outcomes in IPF patients. However, these data are largely from pre-LAS cohorts. In the post-LAS era, reanalysis has shown that DLT is associated with improved outcomes in both propensity-matched and unmatched cohorts of all-comers undergoing lung transplantation, as well as in analyses of patients specifically undergoing transplant for IPF.<sup>37</sup> For patients undergoing lung transplant for COPD, propensity-matched cohorts in the post-LAS era show similar survival whether SLT or DLT is employed.<sup>37</sup> These outcomes in the post-LAS era cohorts are contrary to previously published findings, and are likely explained by the fact that sicker, older patients with more comorbidities, of worse functional status, and with baseline oxygen requirements are being prioritized as a consequence of the LAS algorithm.

Analysis of post-LAS registry data in patients undergoing transplant for IPAH has revealed that those listed for transplantation have significantly worse comorbidities yet have a lower wait-list mortality and a higher incidence of transplant as compared to pre-LAS era.<sup>38</sup> Furthermore, those receiving double lung transplant in the post-LAS era have a survival advantage over those in the pre-LAS era while those receiving heart-lung transplant do not see the same survival advantage when compared to the pre-LAS cohort.<sup>38</sup> Again, these outcomes are contradictory to previously published registry analyses focused on pre-LAS cohorts.

**FIGURE 61-5** Major indications for lung transplantation in adults over time. Since the introduction of the lung allocation score (LAS) in 2005 (marked by the vertical dashed line), there have been more transplants for idiopathic pulmonary fibrosis (IPF) and less for chronic obstructive pulmonary disease (COPD). Figure created using the United Network for Organ Sharing (UNOS) database, based on Organ Procurement and Transplant Network (OPTN) data as of June 17, 2016. CF, cystic fibrosis; Alpha 1, Alpha 1-antitrypsin deficiency emphysema; IPAH, idiopathic pulmonary arterial hypertension; ReTX, retransplantation.)

These recent analyses help to illustrate the fact that the institution of the LAS has had a dramatic impact on lung transplantation in ways that remain largely uncharacterized. Ongoing evaluation of post-LAS cohorts with an emphasis on long-term outcomes is an area of intense focus within the lung-transplant community.

## Contraindications to Lung Transplantation

There are well-established contraindications to lung transplantation (Table 61-4). In general, transplantation is an option that is restricted to patients less than 65 years old, although 9% of recipients in the first half of 2008 exceeded this cutoff.<sup>25</sup> Significant multisystem disease is a contraindication, although multiorgan transplants have occasionally been performed. Absolute contraindications include renal dysfunction, malignancy (bronchoalveolar carcinoma is a contraindication but not nonmelanoma skin cancer), infection with HIV, hepatitis B antigen positivity or hepatitis C infection with biopsy-proven liver disease, infection with pan-resistant respiratory flora, active or recent cigarette

**TABLE 61-4: Recipient Contraindications to Lung Transplantation**

Age $\geq$ 65 years
Significant systemic or multisystem disease (eg, peripheral or cerebrovascular disease, portal hypertension, poorly controlled diabetes mellitus)
Significant irreversible hepatic or renal dysfunction (eg, bilirubin $>$ 3.0 mg/dL, creatinine clearance $<$ 50 mg/mL/min)
Active malignancy
Corticosteroid therapy ( $>$ 10 mg/day)
Pan-resistant respiratory flora
Cachexia or obesity ( $<$ 70% or $>$ 130% ideal body weight)
Current cigarette smoking
Psychiatric illness or history of medical noncompliance
Drug or alcohol abuse
Previous cardiothoracic surgery (considered on a case-by-case basis)
Severe osteoporosis
Prolonged mechanical ventilation
HIV
HBsAg positivity or hepatitis C infection with biopsy proven liver disease

smoking, drug abuse, alcohol abuse, severe psychiatric illness, noncompliance with medical care, extreme obesity, progressive unintentional weight loss, malnutrition, and absence of a consistent and reliable social support network.<sup>29</sup> Relative contraindications include active extrapulmonary infection, symptomatic osteoporosis, and recent history of active peptic ulcer disease. Cigarette smokers must quit smoking and remain abstinent for several months before transplantation. Patients with histories of previous thoracic surgery are evaluated on a case-by-case basis. For patients who require systemic corticosteroids, tapering to the lowest tolerable level, preferably below 10 mg/day, is critical to prevent airway healing complications. Finally, mechanical ventilation is generally considered a contraindication to transplantation; repeated studies have shown that these patients have significantly worse immediate and long-term survival after transplantation.<sup>39</sup> It is important that recipient candidates be educated about lifestyle modifications necessary for the success of a transplant, and willingness to comply with immunosuppression regimens and extensive posttransplant medical and surgical follow-up is mandatory.

### Recipient Management After Listing

It is essential that a candidate's medical condition be optimized before transplantation. Supplemental oxygen is recommended for any patient exhibiting arterial hypoxemia, defined as either an arterial oxygen saturation less than 90% or an arterial PO<sub>2</sub> less than 60 mm Hg at rest, during exertion, or while asleep. Fluid balance is optimized with restriction of dietary water and salt in conjunction with diuretic therapy. Care must be taken with the use of loop diuretics, as these can incite a metabolic alkalosis that can impair the effectiveness of plasma carbon dioxide as a stimulus for breathing.

Primary pulmonary hypertension often requires the use of supplemental oxygen to prevent hypoxia-induced pulmonary vasoconstriction and secondary erythropoiesis. Pulmonary vasodilator therapy with the use of calcium channel blockers and continuous prostacyclin infusions presents another therapeutic option in the management of these patients.<sup>40</sup> Although these drugs exhibit potent systemic effects and must be used with caution, the response rate for calcium channel blockers is approximately 20%. Although a favorable response to short-acting vasodilators during cardiac catheterization is predictive of a successful response to calcium channel therapy, this trend is not seen in long-term prostacyclin infusion.

Interstitial lung disease in patients awaiting transplantation results from a wide variety of diffuse inflammatory processes such as sarcoidosis, asbestosis, and collagen-vascular diseases. Increases in pulmonary vascular resistance leading to right-sided heart failure are thought to arise from interstitial inflammatory infiltrates that entrap and eventually destroy septal arterioles, thus reducing the distensibility of the remaining pulmonary vessels.<sup>41</sup> This process, coupled with closure of peripheral bronchioles, results in arterial hypoxemia, further

aggravating pulmonary hypertension. Corticosteroids are the mainstay of treatment in this class of diseases. The adverse effects of steroids on airway healing are well established,<sup>6,42</sup> and mandate significant dose reductions in anticipation of transplantation.

The multisystem manifestations of CF, particularly chronic bronchopulmonary infection, malabsorption, malnutrition, and diabetes mellitus, pose difficult management problems in potential transplant recipients. These patients require aggressive chest physiotherapy, antibiotics, enteral or parenteral nutritional supplementation, and tight serum glucose control.<sup>43</sup>

## Organ Procurement and Preservation

### DONOR SELECTION

Standard criteria have been established for donor selection (Table 61-5).<sup>44,45</sup> Donors must have sustained irreversible brain death, but owing to the susceptibility of the lungs to edema and infection in the setting of brain death and trauma, suitable organs are often difficult to obtain (available in <20% of all organ donors).

Initial donor evaluation consists of a directed history and physical examination, chest x-ray, 12-lead ECG, arterial blood gases, and serologic screening including human immunodeficiency virus (HIV), hepatitis B surface antigen, hepatitis C antibodies, herpes simplex virus, cytomegalovirus (CMV), *Toxoplasma*, and RPR. A donor age of less than 50 years is preferred. The chest x-ray should be clear and the arterial PO<sub>2</sub> should exceed 140 mm Hg on an FiO<sub>2</sub> of 40% and 300 mm Hg on an FiO<sub>2</sub> of 100%. Lung compliance can be estimated by measuring peak inspiratory pressures, which should be less than 30 cm H<sub>2</sub>O. Bronchoscopy should ensure the absence of purulent secretions or signs of aspiration. Finally, direct inspection and palpation of the lungs at explantation to verify full expansion of any atelectatic segments is an essential part of the donor organ evaluation.

Absolute contraindications to donation include prolonged cardiac arrest (30 minutes), arterial hypoxemia, active

**TABLE 61-5: Donor Selection Criteria**

Age < 40 (heart-lung), <50 (lung)
Smoking history less than 20 pack-years
Arterial PO <sub>2</sub> of 140 mm Hg on an FiO <sub>2</sub> of 40% or 300 mm Hg on an FiO <sub>2</sub> of 100%
Normal chest x-ray
Sputum free of bacteria, fungus, or significant numbers of white blood cells on Gram and fungal staining
Bronchoscopy showing absence of purulent secretions or signs of aspiration
Absence of thoracic trauma
HIV-negative

malignancy (excluding basal cell and squamous cell carcinoma of the skin), and positive HIV status. Relative contraindications include thoracic trauma, sepsis, significant smoking history, prolonged severe hypotension (ie, <60 mm Hg for >6 hours), HBsAg or hepatitis C antibodies, multiple resuscitation attempts, and a prolonged high inotropic requirement (eg, dopamine in excess of 15  $\mu\text{g}/\text{kg}/\text{min}$  for 24 hours). It is important to rule out correctable metabolic or physiologic causes of cardiac rhythm disturbances and electrocardiographic anomalies (eg, brain herniation, hypothermia, hypokalemia).

Over the last decade, there has been a trend toward liberalization of standard donor selection criteria. This strategy, initiated in response to the shortage of donor organs, is employed at a large number of transplant centers.<sup>46-50</sup> Donors ranging in age from 50 to 64 years have been used in thoracic transplantation with good long-term graft survival.<sup>47</sup> However, reports from the ISHLT document worse outcomes in recipients of lung allografts from donors older than 55 years who had ischemic times greater than 6 to 8 hours.<sup>51</sup> In this group of recipients, long-term survival is impaired and the risk of developing bronchiolitis obliterans is increased. Smoking history is another criterion that has been liberalized, with conventional guidelines limiting donor selection to patients with less than 20 pack-years. Modified criteria allow for a more extensive smoking history, assuming there is no evidence of COPD or other lung disease on screening tests.

Traditionally, donor lungs have been ruled out for transplantation based on evidence of infection. In that regard, prolonged ventilation before brain death and procurement has been viewed as a contraindication for organ selection. However, a positive sputum Gram stain (excluding fungus), which was once considered a basis for ruling out an organ has failed to predict the development of early pneumonia, impairment of oxygenation, or duration of mechanical ventilation in the postoperative setting.<sup>52,53</sup> Some groups have accepted donors with small pulmonary infiltrates on chest x-ray, although clinical correlation is necessary. Others have selectively used donor lungs in patients with  $\text{PaO}_2$  less than 300 mm Hg on  $\text{FiO}_2$  of 100%. Gabbay and coworkers in Australia have adopted an aggressive approach to donor management and “organ resuscitation.”<sup>48</sup> By manipulating donors with antibiotic therapy, chest physiotherapy, careful fluid management, ventilator adjustments, and bronchial toilet, 34% of donors with an initial  $\text{PaO}_2$  less than 300 mm Hg on  $\text{FiO}_2$  of 100% had increases in their  $\text{PaO}_2$ , becoming acceptable donors.

Two exciting and rapidly evolving areas in the field of donor organ procurement include the use of allografts obtained from donors after cardiac death (DCD) and rehabilitation of rejected organs using ex vivo lung perfusion (EVLP).

In 2001, Steen and colleagues reported the first clinical lung transplant from a DCD donor (also known as a non-heart-beating donor). After a 54-year-old man expired from an acute myocardial infarction with failed resuscitation, his

next-of-kin consented to lung donation based on the patient's prior wishes. The organ was removed and assessed ex vivo before being transplanted into a 54-year-old woman with COPD.<sup>54</sup> The authors reported good functional results during the first 5 months of follow-up. This landmark report not only introduced an era of DCD lung transplantation, but also the clinical application of EVLP.

Unlike an allograft obtained from a donor after brain death (DBD), lungs from a non-heart-beating donor are exposed to a prolonged period of warm-ischemic time, in which varying degrees of hypotension and shock precede organ cooling and harvest and have unknown consequence on donor organ function. EVLP began as a tool to assess the functional status of DCD lungs and ultimately evolved into a mechanism to both assess and rehabilitate the donor allografts. In 2007, Steen and colleagues reported the first use of EVLP to not only evaluate a previously rejected donor lung, but to actually rehabilitate the discarded organ until, by all conventional measures, it was deemed suitable for transplantation.<sup>55</sup> Again, their experiment resulted in a landmark report demonstrating good functional outcomes after EVLP was utilized to rehabilitate and transplant a rejected donor organ.

By employment of a hyperoncotic perfusate, with carefully selected components to suit the metabolic needs of the lung, Steen's group demonstrated the ability to reduce interstitial edema, improve pulmonary vascular resistance, and increase gas exchange until the donor organ met the criteria for transplantation. Others around the world, most notably Keshavjee's group in Toronto, Canada, have contributed to the immense progress in advancing the techniques for EVLP.<sup>56,57</sup> Multiple reports have demonstrated excellent clinical outcomes.<sup>57-59</sup>

With as many as 40% of the total rejected donor lungs having only minimal microbiologic, physiologic, or histologic deficiencies, there is an incredible potential for organ rescue and significant increase in the donor pool.<sup>60</sup> Ongoing research and long-term outcomes data are highly anticipated, yet the impact of this technology is already clinically apparent and is rapidly spreading throughout the world.

## DONOR MANAGEMENT

The overriding goal in managing the thoracic organ donor is to maintain hemodynamic stability and pulmonary function. Patients suffering from acute brain injury are often hemodynamically unstable because of neurogenic shock, excessive fluid losses, and bradycardia. Donor lungs are prone to neurogenic pulmonary edema, aspiration, nosocomial infection, and contusion. Continuous arterial and central venous pressure monitoring, judicious fluid resuscitation, vasopressors, and inotropes are usually required.

Intravascular volume replacement should be limited to maintain the central venous pressure between 5 and 8 mm Hg. In general, crystalloid fluid boluses are to be avoided.

Diabetes insipidus is common in donors and requires the use of intravenous vasopressin (0.8 to 1.0 unit/h) to prevent excessive urine loss. Dopamine is the standard inotropic agent used to maintain adequate perfusion pressures, although alpha agonists (eg, phenylephrine) are often appropriate. Blood transfusions should be used sparingly to maintain a hemoglobin concentration of approximately 10 g/dL, ensuring adequate myocardial oxygen delivery. CMV-negative and leukocyte-filtered blood should be used whenever possible. Hypothermia should be avoided as it predisposes to ventricular arrhythmias and metabolic acidosis.

With regard to mechanical ventilation,  $F_{iO_2}$  values in excess of 40%, especially 100% oxygen “challenges,” should be avoided, because these oxygen levels may be toxic to the denervated lung. Ventilator settings should include positive end-expiratory pressures (PEEP) between 3 and 5 cm  $H_2O$  to prevent atelectasis.

### DONOR OPERATION

The donor operation is performed via a median sternotomy (Fig. 61-6A). After the sternum is divided, a standard chest retractor is placed, and both pleural spaces are opened followed by immediate inspection of the lungs and pleural spaces, particularly in cases involving trauma. The lungs are briefly deflated, and the pulmonary ligaments are divided inferiorly using electrocautery. After completely excising the thymic remnant, the pericardium is opened vertically and laterally on the diaphragm and cradled during dissection of the great vessels and trachea. The ascending aorta, pulmonary artery, and venae cavae are dissected. Umbilical tapes are placed around the ascending aorta and venae cavae (Fig. 61-6B). The pericardium overlying the trachea is incised vertically, and the trachea is encircled with an umbilical tape between the aorta and superior vena cava at the highest point possible and at least four rings above the carina (see Fig. 61-6B). The entire anterior pericardium is excised back to each hilum (Fig. 61-6C).

Approximately 15 minutes before applying the aortic cross-clamp, prostaglandin  $E_1$  ( $PGE_1$ ) is infused intravenously, initially at a rate of 20 ng/kg/min, followed by incremental increases of 10 ng/kg/min to a target rate of 100 ng/kg/min (Fig. 61-6D). During  $PGE_1$  infusion, the mean arterial blood pressure should be maintained at or above 55 mm Hg. Ventilation is continued with a  $F_{iO_2}$  of 40% and a PEEP of 3 to 5 cm  $H_2O$ . The donor is heparinized with 30,000 units. Cannulation of the aorta and main pulmonary artery is performed, with care taken to ensure adequate flow to both branches of the pulmonary artery during pulmonary plegia.<sup>61</sup> The superior vena cava is ligated and a transverse incision is made across the inferior vena cava. After the heart is allowed to empty, the aortic cross-clamp is applied, and 10 mL/kg of cold crystalloid cardioplegia, commonly the Stanford formulation, is rapidly infused into the aortic root with the bag under pressure at 150 mm Hg. The inferior vena cava is incised, and the

left atrial appendage is amputated to avoid cardiac distention. Although the antegrade cardioplegia is being delivered, Perfadex (Vitrolife Inc., Englewood, CO) is rapidly flushed into the main pulmonary artery at a rate of 15 mL/kg/min for 4 minutes. Ice-cold saline or Physiosol solution (Abbott Laboratories, North Chicago, IL) is immediately poured over the heart and lungs. During the cardioplegic and Perfadex infusions, ventilation is maintained with half-normal tidal volumes of room air.

After delivery of plegic solutions, the lungs are deflated and the great vessels are divided. The heart is reflected anteriorly and a left atriotomy is performed, leaving a 2-cm cuff of atrium around the pulmonary vein orifices. Once this division is complete, the heart is removed from the chest. The lung bloc is then dissected free along the preesophageal plane above the level of the carina. The lungs are inflated and the trachea is stapled at the highest possible point. If needed, the bilateral lung bloc can be further separated into left and right lung blocs. The left atrial cuff containing the orifices of the pulmonary veins is divided in half vertically. The left and right pulmonary arteries are divided at their junction. Finally, the left mainstem bronchus is stapled near its junction with the trachea.

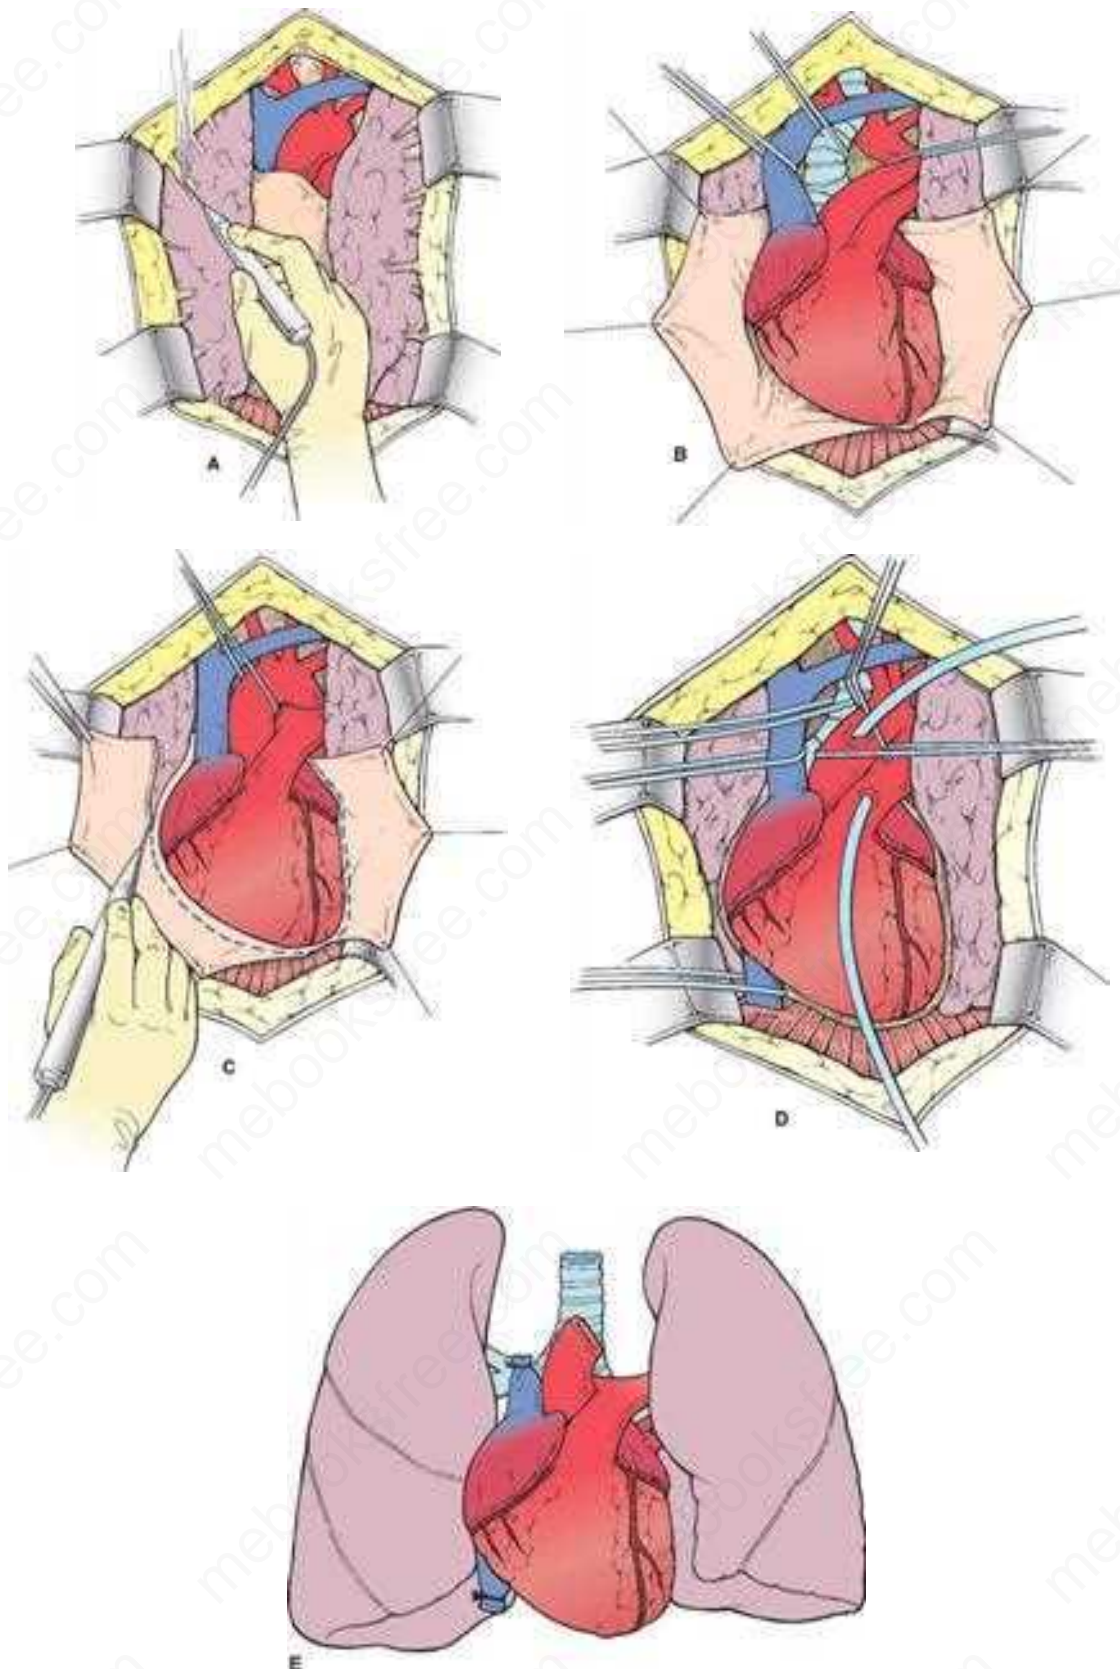

Once removed from the donor, grafts are wrapped in sterile gauze pads and immersed in ice-cold saline at 2 to 4°C in several sterile plastic bags placed within a sterile plastic container. This, in turn, is placed in an ice-filled chest and transported to the transplant center.

### ORGAN PRESERVATION AND TRANSPORT

The principal goal of preservation is to minimize injury to the allograft from ischemia and reperfusion.<sup>62</sup> Ischemia-reperfusion injury is mediated by reactive oxygen species, which disrupt the homeostatic mechanisms in myocytes and endothelial cells. As receptors for leukocyte adhesion molecules are upregulated and leukocyte chemotactic factors released, an inflammatory response ensues, leading to cellular injury. Several approaches for minimizing ischemia-reperfusion injury have developed, including donor pretreatment, use of specialized preservation solutions, and recipient treatments.

Hypothermia is considered by many to be the most important method of organ preservation. It works by reducing tissue metabolic demand by up to 99%. During explantation, organs are flushed with cold plegic solutions (0 to 10°C, depending on the institution and solution employed). Organs are stored at 0 to 10°C, and during implantation they are covered with gauze soaked in saline slush or recipients are cooled through CPB.

A variety of crystalloid pulmonary artery flush solutions are used worldwide, and they can be divided into two categories based on their electrolyte compositions: intracellular and extracellular. Intracellular solutions contain moderate-to-high concentrations of potassium and little calcium and sodium. Euro-Collins, University of Wisconsin (UW), and Cardiazol are examples. Extracellular

**FIGURE 61-6** Donor operation for heart-lung transplantation. (A) Through a median sternotomy, adhesions are lysed and the pulmonary ligaments are divided inferiorly. (B) The pericardium is opened and cradled followed by dissection of the ascending aorta, venae cavae, pulmonary artery, and trachea. (C) The entire anterior pericardium is excised back to each hilum. (D) Cardioplegia and pulmonoplegia are infused simultaneously into the aorta and main pulmonary artery after aortic cross-clamping. Application of topical cold Physiol follows immediately. (E) The venae cavae and aorta are divided, and the heart-lung bloc is dissected free from the esophagus and posterior hilar attachments. After the trachea is stapled and divided at the highest point possible, the entire heart-lung bloc is removed from the chest.

solutions contain high concentrations of sodium and low-to-moderate concentrations of potassium. Low-potassium dextran is an example of this type of solution (eg, Perfadex). Although Euro-Collins is the most frequently used preservation solution, there is a growing body of evidence in support of low potassium, dextran-containing extracellular solutions.<sup>63-65</sup>

Prostaglandins are commonly used for donor pretreatment and as an additive in pulmonary flush solutions. The administration of PGE<sub>1</sub> (a potent vasodilator) counteracts reflex pulmonary vasoconstriction induced by the cold flush and permits uniform distribution of perfusate throughout the lung. Studies in large animals also suggest that PGE<sub>1</sub> treatment may minimize reperfusion injury through its antiinflammatory properties.<sup>66</sup> Another commonly used pretreatment strategy is steroid treatment. Administration of intravenous methylprednisone to the donor inactivates lymphocytes, which are thought to mediate ischemic lung graft injury.

Studies suggest that lung graft function is improved when the explanted organ is inflated, 100% oxygen is used for the inflation, and transport is carried out at 10°C.<sup>67</sup> Research in the field of lung preservation has recently focused on the role of various flush and storage solution additives, such as antioxidants, which may act as free radical scavengers. Other additives shown to decrease reperfusion injury in research models include nitric oxide donors and phosphodiesterase inhibitors. Areas of ongoing research include the development of leukocyte depletion strategies, examining the role of gene therapy to modify donor organ susceptibility to ischemia-reperfusion injury, and the development of colloid-based perfusates.

These preservation techniques, coupled with streamlined donor and recipient protocols, have permitted procurements as far as 1000 miles from the transplant center. Extensive communication and coordination must be maintained between the organ procurement agency, donor-recipient operative teams, medical centers, and abdominal procurement teams. Worldwide, the major procurement agencies include the UNOS in the United States, Multiple Organ Retrieval in Canada, and the EURO Transplant Organization in Europe.

## Recipient Operation

The recipient operation proceeds in two phases. The first is excision of the native organ(s) and the second is implantation of the allograft. Cardiopulmonary bypass is occasionally required for lung transplantation. Regardless, CPB should be available as standby at all times. In our practice, we have favored the use of CPB during bilateral lung transplantation for a variety of reasons. There is improved exposure of the hilar structures, which is particularly helpful in patients with dense adhesions and bronchial collaterals. CPB allows for early pneumonectomies without hemodynamic or respiratory instability, and ischemic time

of the second lung is substantially reduced compared with off-CPB bilateral lung transplants. Its use also prevents overperfusion of the first lung graft with the entire cardiac output. In patients with suppurative lung disease, the use of CPB facilitates careful washout of the distal trachea and proximal bronchi to prevent contamination of the first implanted lung. Others prefer to avoid CPB, as it may be associated with increased blood loss, transfusion needs, and reperfusion injury. More detailed experimental and clinical studies are needed to resolve these questions. At present, the need for CPB should be determined on a case-by-case basis.

Anesthetic monitoring includes arterial pressure monitoring, pulse oximetry, continuous electrocardiography, pulmonary artery catheter monitoring, temperature monitoring, and urine output monitoring. The use of double-lumen endotracheal tubes is particularly helpful, allowing for single-lung ventilation during certain portions of the dissection. Large-bore intravenous lines are placed for volume infusion. Transesophageal echocardiography is often performed during the procedure.

## SINGLE LUNG TRANSPLANTATION

If possible, the poorer functioning lung (as determined by preoperative ventilation-perfusion scan) is selected for replacement. The patient is placed in a standard thoracotomy position with access to the groin, should CPB be needed. A posterolateral thoracotomy is made at the level of the fourth or fifth intercostal space. Adhesions are lysed and the hilar dissection performed. The pulmonary artery, the superior and inferior pulmonary veins, and the mainstem bronchus are isolated. A trial occlusion of the pulmonary artery is used to determine whether the procedure can be conducted without CPB. If the occlusion is tolerated, the pulmonary artery is ligated and divided distal to the upper lobe branch. The pulmonary veins are also ligated and divided. The mainstem bronchus is stapled and divided, and the native lung is explanted.

The donor lung is removed from its transport container and prepared for implantation. The donor bronchus is opened and secretions are aspirated and cultured. The bronchus is trimmed, leaving two cartilaginous rings proximal to the orifice of the upper lobe. Any remaining pericardial and lymphatic tissue is removed, and the left atrial cuff is trimmed as needed. The donor lung is then placed in the recipient's chest and covered with saline slush and iced laparotomy pads.

The sequence of anastomoses is a matter of preference, although most perform the deepest anastomosis (the bronchial anastomosis) first and then proceed to the more superficial ones. The bronchial anastomosis is fashioned with 4-0 polypropylene suture. We favor a continuous suture technique for the entire anastomosis, although the membranous portion can be sewn with interrupted suture. Variations on the end-to-end bronchial anastomosis include the use of a telescoping technique, in which the donor bronchus is intussuscepted

into the recipient bronchus, and an omental pedicle flap is placed around the anastomosis. These techniques were developed to prevent bronchial anastomotic dehiscence but are now rarely performed.

Once the bronchial anastomosis is complete, attention is turned to the anastomoses of the pulmonary veins. A side-biting clamp is applied to the left atrium to include the pulmonary veins. The recipient pulmonary vein stumps are opened and the intervening atrial tissue is cut. This creates a cuff that is anastomosed to the donor atrial remnant using continuous 4-0 polypropylene suture. (This suture is not tied down until reperfusion.) Donor and recipient pulmonary arteries are anastomosed with 5-0 polypropylene suture. Arteries must be trimmed to an appropriate length before fashioning the anastomosis, because kinking can occur upon graft inflation if the vessels are left too long. The pulmonary artery anastomosis is then de-aired. The lung is inflated, and the pulmonary artery clamp is temporarily released to allow flushing of air through the atrial suture line. The left atrial clamp is removed to allow retrograde de-airing of the atrial anastomosis. The pulmonary venous anastomosis is then secured.

After hemostasis is ensured, apical and basal chest tubes are inserted. The ribs are reapproximated and the chest is closed in standard fashion. The double lumen endotracheal tube is exchanged for a single-lumen tube and bronchoscopy is performed to evaluate the bronchial anastomosis.

## BILATERAL LUNG TRANSPLANTATION

Bilateral lung transplantation is performed as sequential single-lung transplants. Although the traditional approach to this technique has been to access the chest via bilateral anterior thoracosternotomy (clamshell) incisions, we have recently transitioned our practice to a median sternotomy approach. The lung with the least amount of function (as determined by a preoperative ventilation-perfusion scan) is removed first and replaced with an allograft as described for SLT above. Once ventilation and perfusion are established in the first allograft, the remaining lung is explanted and the second allograft is implanted. Bilateral chest tubes are placed and the chest is closed. Bronchoscopy is performed to evaluate the bronchial anastomoses.

Although single-lung transplants are usually performed off CPB, the majority of double-lung transplants are still performed on-pump. The use of CPB allows for improved exposure, shorter graft ischemic times, controlled reperfusion, and the use of leukocyte-depleting filters. As the risk of bleeding may be increased with CPB, strategies have been developed to minimize the chance of hemorrhage. These include the use of heparin-coated CPB circuits as well as the argon beam coagulator. Despite these maneuvers, there remains considerable risk associated with CPB, and many centers prefer to perform all lung transplants off-pump if possible.

## Postoperative Management

### GRAFT PHYSIOLOGY

Denervation of the lungs results in a diminished cough reflex and impairment of mucociliary clearance mechanisms. This predisposes recipients to pulmonary infections and necessitates aggressive postoperative pulmonary toilet.<sup>68</sup> Moreover, in the transplanted lung, ischemia-reperfusion injury, along with disrupted pulmonary lymphatics, may result in increased vascular permeability with varying degrees of interstitial edema.

### CLINICAL MANAGEMENT IN THE EARLY POSTOPERATIVE PERIOD

Early postoperative management centers around careful fluid balance and ventilatory management. The primary objective in the immediate postoperative period is to maintain adequate perfusion and gas exchange while minimizing intravenous fluid administration, cardiac work, and barotrauma. Barotrauma and high airway pressures can compromise bronchial mucosal flow. Therefore, lower tidal volumes and flow rates may be necessary to limit peak airway pressures to less than 40 cm H<sub>2</sub>O. After arrival in the ICU, ventilator settings are adjusted every 30 minutes to achieve an arterial PO<sub>2</sub> greater than 75 mm Hg on an FIO<sub>2</sub> of 40%, an arterial carbon dioxide pressure (PaCO<sub>2</sub>) between 30 and 40 mm Hg, and a pH between 7.35 and 7.45. Pulmonary toilet with endotracheal suctioning is an effective means of reducing mucus plugging and atelectasis. Ventilatory weaning is initiated after the patient is stable, awake, and alert, with extubation typically achieved within 24 hours. Subsequent pulmonary care consists of vigorous diuresis, supplemental oxygen for several days, continued aggressive pulmonary toilet, incentive spirometry, and serial chest x-rays.

A diffuse interstitial infiltrate is often found on early postoperative chest x-rays. Previously referred to as a *reimplantation response*, this finding is better defined as graft edema owing to inadequate preservation, reperfusion injury, or early rejection.<sup>69</sup> It appears that the degree of pulmonary edema is inversely related to the quality of preservation. Judicious administration of fluid and loop diuretics is required to maintain fluid balance and minimize this pulmonary edema.

Early lung graft dysfunction occurs in less than 15% of transplants, and is manifest as persistent marginal gas exchange without evidence of infection or rejection.<sup>70</sup> This primary graft failure often results from ischemia-reperfusion injury and histologically evident as diffuse alveolar damage. Of course, technical causes of graft failure such as pulmonary venous anastomotic stenosis or thrombosis must always be considered. In cases of persistent, severe pulmonary graft dysfunction refractory to mechanical ventilatory maneuvers, ECMO<sup>71</sup> and inhaled nitric oxide<sup>72</sup> have been used successfully to stabilize gas exchange. Urgent retransplantation can also be considered if other interventions fail.

## IMMUNOSUPPRESSIVE MANAGEMENT: EARLY AND LATE POSTOPERATIVE REGIMENS

Immunosuppression protocols vary from center to center. In our practice, we typically administer induction therapy of either rabbit antithymocyte globulin (RATG) at a dose of 1.5 mg/kg on POD 1, 2, 3, 5, and 7 or daclizumab at 1 mg/kg (first dose given in OR then every other week for four additional doses). For highly sensitized patients, plasmapheresis with a 1:1.5 volume exchange with fresh-frozen plasma (FFP) is performed intraoperatively, along with intravenous immunoglobulin (IVIG), which is started at 2 g/kg before releasing the cross-clamp. Methylprednisolone is given at 500 mg IV after protamine administration, and a stat retrospective cross-match is performed.

On POD 1, T- and B-cell subset counts are performed and if the cytotoxic crossmatch is positive, RATG is given in 2 doses at 0.75 mg/kg. If the crossmatch is negative or pulmonary edema is present or expected from RATG, daclizumab is administered at 1 mg/kg and repeated every 14 days for a total of five doses. Methylprednisolone is given at 125 mg IV every 8 hours for three doses, CellCept is given at 500 mg PO BID, and Prograf is given at 0.5 mg BID and titrated to a level of 12 to 15 ng/mL. On POD 2, prednisone is started at 0.5 mg/kg PO BID. Hereafter, the patient is maintained on prednisone, Prograf, and CellCept. For sensitized patients, plasmapheresis is repeated in a 1:1.5 volume exchange with 1/2 5% albumin and 1/2 FFP. If the patient was given RATG, a second dose of 0.75 mg/kg is administered. Otherwise, IVIG 100 mg/kg is given. Plasmapheresis is repeated on POD 3 and 4, along with IVIG at 100 mg/kg. Plasmapheresis is completed on POD 5, with administration of IVIG at 1 g/kg on POD 5 and 6. A donor-specific antibody is sent before IVIG on POD 5 and after IVIG on POD 6. Finally, on POD 7 T- and B-cell subset counts are measured (and repeated weekly thereafter) along with administration of Rituximab for two doses with one dose of 375 mg/m<sup>2</sup> given at POD 7 and a second dose given a week later.

## INFECTION PROPHYLAXIS

Antiviral and antifungal prophylaxis remain important components of the postoperative management strategy in heart-lung and lung transplant recipients. Many centers employ CMV prophylaxis with ganciclovir for any CMV-positive recipient and in any CMV-negative recipient receiving an allograft from a CMV-positive donor. Ganciclovir is typically given for a several week course, and can be associated with leukopenia. Some patients may require G-CSF if their white blood cell count falls below 4000. Fungal prophylaxis against mucosal candida infection includes use of itraconazole and nystatin swish and swallow. *Pneumocystis carinii* prophylaxis consists of trimethoprim-sulfamethoxazole or aerosolized pentamidine. In the immediate postoperative period, *Aspergillus* colonization is inhibited by the use of aerosolized amphotericin B. For *Toxoplasma*-negative recipients of grafts from *Toxoplasma*-positive patients,

pyrimethamine prophylaxis is maintained for the first 6 months after transplantation.

## GRAFT SURVEILLANCE: PATIENT FOLLOW-UP SCHEDULE

Routine clinical follow-up is required to monitor graft function and modify immunosuppressive regimens. Regular surveillance protocols developed to monitor graft function typically consist of serial pulmonary function tests, arterial blood gases, and bronchoscopic evaluation. Surveillance is usually conducted at 2, 4 to 6, and 12 weeks, followed by 6 months after transplantation and yearly thereafter. Transbronchial biopsies are obtained from each transplanted lung, and lavage specimens are submitted for staining (ie, Gram, fungal, acid-fast bacillus, silver), culture, and cytology. In addition to routine surveillance, follow-up is often needed to address changes in clinical status. Complications related to transplantation are many, and these must be addressed carefully and expediently to prevent long-term graft failure.

## Postoperative Complications

Early morbidity and mortality after lung transplantation (within 30 days of operation or before initial discharge from hospital) are most commonly a result of primary graft failure or infection. Late mortality is most commonly caused by OB or infection.<sup>73</sup> Causes of death at various time points after transplantation have been compiled by the ISHLT and are presented in Fig. 61-7.

## HEMORRHAGE

Perioperative hemorrhage is an infrequent but significant cause of early death in heart-lung and lung transplantation. The majority of perioperative hemorrhagic complications stem from operating in the midst of dense adhesions caused by previous operations or inflammation from chronic lung infection. As mentioned previously, meticulous attention to hemostasis is mandatory, and all available means should be used to achieve a dry field on completion of the operation.

## HYPERACUTE REJECTION

ABO matching of donor and recipient has decreased the rate of hyperacute rejection. This complication, which is almost universally fatal, is mediated by preformed antibodies in the recipient that recognize antigens on the donor vascular endothelium. This humoral immune response results in activation of inflammatory and coagulation cascades, resulting in extensive thrombosis of graft vessels and subsequent graft failure.<sup>74</sup> To reduce the incidence of hyperacute rejection, a prospective crossmatch should be performed in recipients with a PRA greater than 25%.

**FIGURE 61-7** Causes of death at various periods after isolated lung transplantation. Infection is the major cause of death in the first year after transplant, while bronchiolitis obliterans syndrome is the major cause of death after the early post-transplant period. (Data from Yusen RD, Edwards LB, Kucheryavaya AY, et al: The registry of the International Society for Heart and Lung Transplantation: thirty-first adult lung and heart-lung transplant report—2014; focus theme: retransplantation, *J Heart Lung Transplant*. 2014 Oct;33(10):1009-1024.)

### EARLY GRAFT DYSFUNCTION AND PRIMARY GRAFT FAILURE

Graft dysfunction in the first few days after transplantation is common. It is often referred to as the “reimplantation response,” manifest by abnormal lung function, pulmonary edema, and pulmonary infiltrates on chest x-ray. This phenomenon is thought to be linked to ischemia and reperfusion. Other contributing factors may also include allograft contusion, inadequate preservation, or use of cardiopulmonary bypass during transplantation. Although most cases are mild and resolve with supportive care, some progress to primary graft failure. Reported rates of primary graft failure following lung transplantation range between 10 and 15%. Treatment may include the use of ECMO and inhaled nitric oxide. Unfortunately, primary graft failure is associated with a mortality of more than 60%.<sup>70</sup>

### ACUTE REJECTION

As in cardiac transplantation, the majority of acute rejection episodes occur within the first year after transplant at a rate of 36%.<sup>25</sup> Despite its prevalence, death is very rarely a direct consequence of acute rejection. It is recognized, however, that the number and severity of acute rejection episodes is a risk factor for ultimately developing obliterative bronchitis (OB).

Diagnosis of acute rejection in the early posttransplant period is often based on clinical parameters. Symptoms and signs of rejection include fever, dyspnea, impaired gas exchange (manifest as a decrease in arterial  $PO_2$ ), a diminished forced expiratory volume during 1 second ( $FEV_1$ , a measure

of airway flow), a fall in vital capacity (VC), and the development of characteristic bilateral interstitial infiltrates on chest x-ray (Fig. 61-8). After the first postoperative month, the chest x-ray is frequently normal during episodes of acute rejection, placing greater emphasis on other clinical parameters characteristic of rejection.

It is often difficult to distinguish between the diagnosis of acute lung rejection and pulmonary infection based on clinical findings alone. It is of paramount importance to distinguish between acute rejection and infection before initiating therapy. Fiberoptic bronchoscopy (with transbronchial parenchymal lung biopsy and bronchoalveolar lavage) is the gold standard for the diagnosis of acute lung rejection and pulmonary infection. At least five biopsy specimens are taken from the lung allografts along with bronchoalveolar lavage, which is evaluated for cytology, undergoes microbial staining, and is cultured.<sup>75</sup> In addition to performing bronchoscopy with transbronchial biopsy in response to changes in clinical status and graft performance, most centers maintain a schedule of surveillance biopsies for lung recipients. Interestingly, surveillance bronchoscopy reveals occult rejection or infection in 17 to 25% of transbronchial biopsy specimens from asymptomatic recipients. For patients undergoing bronchoscopy because of a change in clinical condition, 50 to 72% of biopsy specimens have shown evidence of rejection or infection. In most cases, positive biopsies directly guide successful treatment of rejection or infection.<sup>76,77</sup> Acute lung rejection is histologically characterized by lymphocytic perivascular infiltrates (Fig. 61-9). A grading scheme for acute lung rejection was developed by Clelland and Colin<sup>78</sup> and is presented in

**FIGURE 61-8** Acute and resolving lung rejection. (A) Chest radiograph illustrates bilateral infiltrates characteristic of acute pulmonary rejection. (B) Follow-up radiograph after pulsed methylprednisolone treatment of acute rejection demonstrating resolution of infiltrates.

Table 61-6; a similar scheme was also developed by the Lung Rejection Study Group.<sup>75</sup>

As in cardiac transplantation, efforts are being made to develop noninvasive ways of diagnosing early acute lung rejection. Loubeyre and coworkers at the Hôpital Cardiovasculaire et Pneumologique report an association between “ground-glass” density areas seen on high-resolution computed tomography (HRCT) and histologically confirmed

**FIGURE 61-9** Moderate acute lung rejection. Moderate rejection is characterized by perivascular mononuclear cell infiltrates with extension into the adjacent alveolar septa (H&E stain;  $\times 200$ ).

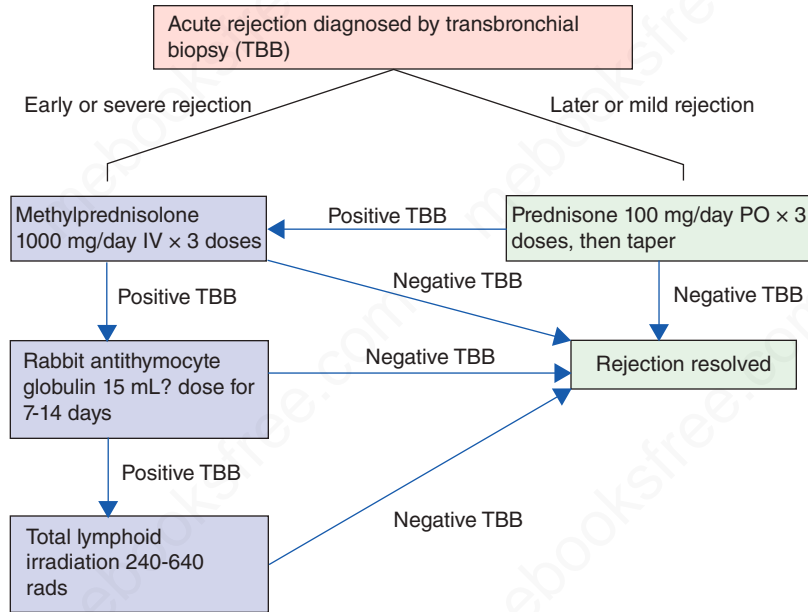

acute lung rejection in heart-lung transplant recipients.<sup>79</sup> They found that ground-glass opacities on HRCT had a sensitivity of 65% for detecting lung rejection and a specificity of 85% for detecting an acute lung complication.

Treatment strategies for rejection involve augmentation of immunosuppression. At most institutions, the timing and severity of rejection episodes dictate therapy. A typical algorithm is shown in Fig. 61-10. Rejection episodes that are graded moderate or severe are treated with a “steroid pulse” (intravenous methylprednisolone 500 to 1000 mg/day for three consecutive days), followed by augmentation of the oral prednisone maintenance dose to 0.6 mg/kg/day. This maintenance dose is then tapered to 0.2 mg/kg/day over 3 to 4 weeks. Clinical and radiographic improvement

**TABLE 61-6: Grading System for Acute Lung Rejection**

Grade	Histologic Appearance (Transbronchial Biopsy)
0	No significant inflammation; normal specimen
1	Small, infrequent perivascular infiltrates with or without bronchiolar lymphocytic infiltrates
2	Larger, more frequent perivascular lymphocytic infiltrates with or without moderate bronchiolar lymphocytic inflammation; occasional neutrophils and eosinophils
3	Extension of infiltrates into alveolar septa and alveolar spaces with or without bronchiolar mucosal ulceration

**FIGURE 61-10** Typical algorithm for treating acute rejection in heart-lung and lung transplant recipients.

(see Fig. 61-8B) after steroid therapy is often dramatic, rapid, and considered confirmatory of rejection. Mild episodes are initially treated by increasing oral prednisone dose, followed by a gradual taper over 3 to 4 weeks. Transbronchial biopsies are repeated 10 to 14 days following antirejection therapy to assess efficacy. Recurrent rejection episodes may be treated by a second steroid pulse and taper. Acute rejection refractory to steroid therapy may be treated with antilymphocyte preparations. Alternatively, primary immunosuppression may be switched between cyclosporine- and tacrolimus-based therapy. Finally, in especially difficult cases of persistent rejection, total lymphoid irradiation may be useful.<sup>80</sup>

**CHRONIC REJECTION**

Chronic lung allograft rejection poses the greatest limitation to the long-term benefits of lung transplantation. Chronic lung rejection most commonly presents as OB. The onset of OB typically occurs after the first 6 months to 1 year after transplantation, with a steadily increasing incidence thereafter. Recent data demonstrate that 50% of lung recipients are diagnosed with OB by the fifth postoperative year<sup>81</sup> (Fig 61-11).

Transbronchial biopsies remain the “gold standard” for diagnosing OB. The sensitivity of transbronchial biopsy for

**FIGURE 61-11** Adult lung transplant recipient freedom from bronchiolitis obliterans syndrome (BOS), conditional on survival to 14 days (transplant follow-ups: April 1994 to June 2013). The dashed green line shows the 95% confidence intervals. (Data from Yusen RD, Edwards LB, Kucheryavaya AY, et al: The registry of the International Society for Heart and Lung Transplantation: thirty-first adult lung and heart-lung transplant report—2014; focus theme: retransplantation, *J Heart Lung Transplant.* 2014 Oct;33(10):1009-1024.)

detecting OB has been reported between 17 and 87%.<sup>76,82</sup> Diagnostic yield of the biopsy procedure is related to the number of specimens taken, and current recommendations advise taking at least five specimens from each transplanted lung. Clearly, OB is a patchy process and therefore a large number of samples will be falsely negative owing to sampling error.

OB is a histologic diagnosis and is characterized by dense eosinophilic, submucosal scar tissue that partially or totally obliterates the lumen of small (2-mm) airways, particularly the terminal and respiratory bronchioles (Fig. 61-12). The physiologic consequences are decreased arterial  $PO_2$ ,  $FEV_1$ ,  $FEF_{25-75}$  forced expiratory flow at 25 to 75% (midrange) of lung volumes, and  $FEF_{50}/FVC$  (ratio of  $FEF_{50}$  to forced vital capacity). A characteristic “bowing” of the expiratory limb of the flow-volume loop has also been associated with OB. Clinical symptoms may be nonspecific, and include cough and dyspnea with or without exertion. The term *bronchiolitis obliterans syndrome* (BOS) was developed to refer to patients who have clinical manifestations of OB with or without proven histologic characteristics (Table 61-7). A standardized working formulation for the clinical staging of BOS was established by the ISHLT and is based on the ratio of the current  $FEV_1$  to the best posttransplant  $FEV_1$ . Patients with a decline of 20% or greater in their  $FEV_1$  (in the absence of infection or other process) are diagnosed with BOS, irrespective of pathologic evidence of OB.<sup>74</sup>

Valentine and the Stanford group reported that measurements of small airway function (ie,  $FEF_{25-75}$ ,  $FEF_{50}/FVC$ ) are more sensitive indicators of BOS than the  $FEV_1$  in bilateral lung transplant recipients.<sup>83</sup> An  $FEF_{50}/FVC$  persistently below 0.7 for 6 consecutive weeks was the most sensitive predictor of OB. Approximately 50% of bilateral lung recipients with biopsy-proven OB developed a fall in their  $FEF_{50}/FVC$

**FIGURE 61-12** Bronchiolitis obliterans. Chronic airway rejection is characterized by luminal narrowing or replacement by dense eosinophilic collagenous scar tissue. Inflammatory cells may be seen in this case (H&E stain;  $\times 150$ ).

**TABLE 61-7: Working Formulation for Bronchiolitis Obliterans Syndrome**

0 <sub>a or b</sub>	No significant abnormality: $FEV_1$ 80% of baseline
1 <sub>a or b</sub>	Mild bronchiolitis obliterans syndrome: $FEV_1$ 66-80% of baseline
2 <sub>a or b</sub>	Moderate bronchiolitis obliterans syndrome: $FEV_1$ 51-65% of baseline

a = Without pathologic evidence of obliterative bronchiolitis;  
b = with pathologic evidence of obliterative bronchiolitis.

nearly 4 months before fulfilling the ISHLT working group criteria for BOS.

Experimental and clinical evidence suggests that the etiology of OB stems from the injury of the bronchial epithelium by one or more mechanisms. These include gastroesophageal reflux disease (GERD), infection (particularly CMV), chronic inflammation owing to impaired mucociliary clearance, and immunologic mechanisms.<sup>69</sup> These insults result in airway epithelial damage and, subsequently, an exaggerated healing response. Along with this injury, there is increased expression of major histocompatibility class II antigens in the bronchial epithelium. In a recent metaanalysis, Sharples and coworkers found that acute rejection is a risk factor for later development of OB.<sup>84</sup> In keeping with this finding is the association between BOS and decreased levels of immunosuppression (as may occur with noncompliance). Lymphocytic bronchitis and bronchiolitis were also closely associated with development of OB. CMV pneumonitis, other pulmonary infections, and HLA mismatching are also linked to the development of OB in small retrospective studies. Novick and coworkers reported on the relationship between OB, donor age, and graft ischemic times.<sup>51</sup> Using data from the ISHLT registry, they found a higher rate of OB at 3 years in recipients of grafts from donors greater than age 55 who were also subjected to 6 to 8 hours of ischemia. GERD has been recently proposed as a mechanism for the development of OB.<sup>85</sup> Up to 75% of patients have demonstrable postoperative reflux based on pH studies, which may result from intraoperative vagal damage, impaired cough and airway mucociliary clearance, immunosuppression, or preexisting GERD.<sup>86</sup> These patients have been shown to demonstrate a survival benefit as well as delayed onset of BOS after antireflux surgery in the postoperative setting.<sup>87,88</sup>

The current management of OB hinges on prevention, close surveillance, and immediate therapeutic intervention when patients become symptomatic or asymptomatic physiologic changes occur. Patients are encouraged to perform incentive spirometry to prevent microatelectasis of lungs that are deprived of native innervation, lack bronchial circulation, and have impaired mucociliary clearance mechanisms. Moreover, all recipients are instructed to contact their transplant center or primary care physician on development of

respiratory tract symptoms so that pulmonary function tests can be performed. Any alterations in  $FEF_{25-75}$ ,  $FEF_{50}/FVC$ , or specific changes in the flow-volume loop are indications for bronchoscopy with bronchoalveolar lavage and transbronchial biopsy, especially in the absence of infectious bronchitis or pulmonary edema.

Augmentation of immunosuppression is the mainstay of therapy for BOS. The prednisone dose is increased to 0.6 to 1.0 mg/kg/day and slowly tapered to 0.2 mg/kg/day while concomitantly optimizing cyclosporine and azathioprine dosing. Ganciclovir is reinstated during treatment for those patients at risk of reactivation CMV infection, and antimicrobial therapy is directed against any organisms isolated from bronchoalveolar lavage. Follow-up pulmonary function tests are performed. Pulmonary function can be stabilized in most patients, but significant improvement is uncommon. Unfortunately, relapse rates are greater than 50% and progressive pulmonary failure or infection because of increased immunosuppression are the most common causes of death in lung transplant patients after the second year.

Retransplantation is the only option for terminal respiratory failure secondary to OB. Although survival for patients undergoing retransplantation for OB is better than for those undergoing retransplantation for other reasons, it is still worse than survival of first-time transplant recipients. Novick and coworkers recently reported results from the Pulmonary Retransplant Registry.<sup>35</sup> They reviewed survival rates in 237 patients who underwent pulmonary retransplantation between 1985 and 1996. At 1, 2, and 3 years after retransplantation, survival was 47, 40, and 33%, respectively. Survival was higher in nonventilated, ambulatory patients and their freedom for OB was comparable to first-time transplant recipients. The authors conclude that pulmonary retransplantation should only be performed in carefully selected recipients who have a reasonable likelihood of long-term survival.

## AIRWAY COMPLICATIONS

Improvements in surgical technique and posttransplant management have resulted in a relatively low incidence of airway complications after lung transplantation. Nevertheless, up to 27% of cases are complicated by stenosis, necrosis, or dehiscence.<sup>89</sup> The avoidance of perioperative steroids has long been considered important in preventing airway complications. However, recent experimental and clinical evidence suggests that the detrimental effect of steroids may be overestimated.<sup>90</sup> The most common airway complications are partial anastomotic dehiscence and stricture. Such complications are usually diagnosed by bronchoscopy. Airway dehiscence is treated by reoperation or close observation and supportive care. Strictures are treated by balloon or bougie dilatation, often with stent placement.

## INFECTION

Bacterial, viral, and fungal infections are leading causes of morbidity and mortality in lung transplantation. The rate

of infection is higher in this transplant group compared with other solid organ transplant recipients. This may be related to the lung allograft's direct exposure to airway colonization and aspiration, as well as its impaired cough reflex and mucociliary clearance. The risk of infection and infection-related death peaks in the first few months after transplantation, declining to a low persistent rate thereafter. Posttransplant infections can be classified broadly into those that occur early or late after transplantation. Early infections, occurring within the first month after transplantation, are commonly bacterial (especially Gram-negative bacilli) and manifest as pneumonia, mediastinitis, urinary tract infections, catheter sepsis, and skin infections. In the late posttransplant period, opportunistic viral, fungal, and protozoan pathogens become more prevalent. The lungs, central nervous system, gastrointestinal tract, and skin are the usual sites of invasion.

Bacterial infections, particularly caused by Gram-negative bacteria, predominate during the early postoperative period. Between 75 and 97% of bronchial washings obtained from donor lungs before organ retrieval culture at least one organism.<sup>91</sup> Posttransplant invasive infections are frequently caused by organisms cultured from the donor. Conversely, bacterial infections developing in patients with septic lung disease, particularly CF, most commonly originate from the recipient's airways and sinuses. Treatment of bacterial infections generally involves characterization of the infective agent (eg, cultures, antibiotic sensitivities), source control (eg, catheter removal, debridement), and appropriate antibiotic regimens.

CMV infection occurs most often at 1 to 3 months after transplantation and presents either as a primary infection or reactivation of a latent infection. By definition, primary infection results when a previously seronegative recipient is infected through contact with tissue or blood from a seropositive individual. The donor organ itself is thought to be the most common vector of primary CMV infections. Reactivation infection occurs when a recipient who is seropositive prior to transplant develops clinical CMV infection during immunosuppressive therapy. Seropositive recipients are also subject to infection by new strains of CMV. Primary infection in previously seronegative recipients is generally more serious than reactivation or reinfection in seropositive patients.

Clinically, CMV infection has protean manifestations, including leukopenia with fever, pneumonia, gastroenteritis, hepatitis, and retinitis. CMV pneumonitis is the most lethal of these, with 13% mortality, and retinitis remains the most refractory to treatment. Diagnosis of CMV infection is made by direct culture of the virus from blood, urine, or tissue specimens, a fourfold increase in antibody titers from baseline, or characteristic histologic changes (ie, markedly enlarged cells and nuclei containing basophilic inclusion bodies). Most cases respond to ganciclovir and hyperimmune globulin.

CMV has been implicated as a trigger for OB69 as well as an inhibitor of cell-mediated immunity. CMV-negative

donors comprise less than 20% of the donor organ pool, and owing to organ scarcity, most transplant centers perform transplants across CMV serologic barriers using ganciclovir and/or hyperimmune globulin prophylactic protocols in CMV-positive donors and/ or recipients. A study by Valantine and coworkers found that the combined use of ganciclovir and hyperimmune globulin was superior to ganciclovir alone as prophylaxis against CMV. Moreover, the ganciclovir/hyperimmune globulin cohort had longer survival at 3 years and greater freedom from OB.<sup>92</sup>

Invasive fungal infections peak in frequency between 10 days and 2 months after transplantation. Treatment consists of fluconazole, itraconazole, or amphotericin B. Reichenspurner and coworkers have reported that the actuarial incidence and linearized rate of fungal infections was significantly reduced in recipients who received inhaled amphotericin prophylaxis.<sup>93</sup>

The institution of prophylaxis with oral trimethoprim-sulfamethoxazole (or inhalational pentamidine for sulfallergic patients) has effectively prevented *P. carinii* pneumonia. The risk of *Pneumocystis* infection is highest during the first year after transplant. However, as infections can also occur late after transplant, most centers recommend prophylactic therapy be continued for life.

Infection prophylaxis is composed of vaccinations, perioperative broad-spectrum antibiotics, and long-term prophylactic antibiotics. Pretransplant inoculations with pneumococcal and hepatitis B vaccines, as well as DPT boosters, are recommended. All transplant recipients should receive annual influenza vaccinations. Although perioperative antibiotic regimens vary widely between transplant centers, first-generation cephalosporins (eg, cefazolin) or vancomycin are commonly used. Long-term prophylaxis typically includes nystatin mouthwash, trimethoprim-sulfamethoxazole, aerosolized amphotericin B, and antivirals such as acyclovir or ganciclovir.

## NEOPLASM

Transplant recipients have a higher incidence of neoplasia than that of the general population.<sup>94</sup> This is undoubtedly due to chronic immunosuppression. Recipients are predisposed to a variety of tumors, including skin cancer, B-cell lymphoproliferative disorders, carcinoma in situ of the cervix, carcinoma of the vulva and anus, and Kaposi's sarcoma. On average, tumors appear approximately 5 years after transplantation.<sup>73</sup>

The incidence of B-cell lymphoproliferative disorders in transplant patients is a staggering 350 times greater than that of the normal age-matched population. Posttransplant lymphoproliferative disorder (PTLD) has been reported in 6% of lung transplant recipients.<sup>95</sup> PTLD most commonly occurs within the first year after transplantation, and is associated with Epstein-Barr virus infection. Treatment consists of reducing immunosuppression and administration of an antiviral agent such as acyclovir or ganciclovir. A response rate of 30 to 40% can be expected, and recurrence is uncommon. Chemotherapy and radiotherapy have been

used successfully in some cases. During therapy, close monitoring of the graft, along with clinical assessment of tumor status is essential.

## Long-Term Results in Lung Transplantation

Pulmonary function measured by spirometry and arterial blood gases is markedly improved within several months after transplantation, with a normalization of ventilation and gas exchange after 1 to 2 years.<sup>96</sup> The long-term survival for lung transplant recipients reported to the Registry of the International Society for Heart and Lung Transplantation is shown in Fig. 61-13. Survival rates among transplants performed between January 1994 and June 2012 were 88% at 3 months, 80% at 1 year, 65% at 3 years, 53% at 5 years, and 32% at 10 years.<sup>81</sup> Survival for double lung transplant exceeds that of SLT, with the underlying indication being an important factor in the outcome between these two groups. Survival is clearly influenced by recipient age, with 1-year survival at 72% among patients older than 65 compared with 80% survival among patients less than 50.<sup>25</sup> Patients with COPD and IPF (who often are older with more comorbidities) tend to fare poorer than those with CF, IPAH, sarcoidosis, and A1 anti-trypsin (AAT) deficiency emphysema (as shown in Fig. 61-14). In an analysis of 10-year survivors, double-lung recipients and patients with fewer hospitalizations for rejection were found to have improved long-term survival after lung transplantation.<sup>97,98</sup> Operative mortality is clearly affected by center volume, with high volume centers ( $\geq 20$  implants per year) having a 30-day mortality rate of just 4.1%.<sup>97</sup> With increasing experience with lung transplantation worldwide, both short- and long-term survival have improved over time.

## HEART-LUNG TRANSPLANTATION

### History of Heart-Lung Transplantation

Long before the first successful human heart-lung transplants were reported, thoracic organ transplantation flourished in the laboratory. In the 1940s, Demikhov developed the first successful method of en bloc heart-lung transplantation in dogs. In his series of 67 dogs, the longest survivor lived for 6 days postoperatively.<sup>99</sup> These remarkable studies demonstrated the technical feasibility of heart and lung replacement, yet remained largely unknown in the West until the 1960s. In 1953, Marcus and colleagues at the Chicago Medical School described a technique for heterotopic heart-lung grafting to the abdominal aorta and inferior vena cava in dogs.<sup>100</sup> Later studies in the 1960s and early 1970s examined the physiologic effect of total denervation on heart and lung function. Studies by Webb and colleagues in 1961 proved discouraging as they showed failure to resume normal spontaneous respiration following heart-lung replacement in dogs.<sup>101</sup> This physiologic phenomenon was confirmed by several other groups using canine models, including Lower and colleagues in 1961.<sup>102</sup>

**FIGURE 61-13** Kaplan-Meier survival by procedure type for adult lung transplants reported to the ISHLT registry from January 1994 through June 2012. (Data from Yusen RD, Edwards LB, Kucheryavaya AY, et al: The registry of the International Society for Heart and Lung Transplantation: thirty-first adult lung and heart-lung transplant report—2014; focus theme: retransplantation, *J Heart Lung Transplant*. 2014 Oct;33(10):1009-1024.)

Fortunately, later studies in primates by Haglin,<sup>103</sup> Nakae,<sup>104</sup> Castaneda,<sup>105,106</sup> and their colleagues showed that unlike dogs, primates resume a normal respiratory pattern after complete denervation with cardiopulmonary replacement. The 1970s saw the development of improved immunosuppressive

medications, particularly cyclosporine, which prevented rejection of primate heart-lung allografts after transplantation. Studies from the Stanford University showed survival for well over 5 years after heart-lung allografting in primates.<sup>107</sup> In the 1980s, Reitz and colleagues reported a modification

**FIGURE 61-14** Kaplan-Meier survival by diagnosis for adult lung transplants reported to the ISHLT registry from January 1990 through June 2012. Alpha 1, Alpha 1-antitrypsin deficiency emphysema; CF, cystic fibrosis; COPD, chronic obstructive pulmonary disease; IPAH, idiopathic pulmonary arterial hypertension; IPF, idiopathic pulmonary fibrosis. (Data from Yusen RD, Edwards LB, Kucheryavaya AY, et al: The registry of the International Society for Heart and Lung Transplantation: thirty-first adult lung and heart-lung transplant report—2014; focus theme: retransplantation, *J Heart Lung Transplant*. 2014 Oct;33(10):1009-1024.)

to the standard technique of heart-lung replacement, using a retained portion of the right atrium for a single inflow anastomosis instead of separate caval anastomoses.<sup>108</sup> This technique preserved the donor sinoatrial node and eliminated the potential for caval anastomotic stenosis. These studies laid the groundwork for a clinical trial of heart-lung transplantation at the Stanford University. On March 9, 1982, Reitz and colleagues performed the first successful human heart-lung transplant in a 45-year-old woman with end-stage primary pulmonary hypertension.<sup>109</sup>

## Indications for Heart-Lung Transplantation

Upon its introduction in 1982, heart-lung transplantation provided a life-saving therapeutic option for patients with end-stage pulmonary and cardiopulmonary disease. However, the number of heart-lung transplants performed peaked in 1990 as the techniques of SLT and DLT began to achieve improved outcomes in patients with isolated end-stage lung disease. This, combined with the donor shortage of heart-lung blocs, has restricted the procedure to patients with severe cardiopulmonary diseases (most commonly congenital heart disease with Eisenmenger's syndrome, idiopathic pulmonary arterial hypertension, and CF). Since 2003, between 75 and 86 heart-lung transplant procedures have been performed worldwide each year.<sup>25</sup>

The diagnostic profile of heart-lung transplant recipients reported to the Registry of the International Society for Heart and Lung Transplantation (ISHLT) is shown in Table 61-8.

**TABLE 61-8: Distribution of Diagnoses Among Adult Heart-Lung Transplant Recipients**

Diagnosis	No. (%)
Congenital heart disease	1178 (35.5)
Idiopathic pulmonary arterial hypertension	907 (27.4)
Cystic fibrosis	459 (13.9)
COPD disease/emphysema	141 (4.3)
Acquired heart disease	180 (5.4)
Idiopathic pulmonary fibrosis	121 (3.7)
AAT deficiency emphysema	62 (1.9)
Sarcoidosis	54 (1.6)
Retransplant:	
Not obliterative bronchiolitis	32 (1.0)
Obliterative bronchiolitis	24 (0.7)
Bronchiectasis	30 (0.9)
Obliterative bronchiolitis (not retransplant)	25 (0.8)
Other	101 (3.0)

AAT, Alpha-1 antitrypsin; COPD, chronic obstructive pulmonary disease. ISHLT Registry patients from January 1982 through June 2013. Reproduced with permission from Yusen RD, Edwards LB, Kucheryavaya AY, et al: The registry of the International Society for Heart and Lung Transplantation: thirty-first adult lung and heart-lung transplant report—2014. *J Heart Lung Transplant.* 2014 Oct;33(10):1009-1024.

Congenital heart disease (atrial and ventricular septal defects, patent ductus arteriosus) with secondary pulmonary hypertension (Eisenmenger's syndrome) is the most frequent indication, found in over one-third of the patients. Complex congenital heart defects that have been treated successfully with heart-lung transplantation include univentricular heart with pulmonary atresia, truncus arteriosus, and hypoplastic left heart syndrome. Data regarding the long-term survival benefit of heart-lung transplantation in patients with Eisenmenger's syndrome are mixed.<sup>110</sup> Some data suggest that pulmonary hypertension in these patients has a more favorable prognostic course than other types of pulmonary hypertension. There is clear evidence, however, that quality of life is improved by transplantation.<sup>111</sup> In patients with simpler cardiac defects, repair of the cardiac defect combined with SLT or bilateral lung transplantation is an alternative option.

Primary pulmonary hypertension with right-sided heart failure is the second most common diagnosis in heart-lung transplant recipients. Nearly one-fourths of patients in the ISHLT registry carry this diagnosis. Recently, there has been a shift toward SLT and bilateral lung transplantation in this population.<sup>112</sup> This new paradigm is based on the finding that normalization of pulmonary pressures following lung transplantation often allows for recovery of right heart function. However, in patients with severe right-sided heart failure and primary pulmonary hypertension, heart-lung transplantation is clearly the operation of choice.

The remainder of heart-lung transplants are performed for a variety of cardiac and pulmonary diseases. These include CF and other septic lung diseases, severe coronary artery disease (CAD) with concomitant end-stage lung disease, and primary parenchymal lung disease with severe right-sided heart failure (eg, IPF, lymphangioleiomyomatosis, sarcoidosis, and desquamative interstitial pneumonitis).

## Patient Selection for Heart-Lung

As in lung transplantation, patients are stratified according to LAS with similar listing criteria and contraindications for both groups of patients. Age restrictions tend to be somewhat more selective in most centers, with an upper recipient age limit of 50 years. Most recipients for heart-lung transplantation also fall within New York Heart Association functional classes III or IV.<sup>113</sup> Careful attention to size matching must be carried out in the donor selection process. In a series of 82 heart-lung transplants at Papworth Hospital, Tamm and coworkers recorded recipient lung volumes posttransplantation, followed by a comparison to preoperative and predicted volumes to evaluate the influence of donor lung size and recipient underlying disease.<sup>114</sup> The investigators demonstrated that, by 1 year after surgery, total lung capacity (TLC) and dynamic lung volume returned to values predicted by the patient's sex, age, and height. They proposed that the simplest method of matching donor lung size to that of the recipient is to use their respective predicted TLC values. Moreover, they concluded that recipients should attain their predicted lung volumes by 1 year posttransplantation, and failure to

do so suggests possible complications within the transplanted lungs.

As in lung transplantation, preoperative HLA matching is not feasible given the necessity of short ischemic times. However, histocompatibility does seem to impact on patient outcomes. Harjula and coworkers at Stanford evaluated the relationship between HLA matching and outcomes in heart-lung transplantation.<sup>115</sup> Among 40 heart-lung transplant recipients evaluated, they found a significant increase in graded OB with total mismatch at the HLA-A locus.

## Operative Technique

### PROCUREMENT

Exposure and cannulation for heart-lung blocs follows the same procedure as for lung procurement. After cross-clamp, the bloc is dissected free from the esophagus commencing at the level of the diaphragm and continuing cephalad to the level of the carina. Dissection is kept close to the esophagus, and care is taken to avoid injury to the trachea, lung, or great vessels. The posterior hilar attachments are divided. The lungs are inflated to a full normal tidal volume, and the trachea is stapled at the highest point possible with a TA-55 stapler (US Surgical, Norwalk, CT), at least four rings above the carina (Fig. 61-6E). The trachea is then divided above the staple line, and the entire heart-lung bloc is removed from the chest.

### RECIPIENT IMPLANT

The recipient is positioned supine and the chest is entered through a median sternotomy. A sternal retractor is placed, and both pleural spaces are opened anteriorly from the level of the diaphragm to the level of the great vessels (Fig. 61-15A). Electrocautery is used to divide any pleural adhesions. The anterior pericardium is excised, and the lateral segments are preserved to support the heart and protect the phrenic nerves. A 3-cm border of the pericardium should be left both anterior and posterior to each phrenic nerve extending from the level of the diaphragm to the level of the great vessels (Fig. 61-15B). An alternative approach is to create posterior pericardial apertures where the pulmonary veins enter into the pericardium. A border of pericardium is left posterior to the phrenic nerves, whereas the entire remaining pericardium anterior to the phrenic nerves is left intact. After fully heparinizing the recipient, the ascending aorta is cannulated near the base of the innominate artery, and the venae cavae are individually cannulated laterally and snared. Cardiopulmonary bypass with systemic cooling to 28 to 30°C is instituted, and the heart is excised at the midatrial level. The aorta is divided just above the aortic valve, and the pulmonary artery is divided at its bifurcation (Fig. 61-15C). The left atrial remnant is then divided vertically at a point halfway between the right and left pulmonary veins.

The posterior edge of the left atrial and pulmonary venous remnant is developed in a manner allowing the left inferior and superior pulmonary veins to be displaced over into the left chest. Following division of the pulmonary ligament, the

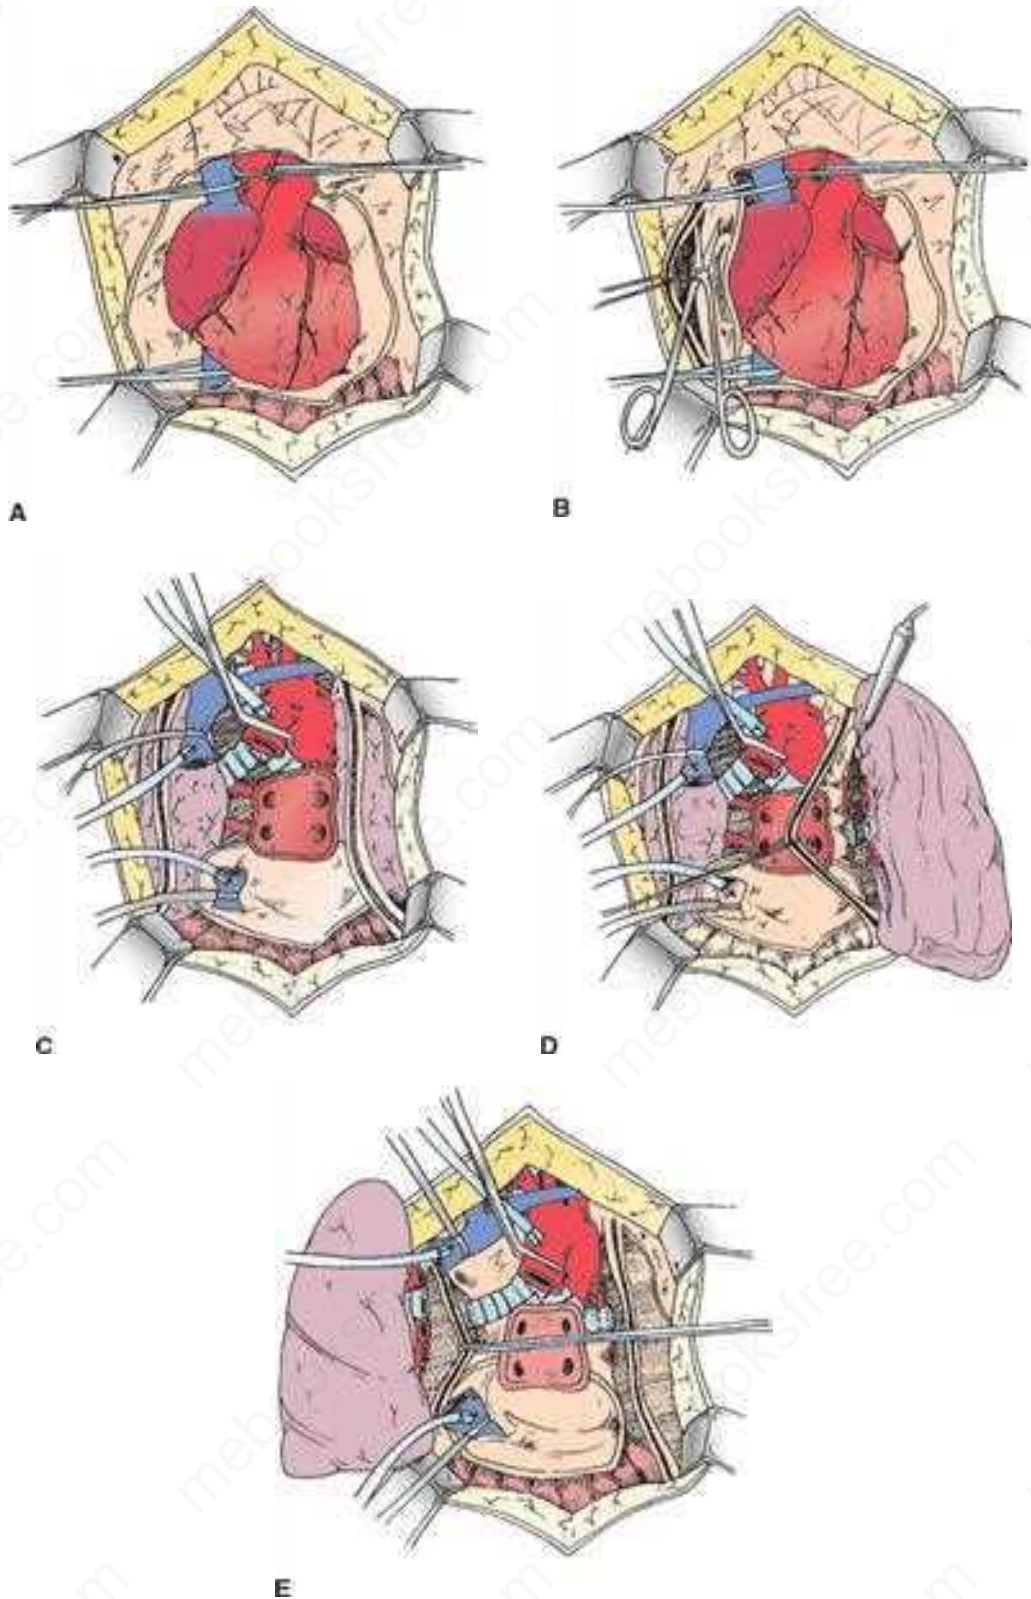

left lung is moved into the field, allowing full dissection of the posterior aspect of the left hilum, with care taken to avoid the vagus nerve posteriorly. Once this is completed, the left main pulmonary artery is divided (Fig. 61-15D), and the left main bronchus is stapled with a TA-30 stapler and divided. The same technique of hilar dissection and division is repeated on the right side (Fig. 61-15E), and both lungs are removed from the chest.

The native main pulmonary artery remnant is removed, leaving a portion of the pulmonary artery intact adjacent to the underside of the aorta (near the ligamentum arteriosus) to preserve the left recurrent laryngeal nerve. Attention is then turned to preparing the distal trachea for anastomosis. The stapled ends of the right and left bronchi are grasped and dissection is carried up to the level of the distal trachea. Bronchial vessels are individually identified and carefully ligated. Patients with congenital heart disease and pulmonary atresia or severe cyanosis secondary to Eisenmenger's syndrome may have large mediastinal bronchial collaterals that must be meticulously ligated. Perfect hemostasis is necessary in this area of the dissection, because it is obscured once graft implantation is complete. Once absolute hemostasis is achieved, the trachea is divided at the carina with a no. 15 blade. The chest is now prepared to receive the heart-lung graft.

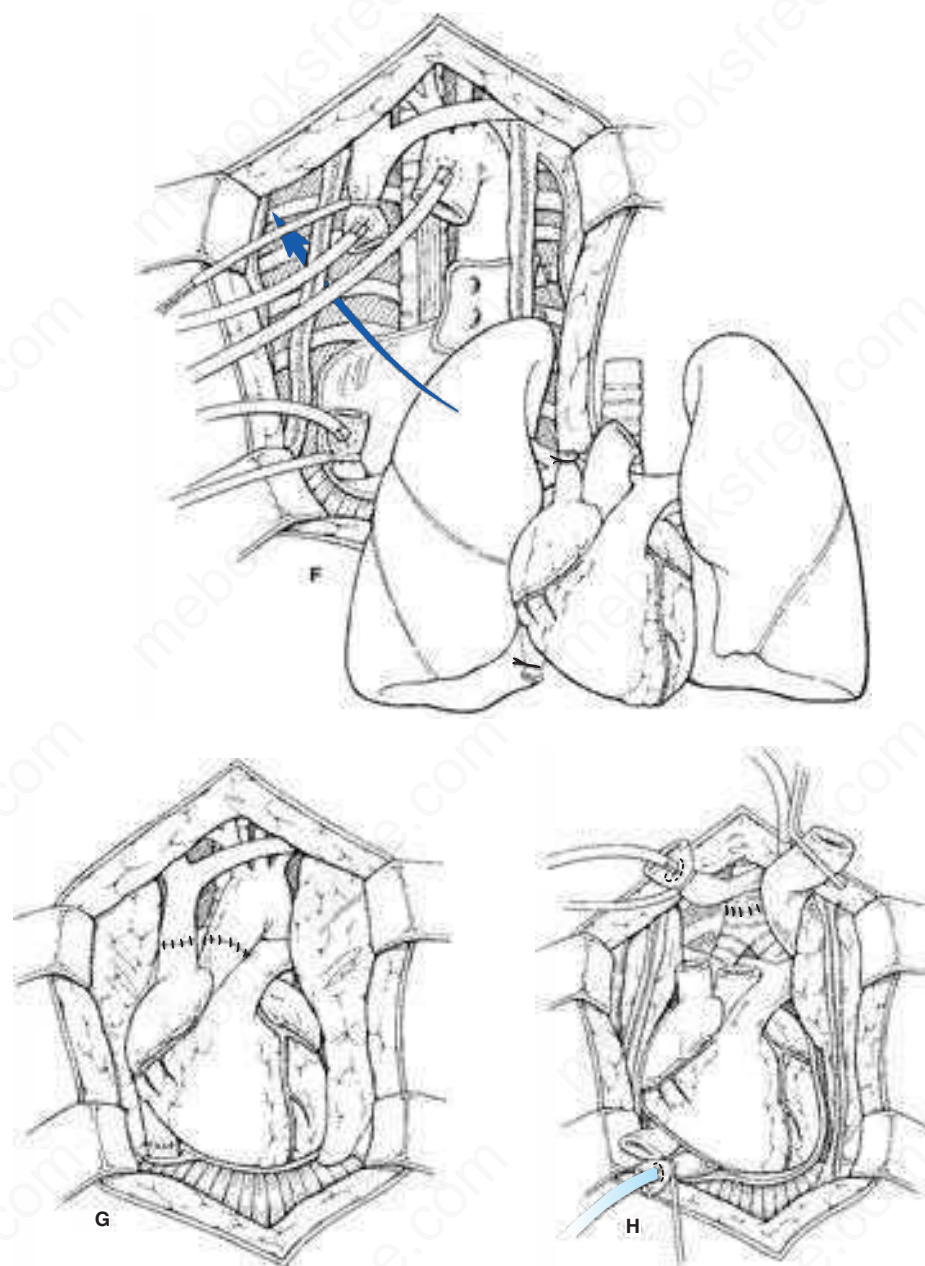

The donor heart-lung bloc is removed from its transport container and prepared by irrigating, aspirating, and culturing the tracheobronchial tree followed by trimming of the trachea to leave one cartilaginous ring above the carina. The heart-lung graft is then lowered into the chest, passing the right lung beneath the right phrenic nerve pedicle. The left lung is then gently manipulated under the left phrenic nerve pedicle (Fig. 61-15F). The tracheal anastomosis is performed using continuous 3-0 polypropylene suture (Fig. 61-15G). The posterior membranous portion of the anastomosis is performed first, followed by completion of the anterior aspect. Ventilation is then carried out with room air at half-normal tidal volumes to inflate the lungs and reduce atelectasis. Topical cooling with a continuous infusion of cold Physiosol into both thoraces is begun. To augment endomyocardial cooling and to exclude air from the graft, a third cold, "bubble-free" line is placed directly into the left atrial appendage.

Next, the bicaval venous anastomosis is performed. The recipient inferior vena cava is anastomosed to the donor inferior vena cava-right atrial junction with a continuous 4-0 polypropylene suture. At this point, the patient is warmed toward 37°C, and the superior vena caval and aortic anastomoses are performed end-to-end with continuous 4-0 polypropylene sutures (Fig. 61-15H). After the ascending aorta and pulmonary artery are cleared of air, the aortic cross-clamp and caval tapes are removed. The left atrial catheter is removed, and the atrium is allowed to drain. The amputated left atrial stump is oversewn, and the pulmonary artery pulmonoplegia infusion site closed. The heart is defibrillated, and the patient is gradually weaned from cardiopulmonary bypass in the standard fashion. Methylprednisolone (500 mg) is administered to the recipient after heparin reversal with protamine sulfate.

PEEP at 3 to 5 cm H<sub>2</sub>O and an FIO<sub>2</sub> of 40% is maintained. As in cardiac transplantation, isoproterenol

**FIGURE 61-15** Recipient operation for heart-lung transplantation. (A) Through a median sternotomy, the anterior pericardium is partially removed and the ascending aorta and both venae cavae are dissected and encircled with tapes. (B) The right phrenic nerve is carefully separated from the right hilum, providing a space for inserting the right lung of the graft. (C) Cannulation for cardiopulmonary bypass consists of a cannula in the high ascending aorta and separate vena caval cannulas. Once on bypass, the native heart is excised in a manner similar to that for standard cardiac explantation. (D,E) Left and right pneumonectomies are performed by dividing the respective inferior pulmonary ligament, pulmonary artery and veins, and mainstem bronchus.

**FIGURE 61-15** (Continued) (F) The heart-lung graft is moved into the chest beginning with passage of the right lung underneath the right phrenic nerve pedicle, followed by manipulation of the left lung beneath the left phrenic nerve pedicle. (G) The caval and aortic anastomoses are performed with a continuous 4-0 polypropylene suture. (H) The tracheal anastomosis is performed with a continuous 3-0 polypropylene suture.

(0.005 to 0.01  $\mu\text{g}/\text{kg}/\text{min}$ ) is usually initiated on graft reperfusion to increase the heart rate (~100-110 bpm) and to lower pulmonary vascular resistance. Temporary right atrial and ventricular pacing wires are placed. Right and left pleural “right angle” chest tubes are placed along each diaphragm, as well as a single mediastinal tube. The chest is closed in the standard fashion. Finally, the double lumen endotracheal tube is exchanged for a single lumen tube and the tracheal anastomosis is visualized by bronchoscopy before transporting the patient to the intensive care unit.

Lick and coworkers describe an interesting alternative to the standard technique in which the pulmonary hila are placed anterior to the phrenic nerves and direct caval anastomoses are used whenever feasible.<sup>116</sup> This modification obviates extensive dissection of the phrenic nerves and posterior mediastinum, decreasing the likelihood of phrenic and vagus nerve injury. Furthermore, the posterior mediastinum can readily be inspected for bleeding after implantation by rotating the heart-lung bloc anterior-medially while still on bypass.

## Graft Physiology

For heart-lung recipients, denervation of the cardiac allograft leads to additional physiologic characteristics beyond what is seen in isolated lung transplantation. The denervated heart loses its sympathetic and parasympathetic autonomic regulation, thereby impacting on heart rate, contractility, and coronary artery vasomotor tone. The resting heart rate is generally higher due to the absence of vagal input. Respiratory sinus arrhythmia and carotid reflex bradycardia are absent. Interestingly, the denervated heart develops an increased sensitivity to catecholamines because of increased beta-adrenergic receptor density and loss of norepinephrine uptake in postganglionic sympathetic neurons.<sup>117,118</sup> This augmented sensitivity plays an important role in maintaining an adequate cardiac response to exercise and stress. During exercise, the recipient experiences a steady but delayed increase in heart rate, primarily because of a rise in circulating catecholamines. This initial rise in heart rate is subsequently accompanied by an immediate increase in filling pressures resulting from increased venous return. These changes lead to increased stroke volume and cardiac output sufficient to sustain activity. Although the coronary circulation's ability to dilate to meet increased myocardial oxygen demand is not eliminated in an uncomplicated heart-lung transplant, this reserve is abnormal in the presence of rejection, hypertrophy, or regional wall abnormalities.

## Postoperative Management

Approximately 10 to 20% of heart-lung graft recipients experience some degree of transient sinus node dysfunction in the immediate perioperative period. This often manifests as sinus bradycardia and usually resolves within a week. The use of bicaval venous anastomoses has been reported to lower the incidence of sinus node dysfunction and improve tricuspid valve function.<sup>119</sup> Because cardiac output is primarily rate dependent after heart-lung transplantation, the heart rate should be maintained between 90 and 110 beats per minute during the first few postoperative days using temporary pacing or isoproterenol (0.005-0.01  $\mu\text{g}/\text{kg}/\text{min}$ ) as needed. Although rarely seen, persistent sinus node dysfunction and bradycardia may require a permanent transvenous pacemaker. Systolic blood pressure should be maintained between 90 and 110 mm Hg using nitroglycerin or nitroprusside for afterload reduction, if necessary. "Renal-dose" dopamine (3-5  $\mu\text{g}/\text{kg}/\text{min}$ ) is used frequently to augment renal blood flow and urine output. The adequacy of cardiac output is indicated by warm extremities and a urine output greater than 0.5 mL/kg/h without diuretics. Cardiac function generally returns to normal within 3 to 4 days, at which time inotropes and vasodilators can be weaned.

Nevertheless, depressed global myocardial performance is occasionally seen during the acute postoperative setting. The myocardium may be subject to prolonged ischemia, inadequate preservation, or catecholamine depletion before implantation. Hypovolemia, cardiac tamponade, sepsis,

and bradycardia are also potential contributors and should be treated expeditiously if they are present. A Swan-Ganz pulmonary artery catheter should be used in cases of persistently abnormal hemodynamics. Surveillance endomyocardial biopsies are performed at 3 months and then annually in heart-lung graft recipients.

## Complications

The most common complications after heart-lung transplantation include hypertension (88.6%), renal dysfunction (28.1%), hyperlipidemia (66.4%), diabetes (20.9%), coronary artery vasculopathy (8.2%), and bronchiolitis obliterans (27.1%).<sup>25</sup> Common causes of death include graft failure and technical complications within the first 30 days, followed by non-CMV infections and BOS in the longer term.<sup>25</sup> Acute rejection remains a challenge, occurring in more than 67% of heart-lung patients within the first year between 1981 and 1994 at Stanford University.<sup>120</sup> Experimental and clinical evidence suggests that pulmonary and cardiac rejections occur independently of one other. Nevertheless, Higenbottam and coworkers at Papworth Hospital reported a surprisingly low diagnostic yield from routine endomyocardial biopsies in heart-lung recipients compared with functional or histologic tests of pulmonary rejection. Based on these findings, the authors concluded that transbronchial biopsy eliminates the need for routine endomyocardial biopsies in heart-lung transplant recipients.<sup>121</sup> These findings were supported by Sibley and coworkers at Stanford University, who demonstrated discordance between findings on endomyocardial and transbronchial biopsies during episodes of acute rejection. Endomyocardial biopsies are most often normal despite findings of pulmonary rejection on transbronchial biopsy.<sup>76</sup> In our practice, surveillance endomyocardial biopsies have been abandoned in patients in whom transbronchial biopsies can be reliably performed. Respiratory failure secondary OB represents a long-term complication of heart-lung transplant at a rate similar to DLT. Among heart-lung recipients with OB, Adams and coworkers at Harefield Hospital noted that retransplant survival rates were worse for those undergoing combined heart-lung replacement compared with patients who underwent isolated lung replacement.<sup>122</sup> The group also noted the following factors were associated with improved survival after retransplant: absence of preformed antibodies, retransplantation at least 18 months after the original transplantation, and negative preoperative sputum cultures.

Accelerated graft CAD or graft atherosclerosis is another major obstacle to long-term survival in heart-lung transplant recipients. Significant graft CAD resulting in diminished coronary artery blood flow may lead to arrhythmias, myocardial infarction, sudden death, or impaired left ventricular function with congestive heart failure. Classic angina caused by myocardial ischemia is usually not noted in transplant recipients because the cardiac graft is not innervated. Multiple etiologies for graft CAD have been proposed, all focusing on chronic, immune-mediated damage to the coronary vascular

**FIGURE 61-16** Cardiac graft atherosclerosis. Complete luminal obliteration by a concentric fibrointimal proliferation was observed at postmortem in this heart-lung transplant patient (Elastin von Gieson stain;  $\times 60$ ).

endothelium. In fact, elevated levels of antiendothelial antibodies have been correlated with graft CAD. Unlike coronary artery occlusive disease in the native heart, which tends to be a more focal process, transplant atherosclerosis is a more diffuse vascular narrowing extending symmetrically into distal branches. Histologically, transplant arteriopathy is characterized by concentric intimal proliferation with smooth muscle hyperplasia (Fig. 61-16).

Coronary angiograms are performed on a yearly basis to identify recipients with accelerated CAD. Angiography is limited, however, to assessment of luminal diameter. Intracoronary ultrasound, by contrast, can assess both

vascular wall morphology and luminal diameter, making it a more sensitive tool to detect the diffuse coronary intimal thickening typical of graft atherosclerosis. Interestingly, graft CAD occurs at a reduced incidence in heart-lung recipients compared with the cardiac transplantation population.<sup>123</sup> A retrospective survey at Stanford revealed 89% of heart-lung recipients were free from graft CAD at 5 years, compared with 73% of heart transplant recipients. Clinically observed risk factors for developing this condition in heart transplant recipients include donor age greater than 35 years, incompatibility at the HLA-A1, A2, and DR loci, hypertriglyceridemia (serum concentration greater than 280 mg/dL), frequent acute rejection episodes, and documented recipient CMV infection. It is not clear whether these risk factors can be extended to the heart-lung transplant population, although CMV infection has been implicated.<sup>124</sup> Percutaneous transluminal coronary angioplasty and coronary artery bypass grafting have been used to treat discrete proximal lesions in some cases of graft CAD. However, the only definitive therapy for diffuse graft CAD is retransplantation. Effective prevention of graft CAD will rely on development of improved immunosuppression, recipient tolerance induction, improved CMV prophylaxis, and inhibition of vascular intimal proliferation.

Infection represents another significant postoperative challenge in heart-lung transplantation. Between 1981 and 1994 at Stanford, only 20% of heart-lung transplant recipients were free from infection 3 months after transplantation. In a retrospective analysis of 200 episodes of serious infections occurring in 73 heart-lung recipients at Stanford between 1981 and 1990, Kramer and coworkers<sup>125</sup> found that half of all infections were caused by bacteria, whereas fungal infections accounted for only 14% of total infections. The most common viral agent was CMV, occurring primarily in the second month after transplantation and comprising 15% of

**FIGURE 61-17** Kaplan-Meier survival for heart-lung transplantation, 1982 through 2012. (Data from Yusen RD, Edwards LB, Kucheryavaya AY, et al: The registry of the International Society for Heart and Lung Transplantation: thirty-first adult lung and heart-lung transplant report—2014; focus theme: retransplantation, *J Heart Lung Transplant*. 2014 Oct;33(10):1009-1024.)

all viral infections. Other viral infections (ie, herpes simplex, adenovirus, respiratory syncytial virus) were less common. Five percent of infections were attributed to *P. carinii*, typically occurring 4 to 6 months after transplantation, and 2% were caused by *Nocardia*, generally appearing after the first year. There was no significant difference in the incidence of infections between patients receiving triple-drug or double-drug (cyclosporine and prednisone) immunosuppression. Infectious mortality comprised 40% of all deaths.

## Long-Term Results in Heart-Lung Transplantation

Survival rates of 72% at 3 months and 64% at 1 year have been reported in the ISHLT registry.<sup>25</sup> Mortality rates taper off significantly at a year posttransplant, as illustrated in Fig. 61-17. As with lung transplantation, outcomes have improved over time and are affected by recipient diagnosis.<sup>25</sup> Graft failure, technical complications, and non-CMV infections are all common causes of 30-day mortality, with BO and non-CMV infections impairing long-term survival.

# Long-term Mechanical Circulatory Support and the Total Artificial Heart

Andrew C. W. Baldwin • Courtney J. Gemmato  
• William E. Cohn • O. H. Frazier

Heart failure (HF) is a leading cause of death in the United States and a significant public health concern throughout the world. Results from the Framingham Heart Study suggest that the lifetime risk of developing HF for Americans over the age of 40 years is approximately 20%, and the incidence of this disease steadily increases with age.<sup>1</sup> An estimated 5.1 million Americans are living with HF. This figure is expected to grow significantly in the coming decades because the average age of the population is increasing, and advancements in medical therapy are allowing patients to live longer with their disease.<sup>2,3</sup> The economic burden of disease is also high, and total healthcare costs attributed to HF exceed \$30 billion in the United States each year.<sup>2,3</sup> In light of the increased mortality associated with HF, strategies for managing this disease have grown increasingly sophisticated.

Treatment of advanced HF is based on three principal methodologies: medical therapy, corrective surgical intervention, and cardiac support or replacement. Appropriate medical management with antihypertensive, diuretic, vasoactive, and inotropic therapy has been shown to improve symptoms, slow the progression of disease, and (in some cases) provide survival benefits.<sup>4</sup> Patients with more severe disease may benefit from specific surgical interventions such as coronary revascularization, valve replacement or repair, and ventricular restoration procedures.<sup>5,6</sup> These procedures often pose a high risk, and surgical candidacy is typically assessed on a case-by-case basis.

Selected patients with severe HF refractory to guideline-directed medical therapy may ultimately be considered candidates for cardiac transplantation or mechanical circulatory support (MCS). Because of a relative scarcity of available donor organs for transplantation, device therapy has become an increasingly popular option for managing end-stage HF and offers documented survival benefits over medical therapy alone.<sup>7</sup> Whereas only 33 centers participated in the original clinical investigation (completed in 2009) of the HeartMate II

left ventricular assist device (LVAD) (Thoratec, Inc., Pleasanton, CA), a total of 145 centers are now approved for device therapy in the United States. This number will likely continue to grow as this technology and other new MCS systems become more widely accessible.<sup>8,9</sup>

MCS is an inclusive term that refers to any device used to assist or replace the failing heart. The options are wide-ranging and include differences in pump location (implantable vs extracorporeal), support capabilities (left, right, or biventricular), and flow characteristics (pulsatile vs continuous). This chapter will focus primarily on the available long-term options for MCS, particularly current LVADs and the total artificial heart (TAH). Although MCS is not without inherent risks, rapid advancements in technology—paired with the practical limitations of transplantation—suggest that device therapy has an important role in both the present and the future of HF surgery.

## HISTORY OF MECHANICAL CIRCULATORY SUPPORT

Open heart surgery was made possible by the pioneering efforts of individuals seeking a method to provide temporary cardiopulmonary support by means of a mechanical pump oxygenator. The first successful use of cardiopulmonary bypass (CPB) was reported in 1953 by John Gibbon,<sup>10</sup> who used a CPB system of his own design to repair an atrial septal defect. Excessive mortality rates led some surgeons, including Gibbon himself, to abandon open heart surgery. In 1954, C. Walton Lillehei<sup>11</sup> reported the use of cross circulation (human-to-human perfusion), using a parent as a temporary source of cardiopulmonary support during the repair of congenital heart defects. Controversy stemming from this approach (particularly the risk of a 200% mortality rate) encouraged ongoing research in the field of mechanical support, and efforts

led by Lillehei, Richard DeWalt, and John Kirklin quickly led to refinements in CPB technology, resulting in improved clinical outcomes.<sup>12</sup> In April 1956, Denton Cooley reported the use of a modified bubble oxygenator in the repair of a postinfarction ventricular septal defect; he would perform 94 open heart procedures (primarily in children) by the end of the year.<sup>13</sup>

The resulting wave of open heart procedures quickly led to the observation that some patients were unable to regain sufficient cardiac function to permit withdrawal from the heart-lung machine. Anecdotal experience suggested that slow weaning (over the course of hours) allowed some hearts to successfully recover function<sup>14</sup> (Fig. 62-1). As a result, interest in prolonged circulatory support led to the concept of a ventricular assist device (VAD). Decades earlier, the eccentric Russian scientist Vladimir Demikhov had successfully designed and tested a device capable of maintaining the perfusion of a dog for several hours.<sup>15</sup> Although this breakthrough occurred in 1937, his experiments were not widely known outside the Soviet Union until years later. Throughout the 1960s, research efforts at a number of institutions were focused on the development of MCS technology. A federally funded program with this goal was established at Baylor College of Medicine, in Houston, with Michael DeBakey as its director.

The first clinical application of an LVAD was performed by DeBakey in 1963, who used the device as a temporizing measure in a patient with cardiogenic shock after aortic valve replacement. Although the pump functioned satisfactorily, the patient succumbed to pulmonary complications

4 days after its implantation. On August 8, 1966, DeBakey implanted an LVAD in a 37-year-old woman with severe HF who could not be weaned from CPB after aortic and mitral valve replacement. An extracorporeal pneumatic device, the pump routed blood from the left atrium to the right axillary artery. After 10 days of support, the patient demonstrated sufficient cardiac reserve to allow elective removal of the pump at the bedside.<sup>14</sup> She later returned to work, resumed normal activity, and survived for 6 years with good cardiac function before dying in an auto accident. In 1969, in an event that will be discussed later in this chapter, Cooley implanted the world's first TAH to great acclaim.<sup>16</sup> Despite this landmark event, effective long-term total heart replacement proved to be an elusive goal over the ensuing decades.

By the early 1970s, the complexities of immunosuppressive therapy led to waning enthusiasm for cardiac transplantation and associated MCS technology. However, research and development efforts focused on VAD therapy were continued steadily and quietly within a selected group of institutions. With support from the National Heart, Lung, and Blood Institute (NHLBI) and in collaboration with Boston-based Thermo Cardiosystems, physicians at the Texas Heart Institute began development of an abdominally positioned, pneumatically driven, pulsatile-flow LVAD. Twenty-two patients were supported by the Model 7 abdominal LVAD, including the first documented mechanical "bridge" to cardiac transplantation, performed in 1978.<sup>17</sup> The introduction of cyclosporine in the 1980s eventually led to renewed widespread interest in the field of transplantation and reestablished a meaningful clinical role for MCS technology. Ongoing research efforts to

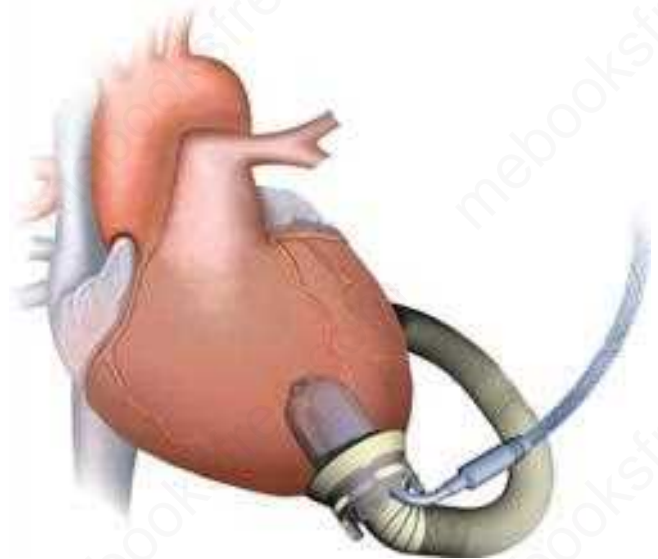

**FIGURE 62-1** Correlation between cardiopulmonary bypass flows, mean arterial pressure, and left atrial pressure in a patient with left ventricular failure after aortic valve replacement. The observed efficacy of gradual weaning from cardiopulmonary bypass helped stimulate interest in mechanical circulatory support. (Reproduced with permission from DeBakey ME. Left ventricular bypass pump for cardiac assistance: clinical experience, *Am J Cardiol.* 1971 Jan;27(1):3-11.)

develop pumps capable of long-term support ultimately led to the HeartMate Implantable Pneumatic pump (Thoratec Corp; Pleasanton, CA), which became the first implantable device to be approved by the United States Food and Drug Administration (FDA) for use as a bridge to transplantation (BTT).<sup>18,19</sup> An electrically powered, percutaneously vented adaptation of this device, the HeartMate Extended Vented Electric (XVE) LVAD, was spawned directly by these research efforts. Upon its inaugural implantation in 1991, it became the first pump to be managed in the outpatient setting.<sup>20</sup>

Simultaneously, research efforts were engaged in the design of a completely different mechanism. The concept of extended nonpulsatile support was inspired by anecdotal reports concerning the use of the extracorporeal BioMedicus centrifugal-force pump (Medtronic; Minneapolis, MN) as both a temporary LVAD and an extracorporeal membrane oxygenator (ECMO). This led to a series of experimental studies that were performed by the senior author of this chapter (OHF) in the Texas Heart Institute laboratories throughout the 1980s. As a result of these efforts (and in collaboration with engineer Richard Wampler) the Hemopump, a small catheter-based, axial-flow device, was developed and successfully implanted in 1988, demonstrating the efficacy and safety of high-speed continuous-flow (CF) support<sup>21</sup> (Fig. 62-2). Also during this period, an association between Texas Heart Institute investigators and researcher Robert Jarvik led to the development of a long-term implantable CF pump that could be placed directly into the left ventricle.<sup>22</sup> The Jarvik 2000 VAD (Jarvik Heart, Inc.; New York, NY) was unique in its utilization of blood-washed bearings (previously thought to be biologically incompatible with the vascular system) and validated the clinical feasibility of axial-based CF pumps<sup>23</sup> (Fig. 62-3). Meanwhile, the clinical success of the Hemopump led the Nimbus Company (later absorbed by Thoratec) to develop

**FIGURE 62-2** The catheter-based hemopump first revealed the safety and feasibility of high-speed continuous-flow circulatory support. (Used with permission from Dr. Richard Wampler.)

**FIGURE 62-3** The Jarvik 2000 was the first left ventricular assist device to incorporate blood-washed bearings in its axial flow design. (Used with permission from Jarvik Heart, Inc.)

the HeartMate II, another implantable axial-flow device, which would eventually become the most commonly used LVAD worldwide. A final step in the development of contemporary MCS systems occurred in 1994, when collaboration between Frazier, Wampler, and financier Robert Fine led to the development of a novel CF design. Originally produced by Kriton Medical, Inc. (and later purchased by HeartWare, Inc., Framingham, MA), the HeartWare HVAD utilizes a magnetically levitated, centrifugal-flow design that permits intrapericardial placement of the discoid-shaped pump housing and can function as both a right- and left-sided VAD.<sup>24</sup> Within the first decade of the new millennium, all three pumps—the Jarvik 2000, the HeartMate II, and the HeartWare HVAD—saw clinical use.

Increasingly sophisticated technology and improving clinical reliability gradually led MCS to shift from an experimental endeavor to a viable treatment option. The Randomized Evaluation of Mechanical Assistance for the Treatment of Congestive Heart Failure (REMATCH) trial was designed to compare outcomes between HF patients treated with the HeartMate XVE and those treated with medical therapy alone.<sup>7</sup> Completed in 2001, REMATCH investigators demonstrated a nearly 50% reduction in mortality among patients with LVAD support (Fig. 62-4). By providing the first statistical evidence of a survival benefit, this study remains a landmark in the advancement of MCS therapy. Following the success of REMATCH, the HeartMate II soon became the first CF device to be approved by the FDA for both BTT indications (in 2007) and for use in patients ineligible for transplantation (2009).<sup>25,26</sup> The HeartWare HVAD was granted BTT status after the release of the results of the ADVANCE trial in 2010, and it is expected to receive broader approval in the near future.<sup>27</sup> With more pumps and

**FIGURE 62-4** Kaplan-Meier survival analysis comparing end-stage heart failure patients randomized to receive either optimal medical therapy or left ventricular assist device support. The REMATCH trial researchers demonstrated a significant survival benefit for device recipients at both 1 and 2 years. (Reproduced with permission from Rose EA, Gelijns AC, Moskowitz AJ, et al: Long-term use of a left ventricular assist device for end-stage heart failure, *N Engl J Med.* 2001 Nov 15;345(20):1435-1443.)

newer designs in the pipeline, options for MCS continue to grow with ever-improving outcomes.

### PULSATILE VERSUS NONPULSATILE FLOW

A critical issue in the field of MCS is the physical mechanism by which flow is created. Quite logically, early efforts in device therapy sought to mimic nature’s model by designing pulsatile systems. Generations of devices have utilized pneumatic compression systems, hydraulic actuators, and pusher plate technology to allow repetitive filling and forceful ejection of blood from a ventricular collection chamber. However, the engineering challenges associated with matching the simplicity and reliability of the human heart—which beats more than 40 million times each year—have been considerable.

A chief cause of late pulsatile-device failure is mechanical wear, which results from the presence of complex moving components and multiple points of contact. For example, although the HeartMate XVE represented a significant step forward, it had a relatively predictable lifespan, with a high failure rate between the first and second years of use, and few of these devices survived for more than 2 years<sup>28</sup> (Fig. 62-5). Pulsatility also requires a number of disadvantageous design elements to accommodate the mechanics of operation. Pneumatic systems use tunneled drivelines to communicate with an external compressor responsible for delivering (and withdrawing) pressurized air. Pusher-plate systems (such as that used for the XVE) require a mechanism to allow external venting and aspiration of air displaced by the cyclic actuation of the pump. As a result of these inescapable challenges, pulsatile pumps are generally large, complex, and vulnerable to wear.

Time	0	1 month	6 months	12 months	18 months
VE patients at risk	167	133	77	37	14
XVE patients at risk	101	84	59	29	4

Improved mechanical reliability of the HeartMate XVE Left Ventricular Assist System, *Ann Thorac Surg.* 2006 Oct;82(4):1413-1418.)

Temporary CF technology was first adopted by Gibbon, who employed roller pumps in the design of his machine that first enabled CPB support during surgery.<sup>10</sup> However, early efforts to develop long-term MCS pumps focused on pulsatile blood flow to replicate natural physiology. The eventual development of CF LVADs was largely due to their associated engineering advantages, and both experimental and clinical studies quickly documented the physiologic tolerance of nonpulsatility. The technical superiority of CF devices was definitively shown in the HeartMate II Destination Therapy (DT) trial,<sup>26</sup> which documented improved adverse event profiles, hospital readmission rates, functional capacity, and overall survival when compared with the HeartMate XVE over a 2-year period (Table 62-1; Fig. 62-6). The widespread use and long-term efficacy of CF devices has further confirmed the important contribution of continuous blood-flow technology to MCS.

Whereas the success of CF devices has proven the body’s tolerance of nonpulsatile blood flow, this technology has created a new physiology, the full effects of which are not yet known. Multiple studies have shown an association between gastrointestinal (GI) bleeding and the loss of pulsatility.<sup>29</sup> Histologic examination of aortic tissue samples have revealed unanticipated degeneration of smooth muscle and elastic fibers in patients supported by CF devices.<sup>30</sup> Ultrasonographic studies have further revealed stasis and thrombus formation representing potential sources of thromboembolism within the carotid bulb and aortic valve cusps of selected patients with nonpulsatile devices.<sup>31</sup> These issues present a

**TABLE 62-1: Comparison of Continuous Flow and Pulsatile LVAD Outcomes and Adverse Event Profiles**

Adverse Event	Continuous Flow LVAD (n = 133)	Pulsatile Flow LVAD (n = 59)	p Value

mobility and offer the potential for completely implantable designs. Although much more remains to be studied, CF technology represents the future of MCS.

## CURRENT OPTIONS FOR MECHANICAL CIRCULATORY SUPPORT

Currently, device therapy involves a wide variety of options, obtainable through federally approved indications or investigational studies. The pumps differ in a number of important ways, including the duration of support permitted, approach to access, mechanisms of flow, and output capabilities. The most frequently used pumps and selected other devices of interest—notably all CF designs—are discussed below. A more thorough listing of currently available devices is provided in Table 62-2.

### ECMO

Oxygenation of the blood by a membrane oxygenator can be achieved through the use of either veno-venous (VV) or veno-arterial (VA) ECMO. The VV option is typically used for the management of isolated respiratory failure, and it relies on the function of the native heart for systemic circulation of oxygenated blood. In contrast, through an arterial return cannula, VA ECMO allows complete cardiopulmonary support, similar to that provided by CPB. Cannulation may be central or peripheral, rendering ECMO particularly useful in both emergent and intraoperative situations. It is generally limited to periods of short-term support (measured in days).

### Paracorporeal and Percutaneous Devices

A subset of devices can be inserted percutaneously or involve extracorporeal pumping components. Recent studies have shown a dramatic increase in the utilization of these short-term devices,<sup>32</sup> which are typically used for temporary MCS in the setting of acute cardiogenic or postcardiotomy shock. The CentriMag (Thoratec Corp.) is an extracorporeal VAD utilizing a magnetically levitated centrifugal flow impeller that can provide both right- and left-sided support (Fig. 62-7a). Access is typically gained via centrally placed CPB cannulas that can be tunneled to allow temporary chest closure. Capable of flows reaching 10 L/min, the CentriMag can also accommodate an oxygenator within the pumping circuit, permitting full cardiopulmonary support. The device is generally used for days to weeks, but support periods exceeding 30 days have been reported.<sup>33</sup>

The TandemHeart Percutaneous Ventricular Assist Device (pVAD) (CardiacAssist Inc.; Pittsburgh, PA) is a percutaneous device that functions as a left atriiofemoral bypass. Inserted under fluoroscopic guidance, the TandemHeart has a transeptal cannula that transfers oxygenated blood from the heart to an extracorporeal, magnetically driven, centrifugal flow pump mounted on the thigh. Using a hydrodynamic

bearing system, the TandemHeart can provide the femoral artery with return flows reaching 4 L/min.<sup>34</sup>

The Impella (Abiomed; Danvers, MA) is a platform of devices based upon a catheter-mounted microaxial design conceptually similar to that of the original Hemopump (Fig. 62-7b). A percutaneous arterial catheter serves as a power source and flow conduit for the pump, and left-sided support is provided in a retrograde fashion across the aortic valve. With a maximal diameter of just 12 F (4 mm), various adaptations of the device allow flows ranging from 2.5 to 5 L/min. A right-sided version, the Impella RP, delivers antegrade flow from the inferior vena cava to the pulmonary artery. It recently became the first percutaneous device approved by the FDA for right ventricular (RV) support.<sup>35</sup>

### Implantable Continuous-Flow LVADs (FDA-Approved)

The HeartMate II axial-flow device is the most widely used LVAD worldwide, with more than 15,000 implants to date (Fig. 62-8a). The pump's electromagnetic motor powers a single hydrodynamically suspended impeller operating at speeds between 6000 and 15,000 rpm (although clinical operating ranges are traditionally much smaller), and capable of flows greater than 10 L/min. Most often implanted via median sternotomy, the sintered titanium pump inlet is placed within the left ventricle with an outflow graft anastomosed to the aorta. A percutaneous driveline communicates with the remainder of the system: an external device controller and two portable batteries.

**FIGURE 62-7** Percutaneous ventricular assist devices. (A) The Thoratec Centrimag utilizes an extracorporeal magnetically levitated centrifugal-flow pump to provide temporary circulatory support. (Reproduced with permission from Thoratec Corporation.) (B) The Impella CP is a catheter-based pump designed to be positioned across the aortic valve and capable of producing flows as high as 4 L/min. (Reproduced with permission from ABIOMED, Inc.)

The HeartWare HVAD has a centrifugal-flow design, with a smaller and more compact profile than the HeartMate II (145 vs 375 g, respectively), integrating the ventricular inlet with the pump housing (Fig. 62-8b). The impeller is suspended via a combination of magnetic and hydrodynamic forces, and it operates at speeds ranging from 1800 to 4000 rpm, again with flows as high as 10 L/min. The flat surface of the

pump body allows intrapericardial positioning and serves as an advantage for right-sided use. Like the HeartMate II, the HVAD relies on external batteries and a controller module connected to the patient by a percutaneous driveline.

A number of additional devices remain in various stages of investigational study in the United States and are likely to be more widely available in the coming years. On the

**FIGURE 62-8** The HeartMate II (A) and the HeartWare HVAD (B) are the two most commonly implanted devices worldwide. While the HeartMate II utilizes an axial-flow design with an extracardiac pump housing, the centrifugal HVAD has a discoid shape designed for intrapericardial placement. Newer-generation devices, such as the HeartWare MVAD (C), reflect increasing miniaturization of mechanical circulatory support technology. (Used with permission from Thoratec Corporation [a] and HeartWare International, Inc. [b and c].)

whole, newer-generation pumps are being designed to produce excellent performance while offering a smaller profile, thus simplifying implantation and expanding potential applications to include smaller-framed and pediatric populations (Fig. 62-8c). TAH technology is discussed later in this chapter.

## GOALS OF THERAPY

Before device implantation, treatment teams must designate an intended goal of therapy. Traditional categories of strategic intent represent the evolution of MCS. Originally, devices were conceived as temporizing measures while the patient awaited a transplant. The eventual inclusion of transplant-ineligible patients for device consideration required a new and separate indication, resulting in the somewhat dichotomous framework in use today. Ideally, the decision to seek device therapy should be based on the need for mechanical support rather than being indirectly affected by the patient's transplant listing status. However, the decision currently serves a critical purpose in regard to patient and device selection, timing of intervention, regulatory oversight, and data acquisition. Clinical trials aimed at seeking device approval have traditionally been designed on this model. Likewise, the United States Centers for Medicare and Medicaid Services (CMS) uses the indicated strategy for device therapy to establish a given patient's eligibility for treatment. The categories are a part of the MCS lexicon and warrant inclusion here.

### Bridge to Transplantation

The original intention for MCS was to provide a "bridge" to eventual cardiac transplantation for patients awaiting a suitable donor organ. Unpredictable waitlist times and a frequently tenuous clinical condition make these patients particularly vulnerable to deterioration while awaiting a transplant. The decision to seek a BTT strategy requires consideration of estimated waitlist times, the potential for a decline in clinical status before transplantation, the patient's quality of life, and the risk of death while on the waiting list. Progressively longer waitlist times throughout the United States have resulted in the relatively standard use of BTT for the treatment of transplant-eligible patients with end-stage HF.<sup>36</sup> Whereas BTT remains the most common implant strategy for MCS (nearly 65% of these patients are designated as transplant candidates), the percentage of patients officially listed for a transplant at the time of device implantation has steadily declined, now totaling just 21.7%.<sup>37</sup>

### Destination Therapy

Patients with end-stage HF who are not eligible for transplantation may benefit from MCS as a means to prolong or improve the quality of their life. The designation of destination therapy (DT) originates from the REMATCH trial, in

which transplant-ineligible patients supported by MCS had better outcomes than patients supported by medical therapy alone.<sup>7</sup> Through this designation, patients with systemic life-threatening illnesses, malignancies, fixed pulmonary hypertension, advanced age, and morbid obesity may benefit from device therapy regardless of their transplant listing status. Designation as DT does not imply a limitation on the timeframe for treatment, as uninterrupted CF support surpassing 9 years has been reported. Over the past 7 years, the proportion of patients categorized as DT candidates at the time of implantation has steadily increased from 14.7 to 41.6%—likely as a result of increased access to FDA-approved devices for DT, as well as recognition of the possibility of reassessing the transplant status throughout the period of device support.

### Bridge to Decision

The use of long-term MCS in the setting of acute hemodynamic collapse or active decompensation results in comparatively poor outcomes.<sup>37</sup> Short-term MCS offers the advantage of rapid and relatively less invasive access to device therapy while allowing stabilization of the patient and consideration of long-term device candidacy. Thus, patients with a myocardial infarction, myocarditis, acute cardiogenic shock, or unsuccessful percutaneous intervention can be quickly transitioned to support in anticipation of recovery, decline, or optimization before the initiation of long-term MCS.

### Myocardial Reconditioning

In a selected subset of patients, a distinct improvement in ventricular function has allowed device weaning and (occasionally) deactivation. Beginning in the 1990s, studies have revealed histologic and clinical evidence of myocardial rehabilitation after periods of both pulsatile and CF device support.<sup>38-40</sup> Often labeled a "bridge to recovery," this phenomenon is perhaps better described as a return to medical HF therapy. A number of institutions have proposed device-weaning strategies, ranging from aggressive medical therapy using high-dose beta blockade to mechanical offloading and gradual reconditioning of the heart through systematic titration of pump speeds.<sup>41-43</sup> Despite promising reports, only a small percentage of patients have successfully experienced this outcome. Although little is known with certainty regarding the precise variables that govern the pace and degree of myocardial response, the potential for de-escalation of therapy supports an aggressive pursuit of weaning strategies in all patients who require device support.

### Fluidity of Implantation Strategy

It is important to recognize that these designations apply only to the stated goal at the time of device implantation. Whereas regulatory guidelines mandate a proposed goal

of therapy, the available choices do not reflect the reality that a patient's clinical status and transplant candidacy may change during periods of mechanical support. Although some patients may have a deteriorating clinical status or develop unexpected contraindications to transplantation, other patients—such as those with preoperative “fixed” pulmonary hypertension—may experience an improvement in conditions that originally precluded transplant listing.<sup>44,45</sup> The dynamic nature of device strategy is represented in reported device usage statistics, in that nearly 26% of patients initially listed for BTT were no longer listed at 1 year, and that number rose to 43.5% by 24 months. Similarly, nearly 15% of patients designated for DT at the time of device implantation were deemed eligible for transplantation by 12 months.<sup>46</sup> Frequent reappraisal and modification of treatment strategies corresponding to clinical status are essential for successful MCS outcomes.

## INDICATIONS FOR DEVICE SUPPORT

Optimal strategies and indications for the initiation of MCS remain subjects of active investigation. Traditional hemodynamic parameters for device support continue to surface in the literature; although not absolute, these variables include blood pressure (BP) < 80 mm Hg, mean arterial pressure (MAP) < 65 mm Hg, cardiac index < 2 L/min/m<sup>2</sup>, and pulmonary capillary wedge pressure (PCWP) > 20 mm Hg.<sup>47</sup> Strict following of hemodynamic markers can be misleading, however, as patients may present not just in acute cardiogenic shock but also with a more insidious manifestation of congestive HF. In 2013, the International Society for Heart and Lung Transplantation (ISHLT) proposed a thorough and broad-ranging compilation of recommendations for the use of MCS.<sup>36</sup> Although many of the proposed guidelines are limited by the relative weakness of available supporting evidence, they represent the most comprehensive and ambitious summary of consensus opinion,

and underscore the multiorgan and multidisciplinary approach to device candidacy.

In 2013, the American College of Cardiology Foundation (ACCF) and American Heart Association (AHA) released a broad slate of guidelines for the management of HF.<sup>4</sup> The report endorsed the use of an alternative to the traditional New York Heart Association (NYHA) staging system, emphasizing disease-specific markers rather than patient-specific symptoms (Table 62-3). The guidelines support the use of durable MCS in patients with so-called Stage D HF (refractory disease requiring specialized interventions) with reduced left ventricular ejection fraction (LVEF) as a means to both prolong survival and BTT. Although the authors refrain from further characterizing patient selection criteria, the guidelines do emphasize the perceived importance of refractory disease, reduced EF, and severe symptomatology.

In 2013, CMS released updated eligibility criteria for the use of MCS as DT in Medicare beneficiaries.<sup>48</sup> More specific than the ACCF/AHA guidelines, the federal standards allow the use of DT only for patients with end-stage HF (NYHA class IV) who are deemed ineligible for transplantation at the time of device implantation and who meet each of the following conditions: (a) failure to respond to optimal medical management for 45 of the last 60 days, balloon pump dependence for 7 days, or IV inotrope dependence for 14 days; (b) LVEF < 25%; and (c) measured peak oxygen consumption of <14 mL/kg/min or an inability to perform the test. The federal requirements for BTT designation are somewhat broader, mandating only that patients be listed for transplantation by an approved transplant center. However, use of a device for any purpose is permitted only if that specific device has been granted FDA approval for the chosen therapeutic goal.

The Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS) database was established in 2008 to facilitate the growth of MCS and improve patient outcomes. Paired with the registry's first report was a proposal

**TABLE 62-3: Comparison of ACCF/AHA Stages of HF and NYHA Functional Classifications**

ACCF/AHA HF stages		NYHA functional classification	
<b>A</b>	At high risk for HF but without structural heart disease or symptoms of HF	<b>I</b>	No limitation of physical activity. Ordinary physical activity does not cause symptoms of HF
<b>B</b>	Structural heart disease but without signs or symptoms of HF	<b>II</b>	Slight limitation of physical activity. Comfortable at rest, but ordinary physical activity results in symptoms of HF
<b>C</b>	Structural heart disease with prior or current symptoms of HF	<b>III</b>	Marked limitation of physical activity. Comfortable at rest, but less than ordinary activity causes symptoms of HF
<b>D</b>	Refractory HF requiring specialized interventions	<b>IV</b>	Unable to carry on any physical activity without symptoms of HF, or symptoms of HF at rest

**TABLE 62-4: INTERMACS Clinical Profiles of Advanced Heart Failure**

Profile	Description	Timeframe for definitive intervention
1	Patient with life-threatening hypotension despite rapidly escalating inotropic support, critical organ hypoperfusion with increasing lactate levels and/or systemic acidosis. “ <i>Crash and burn</i> ”	Needed within hours
2	Patient with declining function despite intravenous inotropic support, may be manifest by worsening renal function, nutritional depletion, inability to restore volume balance. “ <i>Sliding on inotropes</i> ”	Needed within few days
3	Patient with stable blood pressure, organ function, nutrition, and symptoms on continuous intravenous inotropic support, but demonstrating repeated failure to wean owing to recurrent symptomatic hypotension or renal dysfunction. “ <i>Dependent stability</i> ”	Elective over a few weeks
4	Patient can be stabilized close to normal volume status but experiences frequent relapses into fluid retention, generally with high diuretic doses. Symptoms are recurrent rather than refractory. More intensive management strategies should be considered, which in some cases reveal poor compliance. “ <i>Frequent flyer</i> ”	Elective over weeks to months as long as treatment of episodes restores stable baseline, including nutrition
5	Patient is living predominantly within the house, performing activities of daily living and walking from room to room with some difficulty. Patient is comfortable at rest without congestive symptoms, but may have underlying refractory elevated volume status, often with renal dysfunction. “ <i>Housebound</i> ”	Variable, depends upon nutrition, organ function, and activity
6	Patient without evidence of fluid overload is comfortable at rest and with activities of daily living and minor activities outside the home, but fatigues after the first minutes of any meaningful activity. “ <i>Walking wounded</i> ”	Variable, depends upon nutrition, organ function, and activity
7	A placeholder for future specification, patients without recent unstable fluid balance, living comfortably with meaningful activity limited to mild exertion	Transplantation or circulatory support not currently indicated

for a new system of classifying patients with advanced HF.<sup>49</sup> Seven clinical profiles were designed to establish an enhanced method for characterizing patients requiring device therapy (Table 62-4). These profiles represent a stratification of patients diagnosed with advanced HF—defined as NYHA class III and IV symptoms despite optimal therapy. By documenting the profiles of patients undergoing device implantation, INTERMACS provides an opportunity to evaluate data and trends concerning surgical risks and indications. Clinical practice has indeed shifted since the introduction of this system, most notably through de-escalation of the preoperative clinical profile. Whereas more than 60% of patients who received device implants before 2011 were listed as having INTERMACS 1 or 2 status, the proportion of patients classified as having level 3 status has steadily increased, now representing nearly a third of all who receive implants.<sup>8,50</sup> Indications and guidelines continue to evolve, but these results illustrate a clear trend in the management of HF toward intervening during periods of reduced clinical acuity.

## CONTRAINDICATIONS TO DEVICE SUPPORT

Relative contraindications to device therapy include irreversible major end-organ dysfunction, severe hemodynamic instability, profound coagulopathy, complex congenital

anomalies, and restrictive heart disease with decreased ventricular dimensions. Because successful outcomes have nevertheless been reported in these populations, decisions should be made on a case-by-case basis in order to weigh the potential risks and benefits of intervention.<sup>51,52</sup> Surgery should be deferred in the presence of active infection or bacteremia to minimize the risk of bacterial device seeding; current recommendations suggest a minimum of 5 days of culture-documented clearance from infection.<sup>36</sup>

## PREOPERATIVE EVALUATION

Once potential candidacy for device support has been determined, a thorough appraisal of perioperative risk is warranted. If at all possible, implantation of long-term MCS device should be performed electively, not under emergent circumstances. Identification of preoperative risk factors and treatment of reversible comorbidities can greatly improve patient outcomes.

Due to the importance of proper patient selection, efforts to predict early mortality after LVAD implantation have been a consistent theme in MCS research. During the era of pulsatile LVADs, several risk-evaluation scoring systems were developed with variable predictive utility. One of the most widely used of these scales, the Leitz-Miller destination therapy risk score (DTRS), was derived from a cohort of over

**TABLE 62-5: Multivariable Predictors of 90-Day Mortality (HeartMate II Risk Score)**

Parameter	SE	OR (95% CI)	p Value
Age (years)	0.12	1.32 (1.05-1.65)	.018
Albumin (g/dL)	0.23	0.49 (0.31-0.76)	.002
Creatinine (mg/dL)	0.20	2.10 (1.37-3.21)	<.001
INR	0.32	3.11 (1.66-5.84)	<.001
Center volume	0.34	2.24 (1.15-4.37)	.018
	<b>Low risk</b>	<b>Medium risk</b>	<b>High risk</b>
<b>HMRS score</b>	<1.58	1.58-2.48	>2.48
<b>90-Day survival</b>	96% (± 1%)	84% (± 2%)	71% (± 4%)

HMRS =  $(0.0274 \times \text{Age}) - (0.723 \times \text{Alb}) + (0.74 \times \text{Creat}) + (1.136 \times \text{INR}) + (0.807 \times \text{Vol})$ .

300 HeartMate XVE patients and incorporated 9 weighted variables to estimate 90-day in-hospital mortality.<sup>53</sup> When systematically tested in a CF LVAD population; however, DTRS was found to provide only modest discriminatory value.<sup>54</sup> In contrast, the Model of End-Stage Liver Disease (MELD) has been shown to be a predictor of adverse events after implantation of both pulsatile and CF LVADs.<sup>55</sup> Utilizing only the creatinine level, total bilirubin level, and international normalized ratio (INR), the MELD score (and later the anticoagulation-compatible MELD-XI score) was found to correlate with overall and postoperative survival.<sup>56</sup> More recently, a global risk-assessment scale was developed using only CF data culled from the HeartMate II clinical trials database. The HeartMate II multivariable risk score (HMRS) utilizes five variables—patient age, albumin level, creatinine level, INR, and implanting center volume—to predict 90-day postoperative mortality<sup>57</sup> (Table 62-5). While similar to MELD in its direct comparison of predictive results, HMRS is more specifically designed for HF patients and may offer a modest benefit in outcome discrimination.<sup>58</sup> To date, no risk-assessment scale has shown absolute superiority in preoperative risk stratification, but the available models do emphasize the importance of preoperative optimization of overall end-organ function.

## Operative Risk

As with any proposed cardiothoracic procedure, the surgical complexity of each case must be carefully addressed early in the evaluation process. Unfavorable anatomical scenarios—such as a history of previous sternotomies, congenital anomalies, or heavily calcified anastomotic sites—are common in

this patient population and significantly escalate operative risk.

The utility of concomitant cardiac and valvular procedures is poorly understood and remains controversial. Whereas some studies have suggested that concurrent procedures are associated with diminished overall survival, consensus opinion does support intervention in specific situations.<sup>36,59,60</sup> Native aortic insufficiency has been shown not only to adversely affect the performance of CF pumps but also to speed the progression of valvular incompetence.<sup>61</sup> Although clinical practice varies, ISHLT guidelines suggest concurrent intervention for regurgitation deemed moderate or greater.<sup>36</sup> The presence of a mechanical prosthesis entails a prohibitive risk of thromboembolic complications and warrants surgical exclusion through ligation of the LV outflow tract, supra-valvular patch closure, or a placement of a felt sandwich plug.<sup>62-65</sup> Tricuspid regurgitation has been implicated in the development of postoperative right-sided HF (RHF), and guidelines generally support intervention—either replacement or ring repair—for disease classified as moderate or greater.<sup>36,66-68</sup> The presence of mitral regurgitation (MR) does not typically necessitate surgical intervention at the time of device implantation. Whereas MR is common in patients with end-stage HF, this finding is often the result of annular distortion secondary to dilation of the left ventricle and typically improves with mechanical decompression and offloading.<sup>69</sup> Due to an increased risk for right-to-left shunting, atrial septal defects and patent foramen ovale (PFO) should be closed at the time of implant.<sup>70</sup> Unmasking of a previously undetected PFO has been reported after mechanical unloading of the left side of the heart, and this defect must be surgically or endovascularly repaired if systemic postoperative hypoxemia occurs.<sup>69,71</sup>

## End-Organ Function

The presence of multiple medical comorbidities is a common finding in patients with end-stage HF and an ever-present challenge in the surgical management of the disease. Permanent, life-threatening comorbidities (such as preoperative dialysis dependence) are often associated with excessive perioperative risks and frequently preclude eligibility for MCS. However, improvement in end-organ function has been documented after periods of device support.<sup>72-75</sup> Preoperative determination of the severity of end-organ disease is a critical process, and it relies on the collective clinical judgment of the multidisciplinary treatment team.

Renal dysfunction, specifically, is strongly associated with poor outcomes after device implantation.<sup>76,77</sup> As a result, patients who require chronic preoperative dialysis are generally excluded from implantable MCS consideration. Additionally, multiple studies have shown a decline in postoperative survival associated with deranged markers of liver function.<sup>78,79</sup> While acute cardiogenic liver injury can be stabilized, elevations in bilirubin levels, aminotransferase levels, and INR warrant further workup and evaluation. Preoperative mechanical ventilation has been shown to be associated with postoperative respiratory failure, RV failure, and

increased mortality.<sup>80</sup> An assessment of pulmonary reserve is often limited by severe cardiac dysfunction, and no specific pulmonary function criteria have been formally established for device exclusion. Impaired cognitive function or a recent history of stroke obligates a thorough neurologic and cognitive examination. Patients with significant residual deficits should undergo an occupational therapy evaluation to determine whether they possess sufficient physical dexterity to manipulate an MCS device independently.

## Right Ventricular Function

Prevention and treatment of RV dysfunction is a significant challenge in the field of MCS, and postoperative RHF has long been associated with poor clinical outcomes.<sup>37,81,82</sup> Identification of patients at risk for RHF provides an opportunity for implementation of preoperative optimization strategies and enhanced surgical preparedness. However, methods developed thus far to predict RHF after LVAD implantation have been largely based on experience with pulsatile devices and have proven inconsistent, likely due to the variety of clinical definitions, variables, and treatment strategies.<sup>83-86</sup>

Despite the complex pathophysiology underlying this disease process, several recent studies have significantly improved our understanding of variables that predispose to RV dysfunction. In a retrospective analysis of the HeartMate II BTT trial, Kormos and colleagues<sup>87</sup> sought to identify risk factors for the development of postoperative RHF in a CF LVAD population. That study specifically identified preoperative ventilator support, an increased central venous pressure (CVP) and CVP/PCWP ratio, a decreased RV stroke work index, and elevated white blood cell and blood urea nitrogen values as significant predictors of RHF. Echocardiographic parameters have also been suggested as tools for assessing the risk of RHF after LVAD implantation. Ultrasonographic studies have implicated reduced free-wall strain, RV-to-LV diameter ratios, severity of tricuspid regurgitation, and RV EF as predictors of right-sided heart dysfunction.<sup>88-91</sup> Researchers at the University of Pennsylvania recently developed a risk-stratification tool to assess the preoperative likelihood for tolerance of univentricular support.<sup>92</sup> Although limited by its size, patient selection, and single-center design, the study identified preoperative tachycardia, elevated CVP, ventilator support, RV dysfunction, and tricuspid regurgitation as predictors of the need for biventricular support.

Thus, whereas the specific variables that may predispose patients to RHF after LVAD implantation remain unclear, certain principles have emerged to help guide patient selection and management. A consistent theme throughout the majority of these studies is an association between predictors of RHF and predictors of overall mortality.<sup>93,94</sup> Sicker patients—with preoperative evidence of end-organ dysfunction, hemodynamic instability, and impaired RV mechanics—are especially vulnerable to RHF after LVAD implantation. Thoughtful evaluation and preoperative consideration of these risks are paramount in surgical planning.

## Multidisciplinary Assessment/Social Evaluation

Due to the comprehensive nature of device therapy and the commitment required for successful outcomes, candidates for MCS must undergo a comprehensive multidisciplinary assessment. Preoperative nutritional status should be evaluated and optimized, as studies have shown an association between cachexia and perioperative mortality rates.<sup>95,96</sup> A history of psychiatric illness should cause significant concern and warrants a thorough evaluation of competency and ability to adhere consistently to therapy. Routine psychosocial evaluation should be performed by qualified healthcare personnel to explore available personal, social, vocational, financial, and environmental support systems. Advanced patient age alone should not preclude device therapy.<sup>97</sup> Cases should be reviewed on an individual basis by a multidisciplinary committee to ensure that all concerns are addressed before surgery.

## DEVICE SELECTION

Appropriate device selection is determined by a number of factors, including the patient's overall clinical condition, the indication for MCS, the proposed goal of device therapy, and relevant patient-specific considerations.

Patients with an unstable condition or acute decompensation are often best served by short-term devices that are less invasive, faster to place, and less expensive than fully implantable pumps. As a reliable and historically familiar option, VA ECMO is the procedure of choice for emergent situations in many institutions worldwide. Peripheral cannulation may be performed at the bedside, in the catheterization lab, or in the operating theater, and the presence of an oxygenator allows for full cardiopulmonary support for a period of days to weeks. Catheter-based LVADs such as the Impella and TandemHeart are used with increasing frequency for short-term LV support, particularly after high-risk coronary interventions.<sup>32</sup> These percutaneous devices can provide temporary support without the need for surgical access, but they are susceptible to hemolysis and positional disruption, and their use is typically limited to 1 to 2 weeks. For patients for whom more robust flows are required or percutaneous measures have failed, the CentriMag is the most frequently used temporary option. Cannulation is similar to that performed for routine CPB, and the device can be used for temporary uni- or biventricular support for up to 1 month.

Fully implantable CF LVADs are the devices of choice for patients who require long-term MCS and whose condition is stable enough to permit major surgery. Of the various options, the HeartMate II LVAD and the HeartWare HVAD are the most commonly used devices. Although they function in a similar manner, the choice between these pumps is based on factors ranging from anatomical concerns to institutional availability. In the United States, the CMS strictly mandates preoperative designation of patients as either BTT or DT candidates. Despite the fluid nature

of these preimplant strategies, the HeartMate II remains the only device approved by the FDA for use in both BTT and DT patients. The HVAD, by contrast, is currently approved only for BTT in the United States, and clinical trials seeking DT approval are currently underway. No study has yet shown either pump to be superior to the other. Although the advent of smaller CF pumps has lessened the anatomical challenge of implantation, patient body habitus remains an important consideration. For example, the intrapericardial position of the HVAD makes the HeartWare device particularly appealing for smaller-framed patients.

For patients with biventricular HF, the decision to pursue uni- or biventricular MCS greatly affects the available treatment options. For patients with mild-to-moderate RHF, a CF LVAD with temporary right-sided support may be sufficient to allow RV reconditioning. In the event of failed temporary support or severe biventricular disease, dual (right and left) CF devices may be used with relative success despite the logistical complexities associated with multiple controllers and batteries. The pulsatile SynCardia TAH (SynCardia Systems; Tucson, AZ) currently is the only FDA-approved option for implantable biventricular support in patients awaiting transplantation. Although the SynCardia requires considerable intrathoracic volume displacement, it allows mobility and outpatient management by means of a portable pneumatic driver. The continued development of a fully implantable CF TAH is underway and will be discussed later in this chapter.

## SURGICAL TECHNIQUE

As experience with device implantation has grown, surgical techniques have evolved to reflect lessons learned. Early in the development of LVADs, apical positioning of the inlet cannula was advocated, so as to take advantage of the longest measured span within the left ventricle. This positioning, however, often creates unfavorable angulation of the inlet toward the interventricular septum, resulting in arrhythmogenesis and mechanical obstruction of the inlet after a reduction in the LV end-diastolic dimension. Over time, a number of alternative implant strategies have been devised, ranging from a thoracotomy to subcostal incisions and from anterior to lateral pump positions.<sup>98-100</sup> Surgeons at our institution favor a method designed to produce a parallel orientation between the inlet cannula and the interventricular septum by placing the inlet along the diaphragmatic surface of the heart.<sup>101,102</sup> Although it deviates from traditional technique, this method eliminates the need for a preperitoneal pump pocket and creates a more geometrically advantageous alignment.

Whereas the technique described is specifically intended for the HeartMate II, most of the procedure is indistinguishable from implantation of other CF LVADs. Differences involving the HeartWare HVAD—the second most commonly used device worldwide—will be addressed as necessary. Essential components of the procedure include (1) positioning of the inlet cannula along the diaphragmatic aspect of the left ventricle; (2) transdiaphragmatic positioning of the HeartMate II pump housing; (3) proper sizing of the outflow graft to

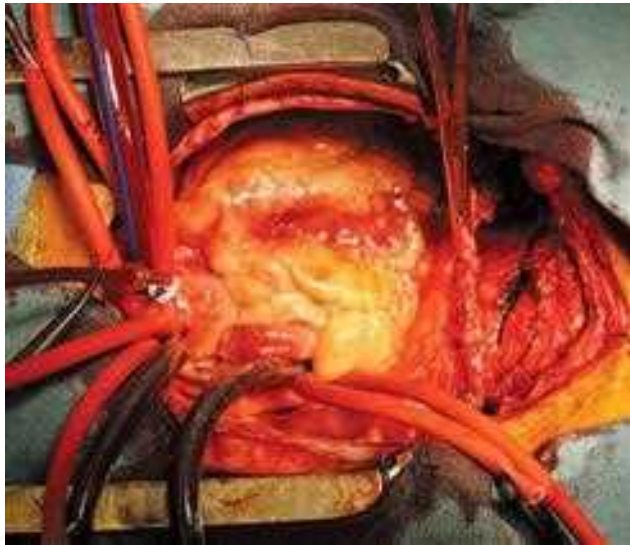

ensure an optimal pump position and avoidance of kinking; (4) thorough de-airing of the heart and pump circuit; and (5) titration of pump speeds under echocardiographic guidance to optimize heart function.

A vertical midline incision is made, followed by a 6-cm subxiphoid extension. A standard sternotomy is then performed with the ratchet of the sternal retractor oriented toward the patient's head to provide adequate inferior exposure. The pericardium is opened in the midline and divided along the length of the diaphragm. Both pleural cavities are entered to assist with positioning of both the pump and outflow conduit. The anterior border of the diaphragm is then incised from the midline to the apex of the heart, permitting entrance into the peritoneal cavity and adequate space for introducing the pump (Fig. 62-9a). A point of entry for the inlet cannula to traverse the diaphragm is selected to correspond with the diaphragmatic surface of the left ventricle and is marked with an electrocautery.

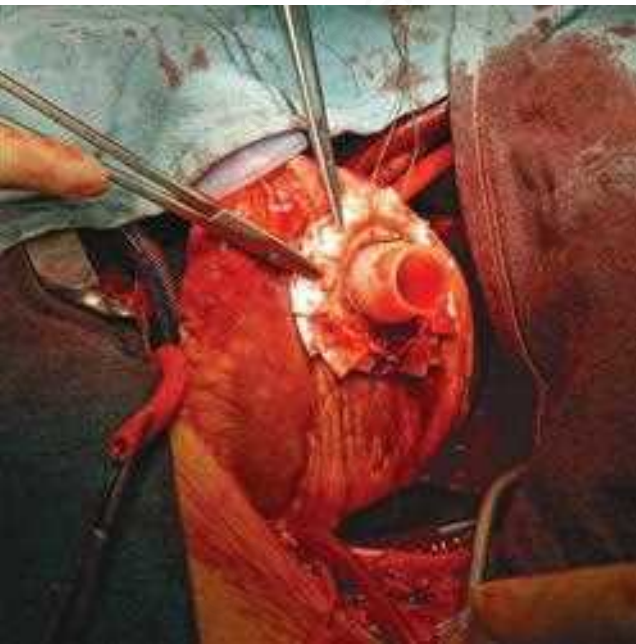

After systemic heparinization is achieved, the ascending aorta is cannulated distally, with consideration for potential future reoperation and transplantation. Venous cannulation is typically achieved by using a dual-stage cannula in the right atrial appendage, except in cases for which a concomitant procedure is planned—such as a tricuspid valve repair or PFO—when bicaval cannulation is preferred. In a reoperative sternotomy, the femoral vessels should be exposed to allow immediate cannulation if mediastinal dissection results in hemodynamic instability.

CPB is then initiated, and the LV apex is brought out of the chest and stabilized with an off-pump suction-cup stabilizer. For inlet placement along the diaphragmatic surface, identification of the appropriate ventriculotomy site is crucial to avoid disruption of the papillary muscles and allow the inlet to lie parallel to the interventricular septum along the short axis of the left ventricle. This is accomplished by selecting a point approximately one-third of the distance from the apex to the base of the heart (thus, anterior to the origin of the papillary muscles), with the medial edge of the sewing ring placed 0.5 to 1 cm lateral to the posterior descending artery. A coring knife—typically provided by the device manufacturer—is used to open the ventricle, with care to stay parallel to the septum and follow posteriorly in the direction of the mitral valve. The ventricular cavity is then thoroughly inspected for evidence of thrombus or potentially obstructive trabeculae.

To secure the Silastic inflow cuff of the HeartMate II, 12 braided polyester full-thickness sutures are placed circumferentially around the ventriculotomy site in a horizontal mattress fashion with broad interlocking felt pledgets. The sutures are passed through the felt sewing ring of the inflow cuff, which is then lowered into position and secured. Hemostasis around the inflow is bolstered by placing a full-thickness purse-string stitch through the pledgeted ring, using a large-caliber monofilament suture (Fig. 62-9b). The HeartWare HVAD utilizes a specialized sewing ring equipped with a locking mechanism to secure the pump in place. The HVAD sewing ring is typically placed before the ventricle is cored,

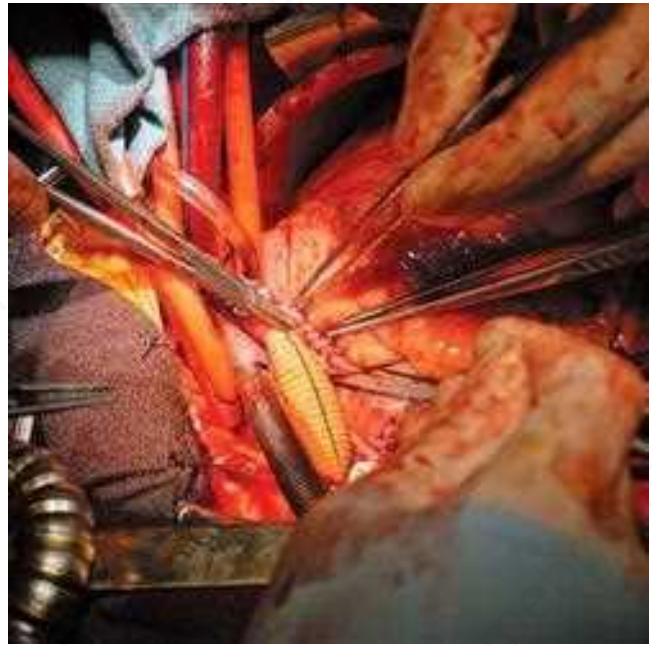

A

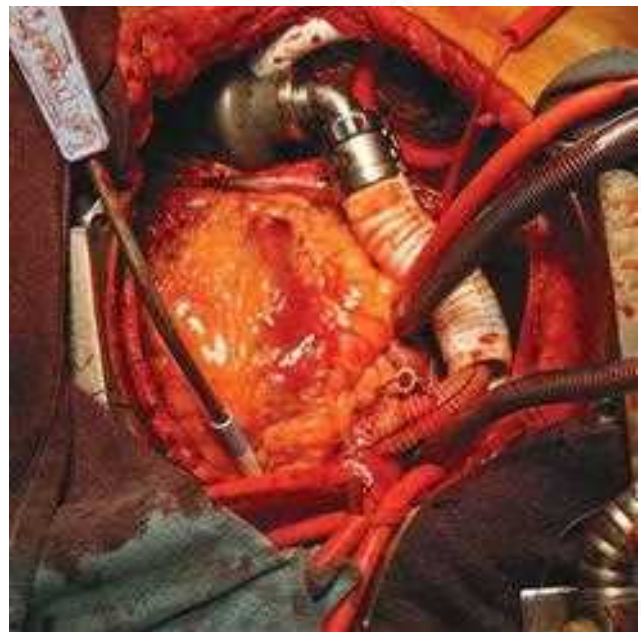

B

C

D

E

**FIGURE 62-9** HeartMate II implantation. (A) Retraction of the diaphragm in anticipation of subdiaphragmatic pump positioning. (B) The ventricle is cored along the diaphragmatic surface of the heart—lateral to the posterior descending artery—and a pledgeted ring secures the Silastic inflow cuff. (C) Transdiaphragmatic positioning of the HeartMate II inflow cannula. (D) Anastomosis of the outflow graft to the ascending aorta, aided by a partial occluding vascular clamp. (E) Final alignment of the pump and outflow conduit. The pump housing lies beneath the diaphragm, and the outflow graft courses toward the right side of the chest. Introduction of a 19-gauge needle permits de-airing of the system.

and the ring is seated with a similar series of horizontal mattress sutures.

Next, the diaphragmatic myotomy—ample enough to admit two fingers—is completed at the previously marked location, and the pump is brought into the field after being prepared and primed on a separate table. The inlet cannula is guided through the diaphragm, inserted within the Silastic ring, and finally secured in place with two ratcheting cable ties (Fig. 62-9c). The pump housing is pulled into the abdomen until the heart lies flush with the diaphragm, and the pump is positioned above the left lobe of the liver. To protect the bowel, the body of the pump is wrapped in available omentum. The discoid shape of the HeartWare HVAD allows intrapericardial pump placement. Although the inlet is placed along the diaphragmatic aspect of the ventricle, entrance into the abdomen is not required.

Next, attention is turned to the outflow graft, which is allowed to fill, then is measured and cut in beveled fashion, with enough length to produce a gentle curve toward the right side of the chest but without excessive redundancy that might lead to kinking. After placement of a partial occluding clamp along the ascending aorta, an aortotomy is created along the anterolateral surface by sequentially firing a 4.4-mm punch. The outflow-graft anastomosis is performed in an end-to-side fashion with continuous 5-0 polypropylene suture (Fig. 62-9d). The partial occluding clamp is then removed, and the graft is de-aired while backflow is prevented by an occlusive vascular clamp.

The driveline exit site is identified two fingerbreadths below the right subcostal margin within the mid-clavicular line. A skin punch allows the introduction of a tunneling device, which is then passed behind the right rectus muscle, anteriorly to the posterior rectus sheath. The driveline is withdrawn with the tunneling device, cleaned, and connected to the device controller, with care to loop the velour-coated portion of the lead within the patient's body, as studies have shown that preservation of the velour-silicone interface beneath the level of the skin is associated with a decreased incidence of driveline infections.<sup>103</sup>

After thorough de-airing, the pump is started at its lowest setting (6000 rpm for the HeartMate II; 1800 rpm for the HeartWare HVAD) with a venting needle in the highest point of the outflow graft (Fig. 62-9e). CPB flows are gradually decreased while the pump speed is adjusted under transesophageal echocardiographic (TEE) guidance to optimize the chamber size, position of the interventricular septum, degree of MR, and RV function.

Protamine is administered, the cannulas are removed, and drains are placed in the mediastinum and pleural spaces. The bare portion of the outflow graft is covered with a 20-mm-diameter ringed Gore-Tex graft (Gore Medical, Newark, DE) to avoid kinking and damage during future sternal reentry. The defect in the diaphragm is partially reapproximated, and the sternum and soft tissues are closed in the standard fashion. If the patient has excessive bleeding related to severe coagulopathy, temporary chest closure may be advisable to allow correction and stabilization before delayed sternal closure is attempted.<sup>104</sup>

## POSTOPERATIVE MANAGEMENT

Diligent and comprehensive patient care is essential for successful MCS outcomes, and proper management begins before surgery. As described earlier, careful patient selection is paramount, as is prompt identification of the most appropriate opportunity for device implantation. To minimize surgical risks, particular emphasis should be placed on the preoperative optimization of end-organ function, reversal of coagulation imbalances, correction of malnutrition, and eradication of preexisting infection. Device recipients with decompensated clinical profiles (INTERMACS levels 1 and 2) are known to experience worse outcomes than patients whose condition is comparatively stable.<sup>37</sup> As a result, aggressive medical management, intraaortic balloon therapy, or temporary device support is often warranted to improve the patient's hemodynamic condition before surgery. Careful planning should also include the recognition of patient-specific risks—such as the potential need for RV support—to avoid lengthy delays in the recognition and treatment of postoperative complications.

Intraoperative measures are also crucial for preventing postoperative complications. In addition to meticulous surgical technique and adequate hemostasis, judicious blood-product administration minimizes the risk of volume overload and RV failure. In the setting of profound coagulopathy, low-dose recombinant factor VIIa (NovoSeven; Novo Nordisk, Plainsboro, NJ) and four-factor prothrombin complex concentrate (Kcentra; CSL Behring GmbH, Marburg, Germany) have shown value as pharmacologic resources without causing an undue risk of device complications or thromboembolic events.<sup>105</sup>

Initial device setup is a critical process that occurs within the operating theater. After the pump is activated, power and flow recordings should be carefully monitored, and any suspected physical impediments to device performance, such as outflow kinking or cannula malpositioning, should be immediately identified and corrected. Intraoperative identification of optimal pump speed is a dynamic process that requires both direct visualization and TEE to assess ventricular chamber size, RV function, and interventricular septal position. The combination of CPB weaning, intravascular fluid shifts, vasoactive medications, and sternal closure can result in sudden and dramatic changes in cardiac function, and continual reassessment is required to maintain an appropriate balance between the patient and device.

Immediate postoperative management in the intensive care unit (ICU) requires an understanding of the delicate balance between pump flow, RV function, and intravascular volume status—often interpreted within the context of a volatile and complex hemodynamic milieu. Baseline comprehensive laboratory panels should be assessed immediately upon the patient's arrival in the ICU to assess acid-base status, coagulation markers, and hematologic reserves. Acidosis should be aggressively corrected and coagulopathy reversed with appropriate blood component resuscitation.

Arterial BP is principally controlled by vasoactive medications and intravascular fluid management, not pump speed.

The flows produced by CF LVADs operating at constant speed are highly dependent on the pressure differential across the pump. The resulting afterload sensitivity, particularly in centrifugal pump designs, requires careful BP titration to ensure sufficient output without causing excessive systemic pressures. Although optimal MAPs in this patient population remain unknown, our practice is to target a range of 60 to 80 mm Hg. Due to the reduction in pulse pressure created by CF LVADs, systemic arterial pressures are expressed as a single mean value and should be continuously monitored in the postoperative period. Noninvasive BP cuff measurements have been found to be unreliable in the setting of CF MCS and frequently underestimate systolic pressures. As a result, Doppler measurements have emerged as the gold-standard noninvasive modality.<sup>106</sup> The control of CVP is also of critical importance in the postoperative period, as excessive volume administration—a frequent obstacle in this patient population—can quickly lead to development of RV dysfunction.

Assessment of appropriate device function is based on system-specific parameters in conjunction with echocardiographic findings. Pump speed (rpm) and power expenditure (watts) are the only directly measured variables provided by the HeartMate II and HeartWare HVAD; estimated flow (L/min) is indirectly calculated and typically corresponds to changes in pump power. The pulsatility index (PI) is a parameter unique to the HeartMate II, and it is designed to indicate ventricular filling and function by interpreting changes in pump flow due to contraction of the left ventricle. Although optimal target levels are unknown, the PI can be expected to decline with increasing pump support.<sup>69</sup> The HeartWare HVAD provides continuous readings of pump speed, power, and flow, and it records values every 15 minutes, thus maintaining a retrievable data log for review of the preceding 30 days. Interpretation of these data recordings has shown a potential for predicting, diagnosing, and managing clinical events, including volume changes, RV dysfunction, and pump thrombosis.<sup>107</sup>

Any deviation in pump data warrants immediate interrogation, including assessment of hemodynamics, volume status, heart rhythm, sources of intrathoracic compression, and ventricular dimensions. Whether emergent or elective, assessment of device function is best achieved by echocardiography focused on end-diastolic dimensions, septal positioning, valvular competence, and aortic valve opening. Systematic assessment across a range of pump speeds—“speed-change” or “ramped-speed” echo—allows optimization of maintenance pump speeds by comparing functional dynamics. The preferred frequency of these studies varies among institutions; at a minimum, it should be performed in the operating room, soon after arrival in the ICU, before hospital discharge, and any time concern is raised about the adequacy of support.

Our practice is to seek early extubation, mobilization, and resumption of nutritional support. Aggressive diuresis is typically warranted for postoperative fluid offloading, and volume status is monitored using daily weights, physical findings, and hemodynamic parameters. The patient should

be weaned from vasoactive and inotropic medications as tolerated. Lines and drains should be removed as early as possible to reduce the risk of postoperative infection, and strict aseptic technique is required for driveline dressing changes. An aggressive physical therapy regimen is initiated as early as possible, as is patient device training.

## Management of Right Ventricular Dysfunction

After LVAD implantation, outcomes are heavily dependent on the preservation of adequate RV function. Whereas RHF is most often the result of inadequate left-sided output, the initiation of LVAD support can adversely affect RV function in several ways. The sudden increase in left-sided cardiac output and venous return requires the unsupported right ventricle to respond immediately to an increased demand. Although LVAD therapy has been shown to reduce the severity of pulmonary hypertension, this resolution may not be immediate, forcing the right ventricle to pump against a relatively high-pressure system. Furthermore, interdependence between the right and left ventricles can result in the distortion of RV and septal architecture upon unloading of the LV, leading to impaired RV contractility. In this way, initiation of device support can lead to sudden demands and strains on the right ventricle to which it cannot adequately respond.

Management personnel must be vigilant in monitoring for signs of acute RHF to allow prompt and aggressive treatment. Signs of impending or evolving RV dysfunction include increasing vasopressor requirements or hemodynamic instability, elevated or rising CVP, decreased urine output, and low mixed venous oxygen saturation (SvO<sub>2</sub>). In 2011, Potapov and colleagues<sup>108</sup> suggested standardized criteria for the diagnosis of RV dysfunction that included the inability to wean from CPB, or any two of the following conditions: MAP < 55 mm Hg, CVP > 16 mm Hg, SvO<sub>2</sub> < 55%, LV flow rate index < 2 L/min/m<sup>2</sup>, or significant inotropic dependence. In addition to hemodynamic markers, echocardiography should remain an essential component of the evaluation, allowing direct assessment of ventricular size, contractility, and septal positioning. Along with traditional signs of depressed right-sided heart function, the failure to maintain appropriate LVAD power consumption and flows in the absence of hypovolemia may suggest inability of the right ventricle to deliver sufficient volume to the pump inlet.

The majority of patients with RV dysfunction will require inotropic support, typically in the form of milrinone, dobutamine, isoproterenol, or epinephrine. Early and aggressive pharmacologic diuresis is essential to reduce RV preload, particularly in the setting of excessive volume loading and massive transfusion. Maintenance of sinus rhythm preserves the RV stroke volume and lessens myocardial strain. Although the results of studies have been contradictory, inhaled nitric oxide therapy appears to have utility in alleviating pulmonary vascular resistance and RV dysfunction through direct pulmonary arterial vasodilatory effects.<sup>108,109</sup> When all other management options have been exhausted, consideration of

mechanical right-sided support, either temporary or permanent, is warranted.<sup>110</sup>

## Anticoagulation

The approach to anticoagulation in patients who require long-term MCS has not yet been standardized and varies considerably between institutions. Whereas thromboembolic complications were a significant challenge for early devices, the unique textured interior surface of the HeartMate XVE resulted in the development of a neointimal blood interface that effectively eliminated the need for systemic anticoagulation.<sup>111</sup> The introduction of the Jarvik 2000, which utilized blood-washed bearings and a CF design, led to the widespread practice of systemic anticoagulation to reduce the perceived risk of pump thrombosis.<sup>112</sup> As a result, initial management strategies for CF devices involved a target INR of 2.5 to 3.5 before experience gained from the HeartMate II pivotal trial led to a suggested target range of 2 to 3 along with early postoperative heparin infusion and antiplatelet therapy in the form of aspirin and dipyridamole.<sup>25,113</sup>

Despite these initial recommendations, the appropriate level of anticoagulation for long-term CF support remains an area of active investigation. Studies have shown that the incidence of hemorrhagic complications is far greater than that of thrombotic events in this patient population, leading to the suggestion that a lower INR target may be appropriate.<sup>37,114</sup> Moreover, patients transitioned directly to warfarin without an early heparin bridge have been shown to experience reduced postoperative transfusion requirements without an increased risk of thrombotic complications.<sup>115</sup> Guidelines published by ISHLT recommend the initiation of heparin therapy on postoperative day 1, with warfarin and aspirin started by postoperative day 3 (target INR 2.0 to 3.0).<sup>36</sup> Our institution follows an alternative protocol, preferring the early introduction of warfarin and aspirin therapy (by postoperative day 1), with heparin infusion reserved for patients in whom anticoagulation remains subtherapeutic by postoperative day 4. Target INRs for this protocol are specific to the type of device, application, and presence of concomitant cardiac pathology. Standard intraoperative heparin reversal with protamine sulfate is accepted practice in most centers.

## Biventricular Device Management

The concomitant use of a right-sided pump adds several complexities to device management. From a hemodynamic standpoint, determination of the appropriate balance between the two pumps can be difficult. Continuous-flow devices are principally governed by two variables: the speed of the rotor and the pressure difference across the device. As a result, the output produced by a CF pump operating at constant speed will reflect the volume of blood delivered to the inlet. This arrangement provides a degree of inherent automaticity that is advantageous when pumps are operated in series. Management of a biventricular system, therefore, requires identification of a right-sided pump speed that permits venous

offloading without development of pulmonary edema—a common complication of RV assistance as a result of reduced afterload established by the low-pressure pulmonary circulation. Left-sided speeds may then be actively titrated to compensate for physiologic variations in the volume delivered to the left ventricle.

Biventricular assist device (BiVAD) support also creates a number of logistical challenges. The surgical complexity of accommodating two pump housings within the thoracic cage can be significant. Whereas the use of dual HeartMate II devices has been reported, the relatively small profile and intrapericardial pump position of the HeartWare HVAD offers a considerable advantage, making this device preferable for high-risk cases or planned biventricular support.<sup>116-118</sup> In our experience, the outflow conduits are best configured in opposing alignments, with the right-sided graft directed posterolaterally to allow anastomosis with the pulmonary artery trunk without interfering with the course of the LVAD graft. A further disadvantage of dual device support is the redundancy of system controllers (two) and batteries (four) required for operation. The resultant physical burden, complexity in daily use, and responsibilities for maintenance present significant challenges for long-term management of patients who require biventricular therapy.

## POSTOPERATIVE OUTCOMES

Over the past 20 years, multicenter studies have documented a progressive improvement in postoperative mortality after LVAD implantation (Fig. 62-10). The landmark REMATCH trial showed a 1-year survival rate of 52% for patients randomized to receive device therapy, compared with 25% survival at 12 months for those treated with medical therapy alone.<sup>7</sup> Six years later, the HeartMate II BTT study showed 68% 1-year survival with CF support, a total that rose to 73% within the larger Continued Access Protocol report.<sup>9,25</sup> In keeping with this trend, the HeartWare ADVANCE trial results were released in 2012 and showed an 86% survival rate at 1 year, which was comparable to contemporary INTERMACS data and led to FDA approval of the HVAD for BTT indications.<sup>27</sup> Likely due to improved patient selection, 30-day perioperative survival has also improved during that timespan, rising from roughly 80% with the HeartMate XVE to more than 90% with contemporary devices.<sup>53,119,120</sup>

Analysis of the INTERMACS registry reveals several statistically significant risk factors for mortality in patients supported by CF LVADs, including severity of the preoperative clinical profile (levels 1 and 2), renal dysfunction, age over 70 years, RV dysfunction, and increased surgical complexity.<sup>8,121</sup> Biventricular device support is consistently associated with increased short-term mortality, although the data suggest some utility in early planned (as opposed to delayed) implementation of biventricular device therapy.<sup>37,122</sup> Importantly, LVAD therapy has been shown to be equivalent to transplantation in terms of 1- and 2-year mortality, and pretransplant MCS has not been shown to negatively affect outcomes for subsequent transplantation.<sup>123,124</sup> Quality-of-life metrics also

**FIGURE 62-10** Actuarial survival curve for adult recipients of primary continuous-flow left ventricular support. Patients were censored at transplantation or device explantation. (Reproduced with permission from Kirklin JK, Naftel DC, Pagani FD, et al: Sixth INTERMACS annual report: a 10,000-patient database, *J Heart Lung Transplant.* 2014 Jun;33(6):555-564.)

reveal a significant improvement with LVAD therapy that is sustained through 24 months after device implantation.<sup>37</sup>

### ADVERSE EVENTS AND DEVICE COMPLICATIONS

The implementation of device therapy is associated with specific perioperative and long-term risks for the patient. To standardize the evaluation of patient outcomes, INTERMACS has established definitions for adverse events associated with MCS. The cumulative incidence of these adverse events within the first 60 days of MCS has been reported to be as high as 89%, many such events being associated with a reduction in long-term survival<sup>125,126</sup> (Fig. 62-11). Implementation

and management of MCS, thus, obligates a consideration of the risks associated with device therapy and an appreciation of the implications of certain events.

### Perioperative Bleeding

Whereas detailed analysis is limited with regard to the currently available data registries, bleeding has historically been cited as the most common complication after LVAD implantation, and bleeding of any type (operative and late onset) is the most common adverse event recorded by INTERMACS.<sup>25,37,126</sup> Surgical bleeding and large-volume blood-product resuscitation has been associated with increased 30-day and 1-year mortality rates, RV dysfunction, acute lung injury, infection, and pretransplant allosensitization.<sup>127</sup> Reported bleeding rates were high in the early pulsatile LVAD experience, with nearly 50% of patients suffering from major bleeding complications.<sup>81</sup> Although the introduction of CF devices resulted in an overall improvement in outcomes, bleeding has remained a significant perioperative challenge. Early experience with the HeartMate II clinical trials showed that between 50 and 80% of patients required perioperative blood product transfusion, with 30% of patients undergoing reoperation for bleeding complications.<sup>25,26</sup> Single-center analyses have since revealed a modest reduction in transfusion requirements.<sup>104,128</sup>

Recently, the comparative analysis of different devices with regard to perioperative bleeding complications has been an area of particular interest. The HeartWare BTT trial investigators reported a lower risk of reoperation for bleeding than did the contemporary INTERMACS control group (largely comprising HeartMate II patients).<sup>27</sup> A single-center analysis subsequently determined that although red blood cell administration was equivalent for the two pumps, HVAD recipients required fewer blood products overall ( $8.3 \pm 13$  vs  $12.6 \pm 14$  units) and had a lower chest-tube output than did

**FIGURE 62-11** Actuarial freedom from major adverse events in patients supported by continuous-flow left ventricular assist devices. (Reproduced with permission from Kirklin JK, Naftel DC, Kormos RL, et al: Fifth INTERMACS annual report: risk factor analysis from more than 6,000 mechanical circulatory support patients, *J Heart Lung Transplant.* 2013 Feb;32(2):141-156.)

HeartMate II patients.<sup>129</sup> As a result, these studies have been used to suggest that, due to a reduction in surgical dissection, the HVAD is associated with fewer bleeding complications. However, whereas differences between pumps may indeed affect bleeding rates, these studies fail to account for wide variations in surgical approach and perioperative management that may contribute to these results. Regardless of the device used, bleeding is a significant challenge in the perioperative period.

## Right-Sided Heart Failure

The identification and management of RV dysfunction has been extensively discussed. Development of RHF presents a major postoperative challenge and is strongly associated with poor clinical outcomes and increased mortality.<sup>37,81,82</sup> Reported criteria for the diagnosis of RV failure vary in the literature. The most commonly used definition of post-LVAD RV failure originates from the HeartMate II BTT trial, which described RV failure as the need for RV support, inotropic support for at least 14 days after implantation, or the initiation of inotropic support after 14 days of LVAD support.<sup>9</sup> INTERMACS utilizes considerably broader criteria for data acquisition purposes, relying primarily on signs and symptoms of elevated CVP and more specific conditions to evaluate the level of severity.<sup>130</sup> The reported incidence of RV failure after LVAD implantation remains highly variable, ranging from 15 to 30%.<sup>82,87,123,126</sup> A subset of patients with RV failure (between 8 and 10% of device recipients) will require mechanical RV support.<sup>37,88,91,126</sup>

## Infection

Device therapy carries a significant risk of infection, primarily due to the presence of foreign material within the body and a percutaneous driveline. With early pulsatile systems, infection rates ranged from 50 to 60% during the lifetime of the pump, and more than 40% of deaths in the LVAD-supported cohort of the REMATCH trial were due to fulminant sepsis.<sup>111,131</sup> Although the incidence has significantly improved with the introduction of newer-generation devices, infection remains a major source of morbidity and mortality during MCS, and it is the second most reported adverse event in the INTERMACS database.<sup>37</sup> With regard to device comparison, the rates of driveline infection and sepsis in the original HeartMate II BTT trial were 14 and 17%, respectively, compared with 12.1 and 11.4% in the subsequent HeartWare BTT trial.<sup>25,27</sup> Creation of a preperitoneal pump pocket during implantation of the HeartMate II likely predisposes those patients to the development of a pump-pocket infection, which can often result in life-threatening sepsis and the need for pump exchange. As a result, our institutional preference is to avoid the need for a pump pocket by placing the pump in a subdiaphragmatic intraperitoneal position.

A review of INTERMACS data revealed percutaneous driveline infections in 9.8% of all patients supported with CF devices.<sup>132</sup> The mean time to development of the infection

is typically greater than 6 months, implying that most such infections occur in the outpatient setting, when patients are more active and responsible for dressing care.<sup>132-134</sup> By 1 year, 19% of patients have developed a driveline infection, while 1 in 4 are diagnosed with a driveline infection by 2 years of CF LVAD support.<sup>37</sup> Whereas most patients in the INTERMACS database were treated with antibiotics alone, surgical intervention was required in 12.5% of cases.<sup>37,132</sup> Specific information regarding the extent of debridement is generally not reported, but vacuum-assisted closure, antibiotic bead therapy, and driveline mobilization have all been described.<sup>135,136</sup> Infection has been shown to adversely impact survival, increasing the 1-year mortality rate as much as 6-fold.<sup>37,132,137</sup> The presence of a documented device infection does not preclude transplantation.

## Renal Failure

As described earlier, preoperative renal dysfunction has been shown to be strongly associated with poor outcomes after LVAD implantation.<sup>76,77</sup> Similarly, the development of postoperative renal failure is a significant predictor of the 1-year mortality rate after device implantation.<sup>125</sup> However, risk factors for postoperative renal failure are poorly understood, and indices of preoperative renal status do not appear to be strong independent predictors of such failure.<sup>77</sup> Although definitions vary, the incidence of postoperative renal failure ranges from 14 to 30%.<sup>125,138,139</sup> Factors associated with the development of this complication appear to include preoperative ventilatory support, elevated CVP, and advanced patient age. The initiation of MCS has been shown to enhance end-organ perfusion, and management options for postoperative renal failure range from supportive medical therapy to temporary or permanent renal replacement.<sup>73</sup> As many as 10 to 20% of patients undergoing LVAD implantation require some form of postoperative renal replacement therapy, and approximately half of that population can be expected to recover independent renal function, typically within the first month.<sup>138,139</sup> Development of postoperative renal failure has been shown to be associated with longer ICU stays, increased ventilator dependence, prolonged inotropic support, and a significant decline in 30-day, 3-month, and 1-year survival.<sup>37,138</sup>

## Stroke and Neurologic Dysfunction

Despite improvements in device reliability and management strategies, stroke remains a significant source of morbidity and mortality in patients who require LVAD support. Clinically apparent strokes can result in significant functional disabilities—a particular challenge for routine device maintenance—along with impaired quality of life, significant rehabilitation needs, and decreased postevent survival. Collectively, the impact of these outcomes highlights neurologic dysfunction as a particularly feared complication of device therapy.

While strokes are typically classified under a singular adverse event heading, the disparate pathogenesis of hemorrhagic and ischemic strokes suggests the likelihood for

multiple causative factors. A detailed analysis comparing stroke etiology in device patients is not yet available, but the incidence of hemorrhagic and ischemic strokes appears to be roughly equal.<sup>26,140,141</sup> Overall, the reported incidence of stroke among device patients in the INTERMACS database is 11% at 1 year and 17% at 2 years postimplantation.<sup>37</sup> Risk factors for stroke during MCS are poorly understood, and many presumed influences—including anticoagulation, atrial fibrillation, diabetes mellitus, and device type—have not been found to be statistically significant.<sup>141</sup> Pulsatility may play a role in the development of embolic strokes. Prolonged closure of the aortic valve has been shown to result in eddies and stasis within the aortic cusps, predisposing some patients to the formation of thrombus that can be released with later opening of the valve.<sup>142</sup> Similarly, some patients have developed thrombus in areas of stasis within the carotid bulb; again, such thrombus is susceptible to dislodgement after the recovery of pulsatility.<sup>31</sup> As a result, routine maintenance of intermittent pulsatility may provide prophylactic washout of these areas and reduce the potential for thromboembolic events. In recent studies, BP has been identified as an additional key determinant in the pathogenesis of stroke. The importance of adequate BP control in this population is suggested by the fact that patients with lower BP at hospital discharge and those receiving aggressive pharmacologic antihypertensive therapy have significantly lower rates of neurologic events.<sup>141,143</sup> Stroke adversely affects survival, entailing a 25% 30-day and nearly 50% 1-year mortality risk.<sup>140,141</sup>

## Nonsurgical and Gastrointestinal Bleeding

As noted previously, bleeding of any type is the most frequent adverse event reported to INTERMACS, and late-onset spontaneous bleeding is a significant source of morbidity for patients supported by CF LVADs.<sup>37</sup> Researchers have consistently documented the frequency of nonsurgical (primarily GI) bleeding, particularly in older patients, and the reported incidence of this complication ranges from 18 to 30%.<sup>144-149</sup> GI sources account for the vast majority (70%) of nonsurgical bleeding episodes. Epistaxis, intracranial, and genitourinary episodes are progressively less common.<sup>149</sup> The location of GI bleeding is divided fairly evenly above and below the ligament of Treitz. Although percentages vary among studies, erosive gastritis and arteriovenous malformations (AVMs) appear to be the most frequent causative factors.<sup>144,145,149</sup> Whereas GI bleeding is a significant source of morbidity—principally because of more frequent hospitalizations and increased transfusion-related alloantigen exposure—no associated impact on overall mortality has been reported.

The relative frequency of GI bleeding in this patient population has led to multiple proposed explanations. Anticoagulation during long-term MCS undoubtedly exposes patients to increased bleeding risks. A comparison between nonpulsatile pumps and the pulsatile HeartMate XVE (which did not necessitate anticoagulation therapy) revealed a significant

difference in bleeding events.<sup>29</sup> However, the frequency of these events remains unexpectedly high, as patients supported by CF LVADs have a substantially higher risk for GI bleeding than do patients who require anticoagulation for cardiovascular disease.<sup>147</sup> Furthermore, bleeding events have been known to occur even without the use of anticoagulation.<sup>150</sup>

Some researchers have suggested that the propensity for GI bleeding may be due to an altered thrombotic physiology resulting from interaction between the device and the bloodstream. Multiple studies have shown that patients supported by CF LVADs can develop an acquired von Willebrand syndrome as a result of the proteolytic cleavage of high-molecular-weight von Willebrand factor multimers.<sup>151-153</sup> However, this explanation alone cannot explain the variability of bleeding events within the LVAD population, as bleeding has been shown to be nearly universal in the setting of axial-flow device support.<sup>154</sup>

An alternative explanation for the frequency of GI bleeding events may lie in the narrow pulse pressure created by CF support. The association between aortic stenosis and AVM formation was first described by Heyde in the 1950s, and a syndrome bearing his name was characterized over the subsequent decades.<sup>155,156</sup> This process is believed to result from hypoperfusion and ischemia of intestinal mucosa, leading to friable neovasculature susceptible to rupture. Application of this concept to CF MCS physiology was first suggested by Letsou and colleagues,<sup>157</sup> who described a series of patients supported by the Jarvik 2000. Recently, a retrospective review also documented a strong association between GI bleeding and both reduced PI and aortic valve closure, suggesting that a reduction in pulsatility may lead to increased rates of nonsurgical bleeding within the first 3 months of LVAD therapy.<sup>149</sup>

ISHLT guidelines suggest that anticoagulation therapy be withdrawn in the setting of clinically significant bleeding. Resumption of anticoagulation is permitted after resolution of the index bleeding event, but a reduction (or permanent cessation) of anticoagulation is justified in the case of recurrent events. When possible, pump speeds are generally reduced to allow increased native pulsatility. Endoscopic evaluation is also warranted for direct control of the bleeding source, although identification of the responsible AVM is often difficult.<sup>36</sup>

## Pump Thrombosis and Device Malfunction

Pump thrombosis is an uncommon but potentially catastrophic complication of LVAD therapy. The HeartMate II BTT trial investigators reported an actuarial freedom from device malfunction (defined as resulting in device replacement or death) of 95% at 6 months and 93% at 1-year postimplantation, one-third of those events being attributed to primary device thrombosis.<sup>9</sup> This degree of reliability and durability represented a significant advance over earlier pulsatile systems, including a nearly 10-fold reduction in the need for device exchange.<sup>158</sup> Between 2011 and 2012, concern was

raised regarding an apparent increase in the rate of pump thrombosis with the HeartMate II. A three-center collaborative study documented an increase in the incidence of pump thrombosis at 3 months from 2.2 to 8.4%; over the same timespan, a federally mandated INTERMACS review similarly described a decline in freedom from pump exchange or death at 6 months from 99 to 94%.<sup>37,159</sup> After extensive investigation, the cause of this discrepancy remained unclear and was likely multifactorial. More recently, however, institutional reports have suggested a reversal in the thrombosis-related trend and the HeartMate II remains the most frequently implanted device worldwide. Nevertheless, understanding the potential factors involved in device thrombosis is critical, as this complication has been shown to negatively impact overall survival.<sup>159</sup>

A major challenge in the prevention of thrombosis events is the complexity of the pathophysiology involved. Indeed, the term “thrombosis” has traditionally been used in a broad sense to describe not just *confirmed* thrombus within the pump housing but also *suspected* thrombus due to various nonstandardized clinical factors. In 2013, INTERMACS updated its definitions, establishing formal categories of *suspected* thrombosis (the criteria for which include hemolysis, unexplained HF symptoms, and abnormal pump parameters) and *confirmed* thrombus found on direct inspection or radiographic imaging.<sup>130</sup> Factors that contribute to thrombosis are likely far-ranging, and proposed mechanisms include inadequate heat dissipation at low speeds, ineffective anticoagulation strategies, surgical and anatomical considerations (such as angulation of the inlet or kinking of the outflow graft), patient-specific predisposition, and pump manufacturing and design elements.<sup>160-162</sup>

Despite the variable etiology of device malfunction, recent studies have led to improved methods for accurately diagnosing thrombotic events. Serum markers for hemolysis have been shown to be associated with pump thrombus formation, presumably due to the increased shear stress placed on red cells traversing the area of flow impedance. Serum-free hemoglobin (sfHb) has traditionally been used by INTERMACS for diagnostic purposes, with levels greater than 40 mg/dL indicative of significant hemolysis.<sup>130</sup> Recent data have shown that lactate dehydrogenase (LDH) may be a more sensitive marker than sfHb for detecting hemolysis and pump thrombosis, and subsequent INTERMACS reviews have shown a strong correlation between rising LDH levels and thrombotic events.<sup>163</sup> Whereas a threshold value of 600 IU/L has been proposed for diagnostic purposes (representing 2.5 times the upper limit of normal), this cutoff does not appear to be absolute, as anecdotal evidence suggests that many patients may exhibit higher LDH levels without tangible evidence of thrombosis. Other diagnostic tools, including speed-change echocardiography and three-dimensional computed tomography, also likely contribute to diagnostic accuracy.<sup>164</sup> Given the variability in presentation, a recent multicenter collaboration led to the development of a useful diagnostic and clinical management algorithm for patients with suspected pump thrombosis.<sup>165</sup>

Treatment strategies for suspected pump thrombosis are limited. Noninvasive measures, such as intravenous anticoagulation (heparin) and direct thrombin inhibitor therapy (bivalirudin or argatroban), are typically initiated early in the management process with variable independent results.<sup>166,167</sup> Success with thrombolytic therapy (both systemic and intraventricular) has also been reported, but this approach entails a risk of intracranial bleeding.<sup>130,168,169</sup> Definitive management of pump thrombosis is surgical, either through pump exchange, pump explantation, or urgent heart transplantation. Pump exchange may be performed through either a redo sternotomy or a subcostal approach, and the pump housing of the HeartMate II can be exchanged directly without disrupting the inlet or outflow conduit.<sup>170,171</sup> Despite the relative short-term safety of the exchange procedure, survival has been shown to decrease with each successive pump exchange, which also increases the likelihood of later infection and neurologic sequelae.<sup>37,160</sup> The mortality rate 6 months after transplantation or initial device replacement is similar to that for patients without a history of thrombosis.<sup>159</sup>

## TOTAL ARTIFICIAL HEART

Whereas LVAD support has emerged as the standard of care for patients with end-stage HF, data registry analysis suggests that a sizeable percentage (typically cited as 8 to 10%) of patients will require biventricular support.<sup>37,87,88,91</sup> Heart transplantation has traditionally served as the gold-standard therapy for this subset of patients, but the scarcity of donor organs has led to a stagnant rate of transplantation, totaling just over 4000 procedures each year worldwide.<sup>172</sup> Mechanical total heart replacement is a logical and relatively inexhaustible solution to this challenge. The use of implantable BiVADs has been reported in the treatment of patients with severe biventricular HF.<sup>116,173,174</sup> However, available devices are designed to function independently, and logistical challenges in their implantation and management as BiVAD systems renders them cumbersome and difficult to operate. As a result, the development of a self-contained, fully implantable total heart replacement device is an important, though elusive, goal.

## Early Development and Experience

The concept of replacing the human heart with a permanent or temporary mechanical device has been postulated for centuries and was first reported in the early nineteenth century by French physiologist Julien Jean Cesar Le Gallois.<sup>175</sup> Since that time, efforts to duplicate nature's design—including the famed collaboration between Charles Lindbergh and Alexis Carrell in the 1920s—have periodically captured the public imagination but failed to produce a reliable self-contained device.<sup>176</sup>

The first tangible step toward the development of a viable TAH came in 1957, when Tetsuzo Akutsu and Willem Kolff replaced the heart of a dog with an experimental pulsatile device.<sup>177</sup> The dog survived for several hours. Although the

**FIGURE 62-12** The Liotta total artificial heart, the first to be implanted in a human. (Courtesy Texas Heart Institute.)

pump was never tested in humans, its brief success highlighted the potential for total heart replacement. Capitalizing on a growing interest in MCS, the National Heart Institute (now termed the NHLBI) established the Artificial Heart Program in 1964, helping to fund and support research and development efforts throughout the field.

The first implantation of a TAH into a human was performed by Denton Cooley on April 4, 1969.<sup>16</sup> The device was placed in a 47-year-old man who could not be weaned from CPB after undergoing an LV aneurysmectomy. Designed by Domingo Liotta, the pump was a pneumatically powered, double-chambered device with Dacron-lined conduits and Wada-Cutter hingeless valves (Fig. 62-12). It was intended to support the patient only until a suitable donor heart was found. Indeed, the TAH performed adequately for 64 hours, after which the patient underwent a transplant. Despite its success, Liotta's pump was never again used clinically, but the experience showed that a TAH could be used safely and effectively for BTT.

## Contemporary Options for Total Heart Replacement

### SYNCARDIA TAH

In the late 1970s, under the leadership of Willem Kolff, researchers at the University of Utah began developing a TAH design that eventually evolved into what is now known

as the SynCardia TAH. The device consists of two separate, pneumatically driven pumps bound only by a Velcro patch along their adjoining walls (Fig. 62-13). Pump operation depends on the pneumatic displacement of a polyurethane diaphragm powered by an external pneumatic driver. Dacron cuffs permit atrial anastomosis after ventriculectomy, and the outflow conduits are similarly composed of woven Dacron grafts. Both components are attached to the pump housing by specialized connecting brackets. Each pump contains large-diameter SynHall valves (derived from the original Medtronic-Hall design) that regulate both inflow and outflow (27 and 25 mm, respectively) and provide minimal resistance to flow. The pneumatic drivelines are tunneled beneath the costal margin to reach the external driver, where pump rate, drive pressure, and systolic duration are controlled. The device produces a stroke volume of 70 mL and a cardiac output as high as 15 L/min.<sup>178,179</sup>

The earliest clinical iteration of this device, labeled the Jarvik-7, was first implanted by William DeVries in 1982, supporting a 61-year-old man with congestive HF for 112 days until he died of multiorgan failure.<sup>180</sup> Despite initially mixed results, clinical trials began in 1985. Over the years, the device was rebranded the Symbion, then the CardioWest TAH, and finally the SynCardia TAH.<sup>181-183</sup>

**FIGURE 62-13** The SynCardia Total Artificial Heart (formerly the Jarvik-7, Symbion, and CardioWest TAH) utilizes two pneumatically driven pumps for biventricular support. (Courtesy: SynCardia Systems, Inc.)

Like many other TAHs, the SynCardia is somewhat restricted by its large size. Generally, candidates are screened for a sufficient body surface area ( $>1.8 \text{ m}^2$ ) and for a chest anteroposterior diameter of  $>10 \text{ cm}$  on computed tomography.<sup>184</sup> Studies have shown that the body surface area is associated with an increased risk of bleeding, infection, and overall mortality.<sup>185</sup> A smaller (50 mL) version of the device is currently under development. Another historic limitation of the SynCardia TAH was the inconvenience of its external components. The original console was large and relatively immobile, effectively eliminating the possibility of prolonged ambulation or outpatient management. The 2010 release of the 13-pound Freedom Driver has done much to alleviate these problems, greatly improving device portability.<sup>186</sup>

The SynCardia TAH is currently approved by the FDA and CMS for BTT in the treatment of biventricular failure and has been successfully used in more than 1100 patients.<sup>187</sup> In 2012, the device also received approval for DT use as a humanitarian exemption. Although the majority of implants have been performed for short-term support, nearly 50 patients have been supported for more than 1 year with the SynCardia, and the median duration of support is approximately 554 days. The survival-to-transplantation rate has been 72% in the long-term population. Complications have included systemic infections (35%), driveline infections (27%), thromboembolism (19%), and device malfunction (10%).<sup>185</sup> Survival rates are most impacted during the early postoperative period, and the vast majority of deaths occur within the first month.<sup>188,189</sup> Despite these limitations, the SynCardia has the potential for long-term reliable total heart replacement.

### ABIOCOR TAH

The AbioCor Implantable Replacement Heart is a self-contained, single-body, electrohydraulic TAH developed by ABIOMED, Inc. (Danvers, MA) and the Texas Heart Institute.<sup>190</sup> The device's principal thoracic component, which is positioned orthotopically after biventriclectomy, consists of two polyurethane hydraulic pumping chambers—each flanked by trileaflet valves—that serve as artificial ventricles and function as opposing compliance chambers (Fig. 62-14). A continuous motor allows shuttling of hydraulic fluid to alternately pressurize the right and left ventricles. Active diastolic filling of the contralateral side is enabled by the negative pressure established by the hydraulic system. Unique to the design of the AbioCor is the use of radiofrequency data transmission and a transcutaneous energy transfer system designed to create a fully implantable system that can communicate with external hardware without penetrating the skin. An electronic and data component is implanted within the abdomen. The pump produces a stroke volume of 65 mL and a cardiac output as high as 12 L/min.

The AbioCor is also the only device designed to address the natural dissymmetry in native ventricular output. Management of a totally implantable pulsatile TAH system requires an understanding of the difference in stroke volumes produced by the right and left sides of the heart. The arterial blood supply to the bronchial tree (totaling 2 to 3 cc with

**FIGURE 62-14** The AbioCor Implantable Replacement Heart. (Reproduced with permission from ABIOMED, Inc.)

each heartbeat) drains directly into the left atrium, thereby avoiding the conventional venous system and resulting in an LV output that exceeds right-sided output by 2 to 5%. Whereas this imbalance seems negligible in the short term, it accounts for as much as 250 L of blood flow each day and must be carefully considered when designing a pulsatile device responsible for producing right- and left-sided flows. To accommodate this discrepancy, the design of the AbioCor involves a right-to-left flow-balancing mechanism designed to account for interventricular physiologic flow differences by shunting hydraulic fluid away from the right-sided pump.<sup>191</sup> The design functioned appropriately in both animal studies and clinical use.

With support from NHLBI, preclinical trials and extensive animal testing began at the Texas Heart Institute in 1993. In 2001, the FDA approved a phase 1 feasibility study for the device, which was first implanted in a 59-year-old man in Louisville, KY who survived for 151 days with the device.<sup>192</sup> Criteria for inclusion in the study were restrictive, and included the diagnosis of irreversible biventricular HF ( $>70\%$  predicted 30-day mortality), with documented ineligibility for transplant. A total of 14 patients were eventually enrolled in the trial, the longest period of survival reaching 512 days. Overall survival metrics were promising, with a 71% 30-day survival rate (compared with 13% in the medical arm) and 40% survival at 2 months.<sup>193</sup>

A major disadvantage of this pump is its relatively large size, which limited candidacy to patients with a thoracic cage deep enough to accommodate the device. Preoperative sizing was generally performed by using three-dimensional computed tomography reconstructions, focusing primarily on anteroposterior thoracic diameter and the position of the

pulmonary bifurcation.<sup>193</sup> Sufficient distance between the bifurcation and diaphragm was required to prevent compression of the left pulmonary veins and lower-lobe bronchus. Due to the level of anatomical complexity, a high degree of confidence with regard to sizing and fit was required before implantation was attempted. Although the AbioCor received FDA approval for use under a humanitarian device exemption in 2006, no implants have been performed since the completion of its initial feasibility study, principally due to the prohibitive economic barriers associated with its implementation.

## Complexities of Mechanical Total Heart Replacement

Initial efforts to develop a viable TAH began in earnest as part of a series of bold scientific initiatives proposed by the Kennedy administration during the idealistic 1960s. Although similarly daring goals, such as manned spaceflight to the moon, were accomplished within the decade, construction of a reliable self-contained device for replacing the human heart proved to be a prohibitive technical challenge. A number of complexities, both physiologic and technologic, are to blame for the ongoing delay in realizing this objective.

From an engineering standpoint, designing a TAH presents a number of challenges, the chief of these being durability. The human heart beats more than 100,000 times each day. As a result, thin diaphragms and hydraulic actuators devised for pulsatile systems are subject to considerable mechanical wear; though capable of providing support beyond 1 year, they are unlikely to withstand the physical demands of long-term operation. Size is also a hurdle in TAH design, and the housing of biventricular volume-displacement chambers capable of producing sufficient cardiac output requires a substantial device profile that can be difficult to accommodate, even in larger patients. Moreover, portability and mobility are crucial considerations for long-term support. Pneumatic systems require drivelines for pressure venting. Even though recent efforts have reduced the size of associated equipment, compressors and power consoles can be cumbersome and limit functionality. Minimization of extracorporeal drivers, drivelines, and tethering equipment would speed postoperative recovery, minimize infectious risks, and improve overall quality of life. Remedying these concerns, however, has proved to be an immense scientific and technological undertaking.

## Future Directions: the CF TAH

A quarter century of clinical experience with CF pumps has revealed the human capacity for physiologic tolerance of nonpulsatile flow and has confirmed the significant design advantages of CF devices over pulsatile TAHs. Continuous-flow devices are not only significantly smaller than pulsatile pumps but also are more anatomically appropriate thus being simpler to implant and operate. Furthermore, with few (or no) points of mechanical contact, CF designs essentially eliminate the potential for mechanical wear, resulting in a level of

clinical durability far surpassing that of pulsatile systems.<sup>194</sup> Hemodynamically, CF pumps also appear well suited for TAH use, because (much as in the native heart) the inherent inflow sensitivity of these devices provides a degree of automaticity in responding to imbalances in right- and left-sided flows. Thus, development of a CF TAH may lead to realization of a long-awaited goal.

Over the past decade at the Texas Heart Institute, extensive research and development efforts have been dedicated to the concept of CF total heart replacement, involving both simulated models and live animal studies. To date, more than 70 calves have been implanted with paired CF VADs to provide completely nonpulsatile circulatory support. The resulting CF TAH model has revealed considerable long-term effectiveness, with more than 30 animals surviving for longer than 7 days, 8 surviving for 30 days, and 2 calves surviving for more than 90 days with nonpulsatile blood flow after CF total heart replacement.<sup>195,196</sup> Tolerance of this altered physiologic state is further evidenced by stable hemodynamic profiles both at rest and during treadmill exercise studies, as well as preserved hematologic and biochemical markers for end-organ function. This extensive experience with large animal models has stimulated a number of collaborative research efforts in search of a viable CF TAH design.

To this end, a novel CF TAH is currently being developed that offers tremendous potential to become a completely implantable long-term cardiac replacement device. The BiVACOR TAH, developed by BiVACOR USA in Houston, Texas, working closely with the Texas Heart Institute, is a small, compact device that utilizes a single magnetically levitated rotor to provide pulmonary and systemic blood flow without the use of bearings or valves<sup>197</sup> (Fig. 62-15). Impellers are mounted on each side of the rotor (which separates the right and left chambers), and its frictionless suspension permits accommodation for physiologic flow

**FIGURE 62-15** The BiVACOR total artificial heart employs a single moving part—a central magnetically levitated rotor—to provide complete cardiopulmonary support. (Reproduced, with permission, from BiVACOR, Inc.)

imbalances by axial displacement the rotor.<sup>198</sup> Also unique to the BiVACOR is the use of dynamic speed profiles to allow establishment of pulsatility in device operation.<sup>199</sup> Feasibility studies have been successfully performed in large animals, with a goal of human trials in the near future. A similar hydrodynamically suspended design is also in development at the Cleveland Clinic, which also has begun animal studies.<sup>200</sup> Thus, innovative engineering efforts and successful utilization of CF technology may soon offer the opportunity for permanent mechanical replacement of the failing human heart.

## KEY POINTS

1. Continuous-flow technology has resulted in smaller, more durable MCS devices. Although the full effects of the resulting physiologic changes remain unknown, nonpulsatile blood flow is well tolerated.
2. Thoughtful patient selection and preoperative optimization of the patient's condition are crucial to ensure good outcomes after LVAD implantation.
3. Surgical considerations at the time of LVAD implantation should include careful alignment of the pump inlet and outflow conduits to minimize the risk of physical impediments to proper device function.
4. Perioperative preservation and optimization of RV function is an essential component of MCS management.
5. Due to the scarcity of available donor organs, development of a CF TAH offers the best means of providing definitive long-term treatment for patients who require total heart replacement.

# Tissue Engineering for Cardiac Valve Surgery

Danielle Gottlieb • John E. Mayer

Tissue engineering is a developing science, comprising elements of engineering and biology, whose aim is to build replacement tissues *de novo*, from individual cellular and structural components. The impetus for our work on tissue-engineered cardiovascular structures arises from the need to replace cardiovascular tissues that failed to develop normally during embryogenesis or have become dysfunctional as a consequence of disease. In pediatric patients, the cardiovascular structures most often afflicted by congenital anomalies involve the cardiac valves and great vessels, and the theoretical advantages of a tissue-engineered structure containing live cells are the ability to grow, remodel, and repair. Although growth potential is not a consideration for the adult population, durability of valve structures remains an important issue for bioprosthetic valves, and a tissue engineering approach offers the potential to improve durability by providing the repair and remodeling capability.

Diseases of the heart valves and large “conduit” arteries account for approximately 60,000 cardiac surgical procedures each year in the United States, and all of the currently available replacement devices have significant limitations.<sup>1,2</sup> Ideally, any valve or artery substitute would function like a normal valve or artery. For valves, this function includes allowing pulsatile blood flow without a transvalvar gradient or valvar regurgitation. The theoretical advantage of engineered tissue replacements is that they could also display other desirable characteristics, such as (1) durability, (2) growth (for infants and children), (3) compatibility with blood components and the absence of thrombosis or destructive inflammation, and (4) resistance to infection. None of the currently available devices, constructed from either synthetic or biologic materials, meet these criteria. Mechanical heart valves are very durable, but they require anticoagulation to reduce the risk of thrombosis and thromboembolism.<sup>1,2</sup> Therapeutic anticoagulation carries associated morbidity, and even among patients who receive therapeutic anticoagulation, the incidence of thromboembolic complications of mechanical heart valve replacement is not zero.<sup>1,2</sup> Biologic valves, whether of allograft or heterograft origin, remain subject to structural deterioration after implantation.<sup>2-4</sup> Neither mechanical nor biologic valves have any growth potential, and this limitation

represents a major source of morbidity for pediatric patients who must undergo multiple reoperations to replace valves and/or valved conduits during the period of maximum somatic growth.

Tissue engineering is an approach based upon the hypothesis that when properly designed and fabricated, these “living” devices will simulate the biology of normal cardiovascular structures, thereby overcoming the shortcomings of currently available heart valve replacements. Of particular relevance to pediatric heart surgery is the long-term function of the engineered valve over time and the potential capacity to grow, self-repair, and remodel. This chapter summarizes some of the progress that has been made in tissue engineering research as it relates to cardiac valves and conduit arteries, and then outlines the areas where additional efforts must be focused in order to direct cardiovascular tissue engineering toward clinical utility.

## NORMAL HEART VALVE BIOLOGY

### Adult Valve Structure and Function

Heart valves open and close approximately 40 million times per year; this coordinated function occurs under the demands of hemodynamic forces of blood pressure and shear stress. The normal semilunar valve presents minimal resistance to opening and no pressure gradient during systolic forward flow. In diastole, the same structure is responsible for rapid and complete closure in order to prevent valve regurgitation. Semilunar valves must additionally resist pressure differences between the diastolic arterial pressure and the diastolic ventricular pressure. The atrioventricular valves must function in a comparable way, opening with minimal resistance during diastole and closing to prevent regurgitation during ventricular systole.

Like many other tissues, valve cusps are composed of cells residing within, the extracellular matrix (ECM). In addition, these same cells act reciprocally on the ECM to which they are attached and receive signals from the ECM. The effects of these cellular level mechanical signals on cell phenotype and behavior have been characterized by Ingber<sup>5,6</sup> using the term

“tensegrity” to describe the interactions between cell adhesion to ECM and the nucleus mediated by the cellular cytoskeleton. Semilunar valve cusps are thin, flexible structures with impressive microscopic and molecular complexity. Much of the strength and flexibility of normal heart valve cusps is due to the specialized proteins and polysaccharide-protein complexes of the ECM, produced by resident valve interstitial cells.<sup>7,8</sup> The microscopic and molecular structure of adult valves reflects the regional mechanical forces experienced by the valve cusps; valve cusp ECM is not homogeneous, and the arrangement of the ECM provides a high degree of flexibility during systole, and a high degree of strength to resist pressure loads during diastole.<sup>7</sup> On the surfaces, a specialized endothelium prevents thrombosis, but also acts as a transducer of mechanical force.<sup>9,10</sup> Beneath the endothelium, valve interstitial cells receive signals sent by the endothelium, and respond to imposed mechanical signals by secreting suitable matrix.<sup>5,6,11</sup>

Semilunar valve ECM is stratified into layers and its distribution is related to valve mechanics.<sup>12</sup> Facing the sinus of Valsalva, where eddy currents occur and diastolic pressure loads are imposed, dense collagen is found in the fibrosa layer. A middle layer of connective tissue, the spongiosa, is particularly rich in glycosaminoglycans, large complex molecules which associate with water, and this layer is thought to act as a “shock absorber,” bearing largely compressive mechanical loads. The ventricularis, an elastin-rich layer facing the lumen and the flow orifice of the semilunar valve is specialized to stretch as the cusps elongate during ejection in systole. The resulting composite structure of the native semilunar valve is anisotropic, with less elasticity in the commissure to commissure direction and greater elasticity in the annulus to free edge direction. The orientation of the collagen bundles in the native semilunar valves have also been demonstrated to affect normal leaflet motion during systole and diastole.<sup>13–15</sup>

Valve structure and function are therefore closely related, and strategies to engineer valves are aimed to mimic normal valve structure and function, potentially at the subcellular, cellular, tissue, and whole heart valve levels.

## Embryologic and Postnatal Development

Valves do not begin development as stratified tissues; as circulatory patterns evolve in fetal and postnatal life, valve morphology also changes.<sup>12</sup> Embryologic valve development, therefore, has relevance to tissue engineering, as a model for normal *in vivo* valve remodeling as programmed by gene regulatory pathways and by applied biomechanical force.

By day 15 of human embryo development, specification of myocardial and endothelial cardiac cells occurs. At day 21, formation of a linear heart tube occurs. These events are followed by rightward (dextro) looping of the heart, resulting in orientation of the cardiac chambers into their final adult positions, and opposition of two specialized segments of ECM, known as cardiac jelly.<sup>16</sup> The first evidence of valvulogenesis occurs in this cardiac jelly, when a subset of endothelial

cells separate from the luminal surface, invade the ECM, and undergo endothelial-to-mesenchymal transformation (EMT).<sup>17</sup> In early fetal valve development, valve interstitial cells are highly proliferative, and reside in a glycosaminoglycan-rich, homogeneous microenvironment. Over the course of fetal development, cell proliferation slows, and production of ECM results in valve cusp elongation. During the late stages of fetal development (20 to 36 weeks of human gestation) and in early postnatal life, valve stratification into a trilaminar structure occurs, and organization and maturation of collagen fibers begins. At the time of birth, through a series of largely undefined molecular steps, changes in oxygenation and blood pressure distinguish the aortic from the pulmonary sides of the circulation.<sup>12</sup> Transitional neonatal circulation has been associated with a change in phenotype from activated to quiescent interstitial cells in pulmonary, but not aortic, valve cusps.<sup>18</sup> Valve maturation and remodeling continue during childhood; cellularity of valve interstitial cells continues to decrease into adulthood.<sup>12</sup> Once thought to be passive structures, increasing evidence shows cardiac valves to be dynamic organs. Mechanistically, the finding that cellular and extracellular components mature is thought to reflect the dramatic changes in flow and biomechanical loading conditions from fetal to adult life.<sup>13,19</sup> Further elucidation of the genetic regulatory events defining valve growth and maturation are likely to provide important information in designing biomimetic replacement devices.

## ENGINEERED VALVE INPUTS

The fundamental concept of creating a tissue-engineered cardiac valve is to develop a tissue composed of living cells which will, at some point, form and remodel their own ECM and thus provide durability and growth potential. The biological and engineering challenge lies in how to provide structural organization for these cells until they are capable of forming their own mature ECM and to provide sufficient structural support and mechanical integrity until the cells form their own ECM. Therefore, the fundamental variables involved in the creation of a living “tissue-engineered” valve involve choice or manipulation of cell phenotype, induction of appropriate ECM formation by mechanical and/or biochemical signals, and provision of structural integrity and cellular organization by the scaffold until new “native” ECM formation occurs.

Approaches to tissue-engineered heart valves (TEHV) can be divided into two paradigms, based upon the type of structural scaffold employed. One approach is to use bioresorbable scaffolds (nonwoven felts, electrospun scaffolds; knitted meshes, hydrogel-based, and combinations), and the other approach involves beginning with decellularized tissue-based scaffolds. The bioresorbable scaffold approach begins with seeding cells and culturing under appropriate biomechanical conditions (static flow, pulsatile flow) and nutrient medium. With regard to tissue mechanical properties, the goal of this approach is fabrication of an adequately strong tissue with approximately constant mechanical properties, requiring that the process of scaffold degradation occurs with a reciprocal

increase in ECM production. Porosity is an important characteristic of bioresorbable scaffolds as it provides a permeable framework for cell migration, nutrient supply, and waste removal. Insufficient porosity leads to nutrient deprivation and cell death. Once a sufficiently stable tissue is formed, *in vivo* implantation would ideally follow, placing a newly synthesized tissue, devoid of foreign elements, in the required site. An alternative approach involves use of an acellular scaffold material which can then be populated by host tissue, either by direct *in-growth* or seeding from the blood stream, or some combination of these two mechanisms.<sup>20,21</sup>

This *de novo* approach using cell-seeded biodegradable scaffolds is the one that has been predominantly employed in our laboratory at Children's Hospital, Boston.<sup>23-29</sup> This approach treats components of tissue as "building blocks," constructing valves from a variety of cell types and scaffold materials. Most *in vivo* studies have been carried out in the lower-pressure pulmonary circulation, which is a more tolerant system than the systemic circulation. This type of approach considers several basic questions as its foundation: (1) What cell type or combination of cell types is necessary to allow the production and maintenance of an appropriate ECM? (2) To what extent can cellular phenotype be altered, guided, or "engineered" to replicate cells found in the normal valve? (3) How can these cells be spatially organized during the development of this tissue-engineered structures until the cells in the construct produce sufficient and appropriate ECM? (4) What biochemical signals are necessary during the development of these structures to ensure proper ECM production? (5) What mechanical signals are necessary for optimal tissue development and growth? (6) Should a tissue-engineered valve construct be completely developed and have the histologic and macroscopic appearance of an adult valve prior to implantation, or can further maturation of an engineered construct occur *in vivo* after implantation? More recently, we have utilized acellular scaffold materials with chemical composition and fabrication processes that yield anisotropic mechanics that closely resemble those of native leaflet.<sup>22</sup>

Proponents of the decellularized tissue method base their approach on the premise that ECM characteristics and signals direct cell behavior, and that the closest structure to the normal valve scaffold is the normal valve ECM scaffold itself. Human aortic valve homografts are currently implanted without tissue-type matching, are found to become mostly acellular after several months *in vivo*, yet retain their mechanical properties for longer periods of time. As the exact features endowing the aortic valve with this improved, but still limited durability are unknown, it is hypothesized that these features are retained after *ex vivo* decellularization. These decellularized scaffolds can either seeded with cells prior to implantation, or implanted without seeded cells, in the expectation that appropriate circulating cell populations will populate the scaffolds *in vivo*. Without seeding of cells prior to implantation, however, some decellularized matrices are insufficiently endothelialized by circulating cells or *ingrowth* from adjacent tissues to resist surface thrombus formation *in vivo*.<sup>21</sup>

The literature of TEHV demonstrates the selection of a variety of cell types, scaffold conditions, and preconditioning regimens, and overall, methods are difficult to compare and results have been inconsistent. Systematic screening of engineered tissue elements and combinatorial approaches to building tissues have recently emerged.<sup>30,31</sup> A complete review of past investigations is beyond the scope of this chapter; however, a summary of the fundamental elements of synthetic, biomaterial-based TEHV will be considered in detail in the following sections. *In vivo* outcomes of these methods will also be considered.

## Cell Origin and Phenotype

As in embryologic valvulogenesis, the "ideal" cell type for a TEHV would fulfill the function of both the valve interstitial and endothelial cells. Conceptually, these cells could be derived from fully differentiated cells capable of ECM synthesis, or from less committed, multipotent or pluripotent stem cells with the additional potential for differentiation into multiple cell types. Alternatively, two separate cell types could be potentially used to form a valve structure with valve endothelial cells on the surface and valve interstitial cells in the inner layers of the valve. The role of host cell *ingrowth* from adjacent tissues and/or seeding from the blood stream represent other alternative sources of cells.

The first TEHV experiments were performed with differentiated cells from artery or vein, including vascular smooth muscle cells, fibroblasts, and endothelial cells derived from the vasculature of immature animals.<sup>20,23-25</sup> These cells were chosen as they were readily accessible, are derived from a cardiovascular source, and can synthesize ECM proteins. A comparison of myofibroblasts from the wall of the ascending aorta with those from segments of saphenous vein revealed that the latter cells exhibit superior collagen formation and mechanical strength when cultured on biodegradable polyurethane scaffolds.<sup>32</sup> In our laboratory at Boston Children's Hospital TEHV based on these differentiated cells from systemic blood vessels functioned for periods of up to 4 months *in vivo*.<sup>20,23</sup> However, enhanced collagen formation may be a double-edged sword. The rapid formation of new tissue in the early culture period could give rise to an overabundance of matrix elements, leading to tissue stiffness and potential tissue contraction. Early studies with dermal fibroblasts demonstrated that valve cusps constructed from these cells developed tissue contraction, which limited the ability of valve leaflets to coapt with each other, resulting in valve regurgitation.<sup>33</sup> In addition to production of excessive or unfavorable types of ECM, mature cells may present a problem of senescence in long-term cell cultures *in vitro*, which limits the ability to quickly produce sufficient numbers of cells to seed a TEHV construct. Finally, the prospect of harvesting segments of artery from an otherwise normal peripheral circulation in order to obtain cells for a TEHV represents an undesirable clinical situation, and therefore led to a search for alternative cell sources for engineered valves.

The emergence of the field of stem cell biology has the potential to change the paradigm for candidate cell types for heart valve tissue engineering. As stem cells differentiate from their embryonic state, they lose pluripotency with each subsequent step. Multiple steps of differentiation form lineages of cells. In embryonic development, differentiation down a specific lineage occurs with biochemical signaling, occurring in a specific mechanical microenvironment.<sup>34</sup> How lineage specification occurs in the developing heart is currently an area of active research, with the goal of understanding the necessary cues to replicate differentiation down valve cell lineages. In normal development, differentiating cells are subject to a rapidly changing three-dimensional extracellular environment, and development is thought to occur by signals originating outside of the cell, from molecules originating in neighboring cells, and in the ECM. The importance of these mechanical interactions between cells and their immediate environment during embryonic development has been emphasized by Ingber.<sup>6</sup> These reciprocal interactions between cells and their environment in developing valves, the regulatory mechanisms which induce cells to secrete and respond to components of appropriate ECM, is thought to be the underlying mechanism stratifying valve cusps into their known compartments. These mechanisms are thought to be largely driven by hemodynamics in developing valves.

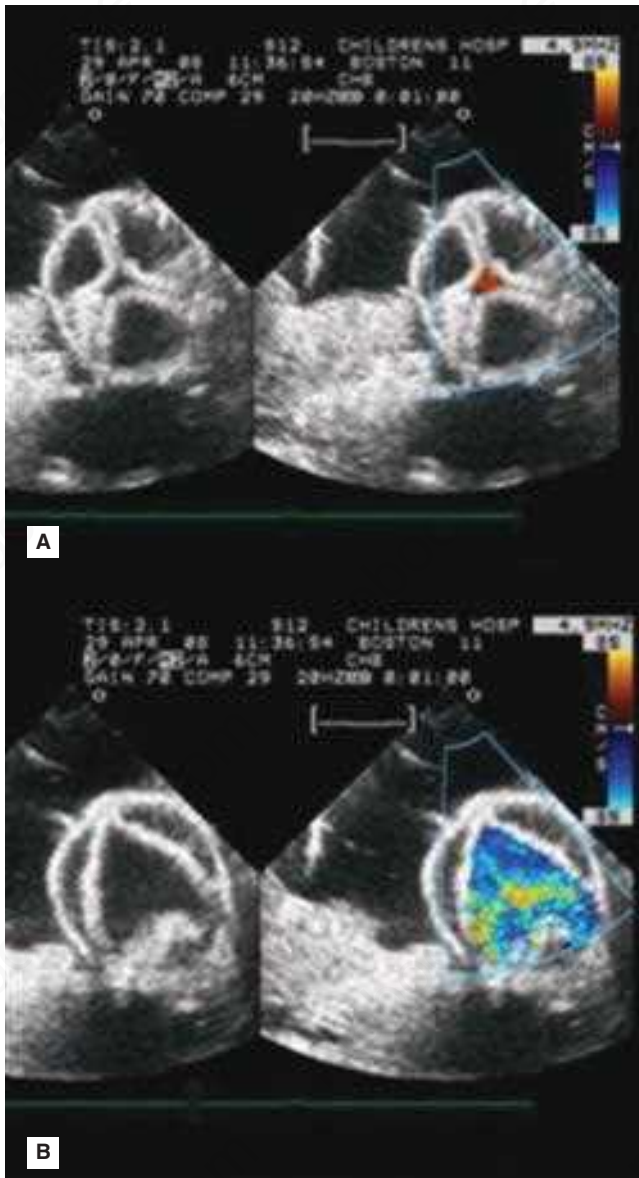

There is also recent evidence that stem cells with proliferative and regenerative capacities reside in many adult tissues. These stem cells are capable of not only acting locally on the tissues in which they reside, but they may also be recruited out of the circulation and enlisted in the regeneration of diverse tissues at distant sites. A recent review details emerging evidence that bone marrow-derived endothelial, hematopoietic stem and progenitor cells can also contribute to tissue vascularization during both embryonic and postnatal life.<sup>35</sup> Visconti and coworkers have made the intriguing observation that cardiac valve interstitial cells in mice appear to originate in the bone marrow as hematopoietic cells.<sup>36</sup> The idea that bone marrow contains cells capable of repairing damaged tissue has been applied to regeneration of cardiac muscle after myocardial infarction, whereby progenitor cells have been isolated from sites outside the heart, then injected back into the heart in an attempt to regain contractile function of ischemic or infarcted myocytes. Results of these trials have been equivocal, marginal, or negative, suggesting that the process of regeneration does not occur by the simple addition of multipotent cells.<sup>37</sup> The early experience with the SynerGraft decellularized heterograft valved conduits which were implanted in children as right ventricle-to-pulmonary artery conduits occurred with the expectation that circulating cells from the bloodstream, or ingrowth from adjacent normal tissue would repopulate the grafts and grow. In this instance, repopulation of the graft by circulating cells occurred, but did not result in adequate function or tissue growth.<sup>38,39</sup> Nonetheless, the progenitor cell populations represent an attractive source of cells for tissue engineering and regeneration, because they have the plasticity necessary to fulfill critical cell functions, and are potentially programmable for lineage specification.

**FIGURE 63-1** The tissue engineered pulmonary valve viewed from below, before implantation.

In addition, these cells can be obtained less invasively than differentiated cells.<sup>35</sup> Our initial experience with progenitor cells in the Mayer laboratory was gained with autologous endothelial progenitor cells (EPCs) isolated from circulating blood in lambs and seeded onto decellularized arterial segments.<sup>20</sup> These seeded arterial grafts were then implanted as an interposition graft in the carotid artery of the donor lamb. These grafts remained patent and functional for up to 130 days. Subsequent animal studies by Sutherland and associates used bone marrow mesenchymal stem cells (MSC) to seed a bioresorbable scaffold formed into a three-leaflet valve within a conduit (Fig. 63-1). These valved conduits were implanted as valved conduits into the main pulmonary artery of neonatal sheep, and remained in place for up to eight postoperative months.<sup>27</sup> This study was followed by that of Gottlieb et al, who implanted valves of similar elements into larger numbers of sheep and followed changes in function with growth of the animals using magnetic resonance imaging (MRI) and echocardiography. While the valves had trace to mild regurgitation at the time of implantation (Fig. 63-2), a loss of valve leaflet surface area was observed, which correlated with increasing valve regurgitation over time.<sup>29</sup> Importantly, the valve leaflets underwent a remodeling process in vivo after implantation, seen also in earlier experiments using myofibroblasts and endothelial cells from systemic arteries, and in both sets of experiments, a layered histologic appearance developed after implantation.<sup>23,27</sup>

Several types of progenitor cells have been used for tissue engineering applications in congenital heart disease. Cebotari and colleagues have recently reported an initial experience seeding EPCs onto homograft valves followed by implantation into two children.<sup>40</sup> Matsumura and associates have shown that when seeded onto a copolymer of lactic acid and  $\epsilon$ -caprolactone, green fluorescent protein-labeled (GFP)

**FIGURE 63-2** Representative echocardiogram images of functioning tissue engineered pulmonary valve following implantation.

cells contributed to the histogenesis of their explanted tissue-engineered vascular graft. These grafts remained patent, and explanted constructs contained GFP-labeled cells expressing both endothelial and mesenchymal markers.<sup>33</sup> The group at Tokyo Women's Medical College has also carried out implants of tissue-engineered vascular grafts in children with congenital heart disease using whole mononuclear cell fractions, seeded onto bioresorbable scaffolds.<sup>41</sup> This work is now ongoing at Yale University, due to encouraging early results.

Increasing evidence supports the idea that for cells, “geography or destination is destiny.” Many cell types, including bone marrow-derived MSC exhibit surprising plasticity, and cell phenotype seems to be related to the microenvironment in which cells reside.<sup>42-44</sup> However, many of the factors

controlling differentiation in these environments remains incompletely defined. There is evidence that EPCs are able to transdifferentiate in response to biochemical signals. Dvorin and colleagues showed that in the presence of transforming growth factor (TGF)- $\beta$ 1, EPCs express  $\alpha$ -smooth muscle actin ( $\alpha$ -SMA), after seeding on a bioresorbable copolymer scaffold.<sup>45</sup> This behavior is not characteristic of endothelium; SMA expression suggests a mesenchymal phenotype, and this observation is a potentially related phenomenon to EMT seen in embryologic valvulogenesis.<sup>45</sup> Human aortic valve endothelial cells, but not vascular endothelial cells, respond to TGF- $\beta$ 1 in a similar fashion, suggesting that EPCs may be suitable as a replacement for valve endothelium. Though stem cells of many types remain promising candidates for tissue engineering, their full potential will be harnessed with an understanding of their normal generative and regenerative roles in vivo.

### Structural Scaffold

Although it has been possible to grow individual cell types in culture for decades, it is more difficult to induce cells to assemble or organize into complex three-dimensional structural arrangements that are found in normal tissues, and to induce cells to produce specific ECM components on demand. Implantation of engineered tissues requires that they have structural integrity at the time of implantation, and for this reason, most tissue engineers employ a scaffold that provides structural integrity, in addition to cellular material.

Given this fundamental requirement, three main strategies for development of a three-dimensional tissue have been used: (1) de novo scaffold synthesis and arrangement into a three-dimensional structure with cellularization prior to implant, (2) decellularization of a whole (usually xenograft) tissue, or (3) de novo biodegradable scaffold without preimplant cellularization.

Any scaffold for tissue engineering applications must be biocompatible and allow cells to adhere and proliferate. For congenital cardiac applications, tissue growth is our target, and therefore, the scaffold must either degrade or be remodeled in vivo. The advantage of the biopolymer approach is that the chemistry of these scaffolds allows for in vivo degradation, usually by hydrolysis.<sup>46</sup> The disadvantage is that heart valves are structurally complex and anisotropic; designing the structural features of the normal heart valve de novo has presented a substantial engineering challenge. The obvious advantage of the decellularization approach is that the three-dimensional complexity is largely preserved, however, there is a shortage of homograft material relative to the clinical demand, and immunogenicity remains a concern with xenografts. Perhaps most importantly, the ECM of decellularized xenografts is dense, and may prevent the penetration of seeded cells into the interstices of the matrix. In our laboratory, we have constructed trileaflet valved conduits from small intestinal submucosa and seeded them with EPCs.<sup>26</sup> After implantation in an ovine model, there was satisfactory short-term function, but there was no penetration of any cells into the depths of

the small intestinal submucosa scaffold. The ECM proteins, when exposed to blood components, can induce inflammation, thrombosis, and calcification, so this material has not been pursued further in our laboratory.

Our primary laboratory efforts to develop heart valves and large arteries have utilized the approach of seeding cells onto a variety of bioresorbable polymer scaffolds. Ideally, there exists an inverse relationship between scaffold degradation and ECM formation by seeded cells. Polymer degradation is related to polymer chemistry, fabrication method, and mechanism of degradation, and therefore, polymers used in tissue engineering differ in their degradation times. The first generation of scaffolds used in heart valve tissue engineering were highly porous, nonwoven felts produced from fibers of polyglycolic acid (PGA). PGA and related polymers continue to be the most widely used for multiple tissue engineering applications.<sup>47-50</sup> The advantage of PGA and related aliphatic polyesters, including poly-L-lactic acid (PLLA), is their safety, biocompatibility, lack of toxicity, and commercial availability. PGA has been used as the commercially available Dexon suture material since the 1970s.<sup>51</sup> PGA can be extruded as a fiber, which allows fabrication of nonwoven sheets with large, open pores. Open pore structures facilitate cell delivery and proliferation by allowing a large surface area for cell attachment, free diffusion of nutrients and dissolved gases, and removal of waste products of metabolism. Material properties of these nonwoven felts are well established, with reproducible hydrolytic degradation times; PGA alone degrades in 2 to 4 weeks, while the majority of fibers of the more hydrophobic PLLA degrade within 4 to 6 weeks. These scaffolds lose strength prior to losing mass, which challenges tissue engineers to seed sufficient numbers of matrix-producing cells so as to replace the scaffold strength as it is lost. Our laboratory has experimented with PGA coated with the thermoplastic polymer poly-4-hydroxybutyrate (P4HB), assembled into a trileaflet structure by attaching leaflets to a flat scaffold sheet, then wrapping the scaffold around a mandrel and heat-welding a seam of attachment. Despite promising early results using the PGA/P4HB composite, subsequent studies showed loss of structural integrity with longer periods of *in vitro* culture, followed by difficulties with suture retention and hemostasis *in vivo*. For these reasons, Sutherland and colleagues in our laboratory developed a scaffold composed of equal parts of PGA and PLLA fibers. As PGA is a stronger but more rapidly degrading polymer, and PLLA is a less strong polymer with a longer degradation time, we expected more uniform strength from the tissue when constructed from this material. The composite nonwoven felt was fabricated into a valved conduit with a trileaflet valve, and had substantially improved surgical handling characteristics.<sup>27</sup>

Although satisfactorily strong, polymer fiber-based scaffolds are significantly stiffer than normal valve leaflets, and with the addition of cell-secreted ECM, these constructs are notably stiff.<sup>46</sup> Scaffold stiffness has been shown to effect cell behavior, and tissue engineers have sought less more flexible materials.<sup>44</sup> Wang and colleagues at the Massachusetts

Institute of Technology designed an elastic polymer with a rapid degradation time, based on sebacic acid, a derivative of castor oil. Polyglycerol sebacate is a strong but elastomeric material, and is currently under investigation for use in heart valve tissue engineering applications.<sup>52</sup>

In addition to their stiffness, polymer-based scaffolds are thick, relative to normal valve leaflets. A thick scaffold leads to a nutrient gradient in culture, and many tissue engineering studies based on nonwoven materials have been limited by the lack of nutrient delivery to the deepest areas of engineered tissues. Two solutions are proposed to overcome this limitation: addition of a blood supply, and design of thinner scaffolds.

Hydrogel-based scaffolds, including collagen, alginate, agarose, gelatin, fibrin, chitosan, polyethylene glycol, hyaluronic acid, and dehydrated sheets of ECM have formed the basis of many experiments in tissue engineering. When gels become solid, cells are trapped in the cell, providing a homogeneous distribution of cells embedded in a temporary matrix. In addition, hydrogels can be laid into thin layers. A bileaflet heart valve was produced in the Tranquillo laboratory using a collagen-based scaffold seeded with dermal fibroblasts.<sup>53</sup> Recent advances in drug delivery technologies and microfluidics have resulted in further control of scaffold characteristics, including orchestration of scaffold polymerization with changes in temperature, pH, or exposure to light; engineering of nano- and microscale cell environments in order to direct cell distribution throughout a scaffold, and microencapsulation of growth factors and adhesion peptides on scaffolds for improved cell attachment and proliferation.<sup>54-58</sup>

Finally, cells and scaffold have been incorporated and directed in nanoscale fabrication techniques such as electrospinning. Still, no perfect material has been identified for heart valve tissue engineering, and in this regard, the search continues.

The complex anisotropy and three-dimensional structure of heart valves has provided another challenge for a biomimetic device. Even if the optimal scaffold material is identified, its fabrication into a three dimensionally accurate valve geometry is nontrivial. Using normal heart valve anatomy derived from computed tomography images, Sodian employed stereolithography to print a three-dimensional model for use as a mold for the thermoplastic polymer P4HB.<sup>59</sup> The mold was used for curing the polymer into three-dimensional valve anatomy. As improvements in imaging technology yield higher spatial and temporal resolution, anatomic definition of thin, moving, anisotropic structures in the heart such as valve leaflets will be more feasible and may be able to account for the nonuniform cellular and ECM distributions that are found in native leaflets. In addition, evolving microfabrication methods will further our ability to fabricate microscale features of valve anatomy. With defined anatomic dimensions and an understanding of outflow tract, great artery, and leaflet motion and growth, tissue engineers will have clear targets for three-dimensional fabrication of heart valve scaffolds.

## Biochemical Signals

The migration and transdifferentiation of endothelial cells in the early stages of valvulogenesis (EMT) has been experimentally modeled in an *ex vivo* chick cardiac cushion explant system.<sup>17</sup> Much progress has been made to understand the signals required for the proper sequencing and execution of these early events. Vascular endothelial growth factor is one such molecule, thought to regulate EMT in an environment of adequate tissue glucose and oxygen saturation. While VEGF is secreted by endothelial cells, other important signals, such as bone morphogenetic proteins 2 and 4, are expressed by myocardium. Hyaluronic acid, a component of the ECM, is thought to regulate downstream signaling through its large, hydrated structure, which regulates ligand availability for receptor binding. Therefore, valvulogenesis is dependent *in vivo* upon signals from myocardium, local ECM, and endothelium.<sup>12,34</sup> Though very early growth of endocardial cushions and valve primordia are less understood, and late regulatory events in valve growth are poorly understood, regulators of endothelial and mesenchymal cell proliferation have been identified. These known pathways have been largely studied in isolation, and as gene regulation in organogenesis is a highly complex process, synthesis of critical gene pathway data is necessary for developing a big-picture view of required events. Current microarray technologies will yield large volumes of data, and will likely provide additional insight into the critical regulatory steps involved in valve growth. This type of information will be high yield in future generations of engineered valves.

## Mechanical Signals

Identification of a suitable cell phenotype is necessary but not sufficient for engineering replacement tissues. Proper cell orientation and three-dimensional ECM microstructure are also required for tissue function; tissues demonstrate organization of cells and matrix across multiple levels of scale. In this regard, engineered tissues, like native tissues, require coordination. Hemodynamics are fundamental to the development and ongoing function of cardiovascular structures, and biomechanical signals are epigenetic regulators of tissue growth and development. Increasing evidence supports a role for endothelial cells as mechanotransducers, sending signals through the underlying ECM to the more deeply embedded valve interstitial cells.<sup>19</sup> Endothelial cells respond to shear stress and cyclic strains.<sup>60</sup> In an environment in which concentrations of soluble growth factors are held constant, endothelial cell programs can be switched between growth, differentiation, and apoptosis by varying the extent to which the cell is spread or stretched.<sup>61</sup> As cells are embedded in, and coupled to, their ECM serves as a vehicle through which signals must pass. Biochemical signals can be sequestered or amplified by ECM, and as cells bind to surrounding ECM via integrin receptors, the binding itself can induce phenotypic changes.<sup>34</sup> When human MSCs are plated onto large

tissue islands that promote cell spreading, they efficiently differentiate into bone cells; when plated onto small islands, the same cells in the same culture medium differentiate into adipocytes.<sup>61</sup>

Clinical observations made from patients undergoing the Ross procedure has provided further evidence for the responsiveness of vascular and valve tissues to hemodynamic forces. In the Ross procedure, a pulmonary valve from the lower-pressure pulmonary circulation is transplanted into the aortic position and subjected to systemic pressure, leading to significant changes in the phenotype of valve interstitial cells, including an increase in matrix metalloproteinase activity, indicating ECM remodeling.<sup>18</sup>

Biophysical signaling is therefore considered fundamental to engineered tissue organization and conditioning, or training, for the *in vivo* environment. Mechanical forces can be applied to growing engineered tissues in a flow-loop containing tissue culture medium, known as a bioreactor. Preconditioning of tissues is thought to be important for the biology and monitoring of engineered cardiovascular tissues. Bioreactors are thought to serve two predominant purposes for engineered heart valves: first, mechanical forces influence cell phenotype and gene expression, and therefore, tissue development, and potentially, growth, are controlled by biomechanical signals. In experiments from our laboratory reported by Hoerstrup and colleagues, flow and pressure were demonstrated to increase the production of collagen in tissue-engineered semilunar valves.<sup>23</sup> In separate experiments, Lee and associates demonstrated the variation of ECM gene transcripts with changes in tightly controlled mechanical strains. Vascular smooth muscle cells seeded onto biodegradable scaffolds, then subjected to cyclic flexure produced more collagen and were stiffer than controls.<sup>63</sup> Similar findings were reproduced using MSCs, and porcine heart valves.<sup>64,65</sup>

In addition, since valves must not be regurgitant at the time of implantation, observation of engineered valve mechanics in a bioreactor prior to implantation has allowed investigators to monitor and predict *in vivo* valve function.

## ENGINEERED VALVE EXPERIMENTAL OUTCOMES

Progress toward a clinically translatable engineered heart valve is not possible without *in vitro* study of valve development and remodeling. Developmental biology and *in vitro* experiments are the fundamental elements of this emerging field. However, *in vivo* experiments are the necessary complement to *in vitro* investigation, and represent the true test of engineered device function over time. The *in vivo* environment is more complex than can be approximated *in vitro*, and remodeling is dependent upon the contributions of circulating progenitor and immune cells only present in whole living organisms.

Four major implantation studies of TEHV have been undertaken using the *de novo* engineered approach.<sup>23,24,29,66</sup>

Several groups have implanted decellularized and recellularized valves into the juvenile lamb circulation,<sup>67,68</sup> and two major studies evaluate the growth of vascular conduits in the pulmonary circulation.<sup>69,70</sup> Several representative studies will be reviewed in terms of valve function, evaluation of valve/conduit growth, and observation of engineered tissue maturation.

## In Vivo Valve Function, Growth and Maturation

Heart valve tissue engineering was conceptually established through proof-of-concept experiments in large animals. The first in vivo TEHV experiment involved implantation of a single leaflet into the pulmonary circulation.<sup>20</sup> Cells were isolated from ovine arteries and sorted into endothelial and fibroblast populations. Cells were labeled, then seeded onto PGA scaffold and subsequently implanted. Labeled cells were visualized in explanted specimens after 6 hours and after 1, 6, 7, 9, or 11 weeks. Cells produced ECM, and leaflets persisted in the circulation at all time points.

A second set of experiments involved implantation of a pulmonary valve composed of autologous ovine endothelial cells and myofibroblasts seeded on a PGA-P4HB composite scaffold.<sup>23</sup> After 14 days of exposure to gradually increasing flow and pressure conditions in a pulse duplicator, valves were implanted into sheep for 1 day, 4, 6, 8, 16, and 20 weeks. Valves demonstrated acceptable hemodynamics and had no evidence of thrombosis, stenosis, or aneurysm formation for up to 20 weeks. Central valvar regurgitation was noted after 16 weeks. Tissue analysis showed a layered structure with central glycosaminoglycans, collagen on the outflow surface, and elastin on the inflow surface. Elastin was detectable in the leaflets by 6 weeks in vivo. Over the 20-week study period, scaffold degradation corresponded to decreased leaflet stiffness. Histological, biochemical, and biomechanical parameters were similar to those of native pulmonary artery and leaflet tissue.

Using bone marrow-derived MSCs on a PGA/PLLA scaffold, investigators fabricated and implanted valved conduits in the pulmonary position of juvenile sheep.<sup>27</sup> Valves were evaluated by in vivo echocardiography; explanted tissues were analyzed by histology and immunostaining. At the time of implantation, echocardiograms demonstrated a maximum instantaneous gradient of  $17.2 \pm 1.33$  mm Hg, with estimates of regurgitation ranging from trivial to mild. Four animals survived the immediate postoperative period. After 4 months in vivo, there were no statistically significant difference in maximum instantaneous gradient, mean gradient or effective orifice area from the time of implantation. Histologic analysis at eight postoperative months showed explanted tissue to have a layered organization, with elastin fibers identified on the inflow surface and collagen dominating the outflow surface. Glycosaminoglycans were distributed throughout the remainder of the valve. At the time of implantation, cells uniformly expressed the mesenchymal cell marker  $\alpha$ -SMA, but at the time of valve explant, these cells were confined to

the subendothelial layer, while surface cells expressed von Willebrand factor, suggesting in vivo endothelialization of the graft. This study demonstrated the feasibility of implantation of a pulmonary valve using stem cells.

Further work in our laboratory has reproduced some of these initial findings, and studied valve function over time in larger numbers of animals.<sup>29</sup> Using the same scaffold material (PGA-PLLA composite nonwoven felt) and cells (MSCs), nineteen animals underwent implantation of valved conduits into the main pulmonary artery of neonatal sheep after resection of the native pulmonary leaflets. Valve function, cusp and conduit dimensions were evaluated at implantation (echocardiography), at the experimental midpoint (MRI), and at explant at 1 day; 6, 12, or 20 weeks postoperatively. At implantation, valved conduit function was excellent; maximum transvalvar pressure gradient by Doppler echocardiography was 17 mm Hg; most valved conduits showed trivial pulmonary regurgitation. At  $\geq 12$  weeks, valved conduit cusps were increasingly attenuated and regurgitant. Valved conduit diameter remained unchanged over 20 weeks. Dimensional measurements by MRI correlated with direct measurement at explant. These studies demonstrated autologous engineered valved conduits that functioned well at implantation, with subsequent monitoring of dimensions and function in real time by MRI. The valves underwent structural and functional remodeling without stenosis, but worsening pulmonary regurgitation was noted after 6 weeks.

When fibrin-based valves were implanted in sheep for 3 months, valved conduits exhibited the gross appearance of intact tissue, however, leaflets demonstrated pulmonary regurgitation due to tissue contraction.<sup>66</sup>

Most recent experiments have involved implantation of single electrospun anisotropic poly-carbonate urethane urea (PCUU) leaflets into the ovine pulmonary valve root without pre-implant cellularization. These studies have shown good overall valve function and repopulation of these leaflets with cells (Fig. 63-3). However, leaflet excursion did decrease with time, after implant.<sup>71</sup>

To date, no group has implanted valve leaflets that demonstrated in vivo growth. In many experiments, however, the microscopic structure of the valve leaflets evolved from a relatively homogeneous appearance to a layered structure. The mechanisms by which this in vivo evolution of structure and cellular activity occurs remain completely unexplored, but these observations suggest that a tissue-engineered valve may not have to be in a mature, adult form at the time of implantation into the circulation.

## FUTURE DIRECTIONS

After a decade of effort toward a TEHV replacement, the clinical need for a more durable valve replacement still exists. Modes of failure of currently available heart valve replacements are well described and provide insight into strengths and weaknesses of valve designs. Though the appropriate cell source and scaffold material for heart valve tissue engineering have been areas of substantial experimental effort, the optimal

**A** 6 weeks explant

**B**

**FIGURE 63-3** Gross section (A) and histologic section (B) of implanted tissue engineered valve leaflet after six weeks of in vivo implantation.

cell type, scaffold material, and in vitro culture conditions for a TEHV still remain unknown. Stem cells and adult progenitor cells offer promise toward this end, as they possess the capacity for self-renewal and multilineage differentiation, and therefore, growth potential. Evolving imaging technologies will allow a more complete understanding of postimplantation remodeling and growth. Though many details of in vitro preconditioning regimens are yet to be understood, bioreactor preconditioning has the potential to reduce in vitro culture times by stimulating tissue formation, and may offer a controllable environment for evaluation of valve function prior to implantation.

Complex biological events, such as heart valve development, occur through both biochemical and biophysical cues, occurring in parallel, at the cellular, tissue and organ levels. A detailed understanding of the molecular sequence of critical developmental events may allow engineering of appropriate microenvironments and three-dimensional structures

leading to the ultimate goal: a clinically translatable heart valve replacement with the capacity to grow and remain durable for a lifetime of cardiac cycles.
