Foreword

It is a distinct honor and privilege to have been asked to write the foreword for this edition of Shafer's Textbook of Oral Pathology. Dr Shafer, through the text that he co-authored with Drs Maynard Hine and Barnet Levy, made a tremendous impact on the practice of dentistry from the first edition, published in 1958, to the last edition, published in 1983. It is likely that no other text has ever had such a widespread influence on the perception of a specialty of dentistry, essentially establishing that the clinical and histopathologic diagnosis of oral disease belonged to the practice of dentistry, and the practice of oral and maxillofacial pathology specifically.

I was fortunate to have been one of more than 60 individuals who were trained under 'the Chief', as he was widely known by the people who passed through his department. Understand that he was a stern taskmaster, and he was serious about the practice of oral pathology. When a resident made a diagnosis, Dr Shafer expected that resident to know everything about that disease, and we spent hours in the library (this was in the days before computers!) tracking down who first reported that specific disease, in what year, and in what journal, as well as the most recent references related to the disease. He never allowed any of his residents to use his text as a reference, either. Perhaps he imparted the most significant concept, consciously or unconsciously, to us: knowledge and understanding of disease is an ever-changing, evolving process, and the practitioner must continually keep up with the dental and medical literature in order to remain current and provide the most accurate, up-to-date patient care.

This textbook, then, provides the dental clinician with some of the most current viewpoints related to the vast spectrum of disease that is encountered in the oral and maxillofacial region. The editors are to be commended on continuing Dr Shafer's legacy to the dental and oral pathology communities. By updating and amplifying the textbook, the authors will ensure that this knowledge will be handed down to future generations of practitioners. Future editions will include the inevitable advances in our understanding of disease processes, and hopefully will provide the stimulus for new investigators wishing to advance the science of oral and maxillofacial pathology. Undoubtedly, this textbook will maintain the tradition of excellence in oral pathology education that was established by Dr Shafer and will serve as a valuable resource for students, instructors and clinicians alike.

Preface to the Seventh Edition

The periodic and timely revisions of *Shafer's Textbook of Oral Pathology* have brought out a treatise, well conceived and written with the aim of updating the student all necessary nuances of the specialty. The scope of the present edition is an extension of this goal aimed at understanding the disease processes at a more fundamental level, the impetus being those in the maxillofacial region. While the subject appears more of loco-regional nature, as the text unfolds, its wider ramifications become more apparent and the disease entities described here appear wider in scope and nature. As in the past, this edition has also undergone an extensive revision and new topics have been included. A well thought out decision of incorporating 'cutting edge' technologies of relevance such as molecular markers and disease profiling, continues to be incorporated in the text with the aim of updating the subject and making it more contemporary. Scattered throughout the text one finds highlighted 'boxes' which stand out, yet merge imperceptibly with the rest, denoting advanced information perhaps beyond the ambit of the undergraduate curriculum. In this way, the text has been user friendly, though discriminatory of the scope and choice of its contents. We believe this approach is sensible and will be well taken by the readership. This textbook represents a treasury of information based for the most part, on the publications of our contemporaries and predecessors. In order to present the material in an informal manner, continuous referencing to these sources have been discarded. However, the reader will find a list of suggested references of wider scope at the end of each chapter.

This edition is peculiar in having new pieces of four-color art schematics, flowcharts and diagrams primarily aimed at comprehension of its contents and to facilitate reasoning of concepts such as the molecular basis of cancer. A change which is far reaching and marked is the hard copy format of the text which intends to minimize structural fatigue and maximize ease of usage. Finally, as was true of the fifth and sixth editions, all of our associations with the publisher, Elsevier India were pleasant and helpful. We want to thank the editorial staff of Elsevier India for their skilled and friendly assistance in helping us publish this project to completion successfully.

Deficiencies and shortcomings are rather inevitable in an effort of this magnitude and for which we shall be solely responsible. This textbook is dedicated to our contemporaries and predecessors who have made this effort a reality.

R Rajendran
B Sivapathasundharam

Preface to the First Edition

ORAL PATHOLOGY represents the confluence of the basic sciences and clinical dentistry. Since it has no methods of its own, knowledge in this field is acquired through the adaptation of methods and disciplines of those sciences basic to dental practice, such as gross and microscopic anatomy, chemistry, microbiology and physiology, and through information obtained by clinical histories and observation of patients. Through the science of oral pathology, an attempt is made to correlate human biology with the signs and symptoms of human disease. The oral pathologist attempts to understand oral disease so that it can be properly diagnosed and adequately treated.

In this text we have attempted to bring the reader to an understanding of the patient and his problems through applied basic science. We have tried to explain clinical signs and symptoms in the light of known histologic, chemical and physiologic alterations. Where possible, the prognosis of each disease is considered as a reflection of the underlying tissue changes and what we know can be done about them today.

In numerous sections of the text we have attempted to integrate information from many of the basic sciences for adequate diagnosis of oral disease. This approach is a departure from that of the usual textbook of oral pathology, representing an effort to place more emphasis on the physiologic and chemical aspects of oral disease.

The references at the end of each chapter are extensive enough to be of value to those interested in additional reading. Only those papers which constitute good review articles or exceptional discussions or which are of historical importance are included. Because the field of oral pathology is large, much of the bibliographic material has had to be curtailed or omitted. The highlights alone have been stressed. It is our hope that this book will prove to be a stimulus to study as well as a guide for undergraduate and postgraduate students and practitioners of both dentistry and medicine.

CHAPTER OUTLINE

CRANIOFACIAL ANOMALIES

Craniofacial anomalies (CFA) are a diverse group of deformities in the growth of the head and facial bones. Anomaly is a medical term meaning 'irregularity' or 'different from normal'. These abnormalities are congenital (present at birth) and have numerous variations: some are mild, others are severe and require surgery.

There is no single factor that causes these abnormalities. Instead, there are many factors that may contribute to their development, including the following:

- **Combination of genes.** A child may receive a particular combination of gene(s) from one or both parents, or there may be a change in the genes at the time of conception, which results in a craniofacial anomaly.
- **Environmental.** There is no data that shows a direct correlation between any specific drug or chemical exposure causing a craniofacial anomaly. However, any prenatal exposure should be evaluated.
- **Folic acid deficiency.** Folic acid is a B vitamin found in orange juice, fortified breakfast cereals, enriched grain products, and green, leafy vegetables. Studies have shown that women who do not take sufficient folic acid during pregnancy, or have a diet lacking in folic acid, may have a higher risk of having a baby with certain congenital anomalies, including cleft lip and/or cleft palate.

Some of the most common types of craniofacial anomalies (Table 1-1) include:

- **Cleft lip and/or cleft palate.** A separation that occurs in the lip or the palate or both. Cleft lip and cleft palate are the most common congenital craniofacial anomalies seen at birth.

  Cleft lip. An abnormality in which the lip does not completely form. The degree of the cleft lip can vary greatly, from mild (notching of the lip) to severe (large opening from the lip up through the nose).
  Cleft palate. Occurs when the roof of the mouth does not completely close, leaving an opening that can extend into the nasal cavity. The cleft may involve either side of the palate. It can extend from the front of the mouth (hard palate) to the throat (soft palate). The cleft may also include the lip.

- **Craniosynostosis.** A condition in which the sutures in the skull of an infant close too early, causing problems with normal brain and skull growth. Premature closure of the sutures may also cause the pressure inside the head to increase and the skull or facial bones to change from a normal, symmetrical appearance.
- **Hemifacial microsomia.** A condition in which the tissues on one side of the face are underdeveloped, affecting primarily the ear (aural), mouth (oral), and jaw (mandibular) areas. Sometimes, both sides of the face

Table 1-1: Examples of most common craniofacial anomalies

	Prevalence at birth: per 10,000
Cleft lip ± palate	
Caucasian	10
Japanese	20
Native (North) Americans	36
African-American population	3
Cleft palate	
Average across races	5
Craniosynostosis	3
Crouzon syndrome	0.4
Apert syndrome	0.15
Otomandibular anomalies	1.2
Treacher Collins syndrome	0.2
CHARGE association	1
Holoprosencephaly	1.2
Stickler syndrome	1
Fetal alcohol syndrome	2

can be affected and may involve the skull as well as the face. Hemifacial microsomia is also known as Goldenhar syndrome, brachial arch syndrome, facio-auriculovertebral syndrome (FAV), oculo-auriculovertebral spectrum (OAV), or lateral facial dysplasia.

- **Vascular malformation.** A birthmark or a growth, present at birth, which is composed of blood vessels that can cause functional or esthetic problems. Vascular malformations may involve multiple body systems. There are several different types of malformations, named after the type of blood vessel that is predominantly affected. Vascular malformations are also known as lymphangiomas, arteriovenous malformations, and vascular gigantism.
- **Hemangioma.** A type of birthmark; the most common benign (noncancerous) tumor of the skin. Hemangiomas may be present at birth (faint red mark) or appear in the first month after birth. A hemangioma is also known as a port wine stain, strawberry hemangioma, and salmon patch.
- **Deformational (or positional) plagiocephaly.** A misshapen (asymmetrical) shape of the head (cranium) from repeated pressure to the same area of the head. Plagiocephaly literally means 'oblique head' (from the Greek '*plagio*' for oblique and '*cephale*' for head).

Collectively they affect a significant proportion of the global society (Table 1-1).

GLOBAL EPIDEMIOLOGY

The frequency of occurrence of cleft lip, with or without cleft palate, has been computed on a global scale and is estimated to be 1 in every 800 newborn babies (Tables 1-2 and 1-3). A child is therefore born with a cleft somewhere in the world approximately every two-and-half minutes. Accurate data on the frequency of occurrence of these disorders is relevant for implementing strategies aimed at primary prevention and effective management of these disabled children (Table 1-2). Like anywhere else, the epidemiological data in this situation is also inherently handicapped by:

- The heterogeneity of orofacial clefting,
- The lack of standard criteria for collection of data, and
- In particular, the lack of and/or failure to apply an internationally comparable classification for orofacial clefting.

Defining the affected population is also problematic because, on many occasions, the terminology is so vague that it is not clear whether it denotes all birth, or all live births. The word 'births' is again somewhat ambiguous because it usually includes stillbirths, a term which lacks clarity.

REGISTRATION OF TARGETED CRANIOFACIAL ANOMALIES IN INDIA

1. Three multicenter studies in India have provided almost similar frequency of CFA: meta-analysis of 25 early studies from 1960–1979, involving 407,025 births, showed:
   CL/P = 440 cases, 1.08 per 1,000 births,
   CP = 95 cases, 0.23 per 1,000 births.
2. A prospective national study of malformations in 17 centers from all over India from September 1989 to September 1990 involving 47,787 births showed:
   CL/P = 64 cases, 1.3 per 1,000 births,
   CP = 6 cases, 0.12 per 1,000 births.
3. The latest three-center study, conducted in 1994–1996, involved 94,610 births in Baroda, Delhi and Mumbai, and showed a frequency of:
   CL/P = 0.93 per 1,000 births,
   CP = 0.17 per 1,000 births.
   This was the most rigorously conducted study and it found the number of infants born every year with CLP to be 28,600; this means 78 affected infants are born every day, or three infants with clefts are born every hour (Table 1-4)!

CFA are not lethal but they are disfiguring, and thus cause a tremendous social burden. However, these disorders have an excellent outcome if surgical repair is carried out competently. Recent information regarding the etiology of CFA provides the means to carry out primary or secondary prevention. Maintaining a registry would be very useful as a benefit to the community and in reducing the burden of these anomalies, either by prevention or surgical repair.

Another reason why a registry would be desirable is the changing pattern of morbidity and mortality in India emerging as a result of the achievements in immunization, the success in providing primary health care and the existence of a well-developed health infrastructure. In many university and city hospitals congenital malformations and genetic disorders have become important causes of illness. All these reasons show that starting a registry of these disorders deserves high priority in India.

EXISTING EPIDEMIOLOGICAL DATA ON CFA

The epidemiological information that exists on CFA anomalies in India needs to be examined to decide what data should be collected for the registry:

- Higher frequency of CL+CP among Indian males is similar to that observed among Caucasians. The ratio is more than that observed in Africans and Japanese.
- The higher prevalence of CL+CP as compared with CL among Indians is like that observed in Africans, and is more than that observed in Caucasians.
- Children born prematurely are more frequently affected in India, as elsewhere.
- About 10.9% of 459 cases of all clefts are syndromic in Chennai. Of these, about 50 % are due to single-gene disorders, about 18% due to chromosomal disorders, and the rest due to undetermined causes.

* *Abortion for birth defect not permitted.*

↑ *= 99% significantly higher than the mean.*

↓ *= 99% significantly lower than the mean.*

- Chromosomal studies would be desirable in cases with associated abnormalities.
- Syndromes are more commonly associated with CP than with CL, as elsewhere.
- Lateralization (more clefts on the left side) in India is similar to that observed in other races.
- In one study in India, the intake of drugs was observed in 18% of parents — mostly steroidal compounds (progestogens as tests for pregnancy).
- A greater history of terminated pregnancies has been observed among cases, as compared with controls.
- History of severe vomiting has been observed to be about six times more common among case mothers than among controls.
- There is some difference in the frequency of orofacial clefts in different states in India; however, this needs verification. The state of origin (or mother tongue) of the parents should be recorded.

Table 1-4: Number of infants with common malformations born every year in India

Malformation	Rate per 10,000	Total number per year
Neural tube defects	36.3	88,935
Talipes equinovarus	14.5	35,525
Polydactyly	11.6	28,420
Hydrocephalus alone	9.5	23,275
Cleft lip with cleft palate (CLP)	9.3	22,786
Congenital heart disease	7.1	17,395
Hypospadias	5.0	12,250
Cleft palate alone (CP)	1.7	4,145

Source: Global registry and database on craniofacial anomalies: Report of a WHO registry on craniofacial anomalies, 2001.

- Clefts are more commonly found in certain caste groups among Hindus.
- In India CP has less frequency in those with blood group A.
- CL occurs more in those with group O and AB.
- Association of clefts with certain HLA types has been documented in India.
- In a study in Chennai, significantly more consanguinity was observed among couples having children with clefts as compared with controls.

GENETICS: PRINCIPLES AND TERMINOLOGY

Genotype and Phenotype

The science of genetics is concerned with the inheritance of traits, whether normal or abnormal, and with the interaction of

Table 1-5: Genes involved in craniofacial and dental disorders, sorted by acronym gene name

Acronym	Full name

genes and the environment. This latter concept is of particular relevance to medical genetics, since the effects of genes can be modified by the environment.

Consideration of the heritability of a particular feature or trait requires a consideration of the relationship between genotype and phenotype. Genotype is defined as the genetic constitution of an individual, and may refer to specified gene loci or to all loci in general. An individual's phenotype is the final product of a combination of genetic and environmental influences. Phenotype may refer to a specified character or to all the observable characteristics of the individual. The proportion of the phenotypic variance attributable to the genotype is referred to as heritability.

Genetic variation in man may be observed at two levels:

In specific traits, individual genotypes are readily identified and differences are qualitative (discrete), for example, the ABO blood antigen system. Gene frequencies can be estimated and the Mendelian type of analysis can be applied.

In continuous traits such as height, weight or tooth size, differences are characterized quantitatively between individuals. These quantitative traits in man are more elusive to study because they are determined by the alleles of many gene loci, and therefore, the Mendelian type of analysis is not appropriate. They are further modified by environmental conditions which obscure the genetic picture. If the genetic variation of a particular phenotypic trait is dependent on the simultaneous segregation of many genes and affected by environment it is referred to as being subject to multifactorial inheritance. Genetic differences caused by the segregation of many genes is referred to as polygenic variation and the genes concerned are referred to as polygenes. These genes are, of course, subject to the same laws of transmission and have the same general properties as the single genes involved in qualitative traits, but segregation of genes is translated into genetic variations seen in continuous traits through polygenes.

Different types of genetic 'product' can be thought of as being different distances from the fundamental level of gene activity. Enzymes, for instance, are almost direct products of gene action, and in most cases where genetic variation of enzyme structure has been demonstrated, it has been shown that a single locus is responsible for the structure of a single enzyme. The structure, and consequently, the activity of an enzyme is therefore usually simply and directly related to allele substitutions at a single locus.

Morphological characters, on the other hand, such as the numerous dimensions used to describe the shape of the face and jaws, are furthest removed from the fundamental genetic level and are the end results of a vast complexity of interacting, hierarchical, biochemical, and developmental processes. Each gene is therefore likely to influence many morphological characters so that a deleterious mutation, although producing a unitary effect at the molecular level, almost always results in a syndrome of morphological abnormalities. When a gene is known to affect a number of different characters in this way its action is said to be pleiotropic. A reverse hierarchy also exists, making each morphological character dependent on many different genes (Mossey, 1999).

Modes of Inheritance

Population genetics deals with the study of the mode of inheritance of traits and the distribution of genes in populations.

All chromosomes exist in pairs so our cells contain two copies of each gene, which may be alike or may differ in their substructure and their product. Different forms of genes at the same locus or position on the chromosome are called alleles. If both copies of the gene are identical, the individual is described as homozygous, while if they differ, the term used is heterozygous.

The exception to the rule that cells contain pairs of chromosomes applies to the gametes, sperm and ovum, which contain only single representatives of each pair of chromosomes, and therefore, of each pair of genes. When the two gametes join at fertilization, the new individual produced again has paired genes, one from the father and one from the mother. If a trait or disease manifests itself when the affected person carries only one copy of the gene responsible, along with one normal allele, the mode of inheritance of the trait is called dominant (Fig. 1-1A). If two copies of the defective gene are required for expression of the trait, the mode of inheritance is called recessive (Fig. 1-1B).

The special case of genes carried on the X chromosome produces yet different pedigrees. Since male-to-male transmission is impossible and since females do not express the disease when they carry only one copy of the diseased gene (since it is modified by the homologous X chromosome), the usual pedigree consists of an affected male with clinically normal parents and children, but with affected brothers, maternal uncles, and other maternal male relatives (Fig. 1-1C). This mode of inheritance is described as X-linked recessive.

It has been long appreciated that many normal traits, such as height, intelligence, and birth weight, have a significant genetic component, as do a number of common diseases, such as diabetes mellitus, schizophrenia, hypertension, and cleft lip and palate. However, the pattern of inheritance of these traits does not follow the simple modes just described. Mathematical analysis of many of these has led to the conclusion that they follow the rules of polygenic inheritance, i.e. determined by a constellation of several genes, some derived from each parent.

The determination of heritability for polygenic or multifactorial characters is difficult, as a feature of continuous variation is that different individuals may occupy the same position on the continuous scale for different reasons. Using mandibular length as an example, micrognathia can occur in chromosomal disorders, such as Turner's syndrome, in monogenic disorders such as Treacher Collins syndrome or Stickler syndrome, or due to an intrauterine environmental problem, such as fetal alcohol syndrome. Combined with this the concept of etiological heterogeneity encompasses the principle of the same gene defect producing different phenotypic anomalies, and syndromes can be due to defective gene activity in different cells. Conversely, different gene defects or combinations of defective genes can produce a similar phenotypic abnormality. Genetic lethality or reduced reproductive fitness can also complicate the diagnostic picture

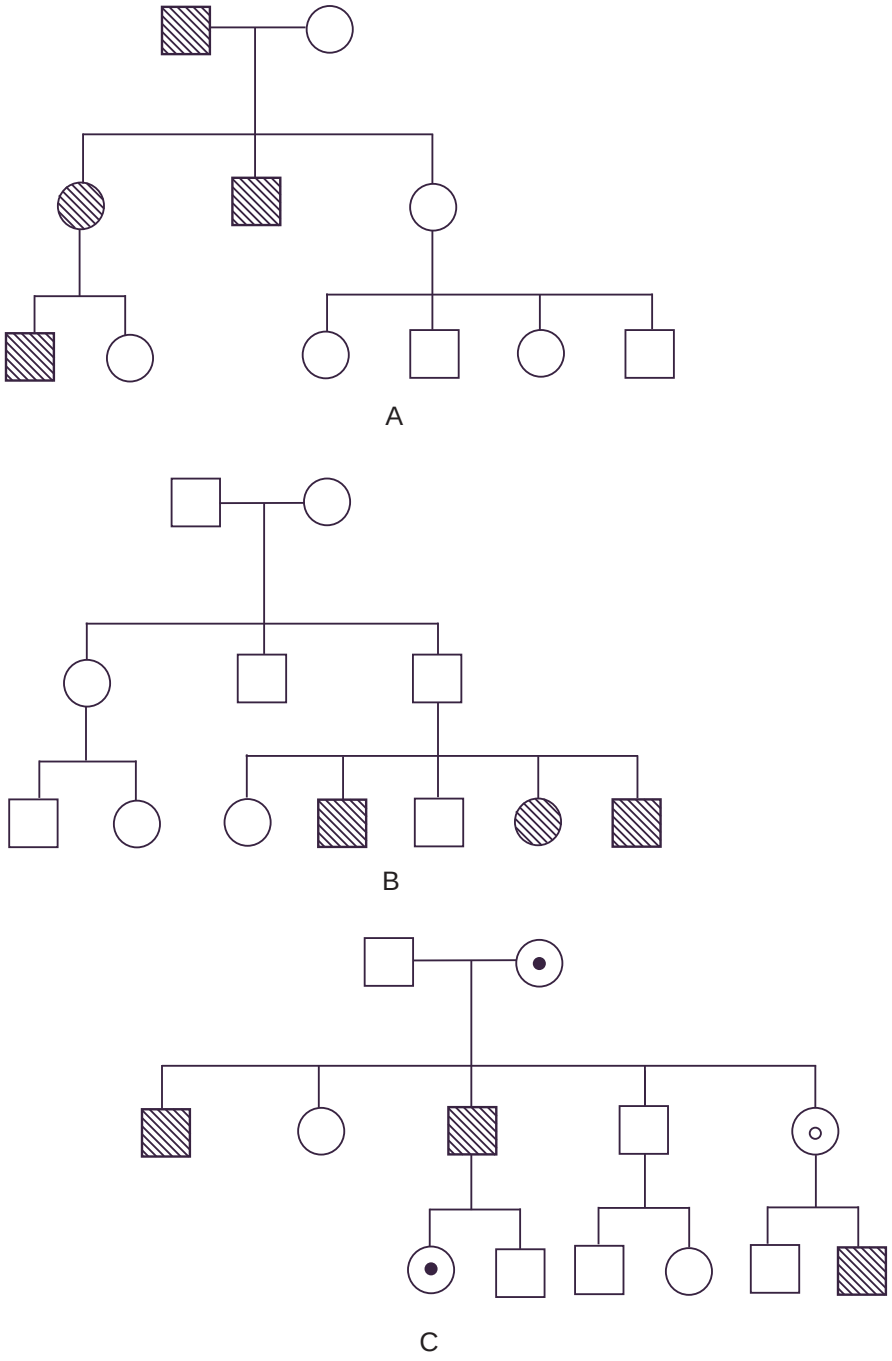

Figure 1-1. (A) Autosomal dominant pedigree. (B) Autosomal recessive pedigree. (C) X-linked recessive pedigree.
(Courtesy of PA Mossey, 1999).

and genomic imprinting can result in a gene defect 'skipping' a generation. These complexities serve to hamper progress in the understanding of polygenic or multifactorial disorders such as orofacial clefting (Mossey, 1999).

Multifactorial Inheritance. In contrast to single-gene inheritance, either autosomal or sex-linked, the pedigree pattern does not afford a diagnosis of multifactorial inheritance. In multifactorial traits, the trait is determined by the interaction of a number of genes at different loci, each with a small, but additive effect, together with environmental factors (i.e., the genes are rendering the individual unduly susceptible to the environmental agents). Many congenital malformations (Table 1-6) and common diseases of adult life are inherited as multifactorial traits and these are categorized as either continuous or discontinuous.

Molecular Genetics in Dental Development. The first sign of tooth development is a local thickening of oral epithelium, which subsequently invaginates into neural crest derived mesenchyme and forms a tooth bud. Subsequent epithelial folding and rapid cell proliferation result in first the cap, and then the bell stage of tooth morphogenesis. During the bell stage, the dentine producing odontoblasts and enamel

secreting ameloblasts differentiate. Tooth development, like the development of all epithelial appendages, is regulated by inductive tissue interactions between the epithelium and mesenchyme (Thesleff, 1995).

There is now increasing evidence that a number of different mesenchymal molecules and their receptors act as mediators of the epithelial-mesenchymal interactions during tooth development. Of the bone morphogenetic proteins (BMPs) 2, 4, and 7 mRNAs shift between the epithelium and mesenchyme in the regulation of tooth morphogenesis (Aberg et al, 1997). The fibroblast growth factor (FGF) family have also been localized in epithelial and mesenchymal components of the tooth by immunohistochemistry (Cam et al, 1992); and in dental mesenchyme tooth development and shape is regulated by FGF8 and FGF9 via downstream factors MSX1 and PAX9 (Kettunen and Thesleff, 1998).

Control of Tooth Development. Homeobox genes have particular implications in tooth development. Muscle specific homeobox genes Msx-1 and Msx-2 appear to be involved in epithelial mesenchymal interactions, and are implicated in craniofacial development, and in particular, in the initiation developmental position (Msx-1) and further development (Msx-2) of the tooth buds (MacKenzie et al, 1991; Jowett et al, 1993). Further evidence of the role of Msx-1 comes from gene knock-out experiments which results in disruption of tooth morphogenesis among other defects (Satokata and Maas, 1994). Pax-9 is also transcription factor necessary for tooth morphogenesis (Neubuser et al, 1997). BMPs are members of the growth factor family (TGF) and they function in many aspects of craniofacial development with tissue specific functions. BMPs have been found to have multiple roles not only in bone morphogenesis, (BMP 5, for example, induces endochondral osteogenesis *in vivo*), but BMP 7 appears to induce dentinogenesis (Thesleff, 1995).

Disorders in Tooth Morphogenesis. Advances in the field of molecular genetics have made great progress in the understanding of a number of dental anomalies with a genetic component.

CONGENITAL DEFORMATIONS OF HEAD AND NECK

These are common, and mostly resolve spontaneously within the first few days of postnatal life. When they do not, further evaluation may be necessary to plan therapeutic interventions that may prevent long-term consequences. Approximately 2% of infants are born with extrinsically caused deformations that usually arise during late fetal life from intrauterine causes. Approximately 30% of deformed infants have two or more deformations. Deformed infants tend to show catch-up growth during the first few postnatal months after release from the intrauterine environment. The common deformations considered under the craniofacial category are nasal, auricular and mandibular deformities.

Teratogenic Agents

Teratogens are agents that may cause birth defects when present in the fetal environment. Included under such a definition are a wide array of drugs, chemicals, and infectious, physical, and metabolic agents that may adversely affect the intrauterine environment of the developing fetus. Such factors may operate by exceedingly heterogeneous pathogenetic mechanisms to produce alterations of form and function as well as embryonic and/or fetal death (Gorlin et al, 1990).

The mechanisms of teratogenesis are selective in terms of the target and effect. Thus, characteristic patterns of abnormalities can be expected to be associated with particular teratogenic agents. However, the extent to which an individual may be adversely affected by exposure to a given teratogen varies widely. This depends on the following four factors:

1. Differences in dose
2. Developmental timing of exposure
3. Differences in susceptibility
4. Interactions among environmental exposures.

It is of considerable interest to the dental profession that experimental studies of teratogenic agents have almost invariably revealed a variety of head, neck and oral malformations. Conway and Wagner have compiled a list of the most common malformations of the head and neck as shown in Table 1-7.

Stem cells

Stem cells are clonogenic cells that have the capacity for self-renewal and multilineage differentiation. The microenvironment in which stem cells reside is called a stem cell niche and is composed of heterologous cell types, extracellular matrix and soluble factors to support the maintenance and self-renewal of the stem cells. Stem cells have been isolated and characterized from a wide variety of sources. Adult progenitor cellular populations have been isolated from distinctive tissues and fluids, such as bone marrow, peripheral blood, umbilical cord blood, Wharton's jelly, placenta, amniotic fluid and membrane, adipose tissue, dermis, hair follicles, synovial membrane, skeletal muscle, central nervous system, olfactory bulb, retina, and liver among others. From these biological sources, progenitors of the mesenchymal, epithelial, hematopoetic (discussed elsewhere), neural, endothelial and trophoblastic lineages have been identified (Fig. 1-2).

In tissue engineering applications, mesenchymal stem cells are among the most used populations because of the wide variety of sources from which they can be harvested, their ability to self-renew, and their multilineage potential following adequate induction. Moreover, the vast majority of the tissues relevant in surgical repair / regeneration are of mesenchymal origin. This is of particular relevance in the craniofacial area because during development cells originating from the neural crest are known to migrate, differentiate, and participate in the morphogenesis of virtually all structures of the region including muscle, ligament, bone, cartilage, periodontal tissues and teeth.

There are two major categories of stem cells, which are of relevance to dentistry:

1. Embryonic stem cells
2. Adult or somatic stem cells.

Totipotent embryonic stem cells are derived from the inner cell mass of mammalian blastocyst and can be maintained indefinitely in culture. Somatic stem cells have a limitation in their potential of differentiation. The differentiation potential of dental stem cells lies in the formation of dentin or periodontium associated tissues, whether these cells are derived from pulp, periodontal ligament or dental follicle. It is obvious that dental ectomesenchymal stem cells can be classified into two different groups with respect to their differentiation potential. The first group is associated with the dental pulp, consisting of dental pulp stem cells (DPSCs), stem cells from exfoliated deciduous teeth (SCEDs), and stem cells from apical papilla (SCAPs); the second group contains periodontal ligament stem cells (PLSCs) and dental follicle progenitor cells (DFPCs), related to the periodontium.

The odontogenic stem cells are further divided into:

1. Epithelial stem cells (ESCs)
2. Mesenchymal stem cells (MSCs).

Dental epithelial stem cells

Embryonic dental epithelium is capable of inducing the development of a tooth germ in combination with non-dental ectomesenchymal tissue. However, oral ectomesenchyme in combination with non-dental epithelium did not induce tooth development. Later steps in tooth development are driven by a complex interaction of both ectodermal and ectomesenchymal tissues along with growth promoting factors of bone morphogenic protein-4 (BMP-4) and fibroblast growth factor-8 (FGF-8), produced by the oral ectoderm for the initiation of tooth development.

Oral ectoderm derived ameloblasts are unable to proliferate or regenerate once they have reached the maturation stage of development. Continuously growing mouse incisors and molars in some mammalian species show replenishing populations of enamel organs composed of stellate reticulum, stratum intermedium and enamel epithelial cells which provide models for dental epithelial stem cells. Mice have an epithelial stem cell niche located at their incisor labial apical ends, known as the cervical loop. The cervical loop has been considered to be a determinative region in odontogenesis due to its ability to produce enamel and dentin. One specialized structure found at the apical region of the labial cervical loop in mouse incisors, "apical bud" (Ohshima H et al, 2003), is suggested as stem cell compartment that could differentiate into ameloblast through interaction with mesenchymal cells and growth factors.

In humans, these dental epithelial stem cells are lost after tooth eruption; therefore, are not available for studies on dental development. In contrast to dental epithelial stem cells, undifferentiated cells of the oral ectomesenchyme are not entirely lost after tooth eruption in humans. It became possible to isolate precursor cells from the dental pulp and ectomesenchymal stem cells were isolated from the dental pulp of extracted wisdom teeth.

Dental mesenchymal stem cells

They are a heterogeneous population of multipotent self-renewal cells that possess clonogenic competence and the capacity to differentiate into all cell lineages of the mesenchymal and connective tissue elements. They also seem to be able to differentiate into epithelial cells and lineages derived from neuroectoderm. Mesenchymal stem cells have been shown to produce a wide range of bioactive molecules capable of immunomodulatory functions along with the ability to modulate the regenerative processes in the human body (Ohshima H et al, 2001).

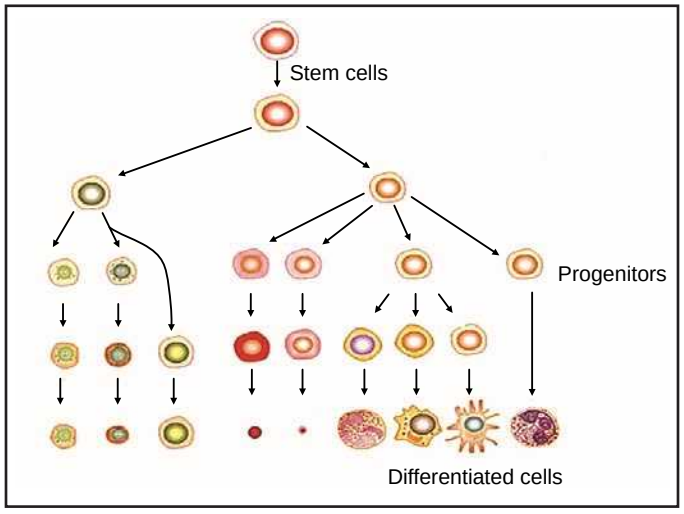

Figure 1-2. Mandibular micrognathia.

DEVELOPMENTAL DISTURBANCES OF JAWS

Agnathia

(Otocephaly, holoprosencephaly agnathia)

Agnathia is a lethal anomaly characterized by hypoplasia or absence of the mandible with abnormally positioned ears having an autosomal recessive mode of inheritance. More commonly, only a portion of one jaw is missing. In the case of the maxilla, this may be one maxillary process or even the premaxilla. Partial absence of the mandible is even more common. The entire mandible on one side may be missing, or more frequently, only the condyle or the entire ramus, although bilateral agenesis of the condyles and of the rami also has been reported. In cases of unilateral absence of the mandibular ramus, it is not unusual for the ear to be deformed or absent as well. It is probably due to failure of migration of neural crest mesenchyme into the maxillary prominence at the fourth to fifth week of gestation (postconception). The prevalence is unknown and less than 10 cases are described. The prognosis of this condition is very poor and it is considered to be lethal.

Micrognathia

Micrognathia literally means a small jaw, and either the maxilla or the mandible may be affected. Many cases of apparent micrognathia are not due to an abnormally small jaw in terms of absolute size, but rather to an abnormal positioning or an abnormal relation of one jaw to the other or to the skull, which produces the illusion of micrognathia.

True micrognathia may be classified as either congenital, or acquired. The etiology of the *congenital* type is unknown, although in many instances it is associated with other congenital abnormalities, including congenital heart disease and the Pierre Robin syndrome (q.v.) This form of the disease has been discussed by Monroe and Ogo. It occasionally follows a hereditary pattern. Micrognathia of the maxilla frequently occurs due to a deficiency in the premaxillary area, and patients with this deformity appear to have the middle third of the face retracted. Although it has been suggested that mouth-breathing is a cause of maxillary micrognathia, it is more likely that the micrognathia may be one of the predisposing factors in mouth-breathing, owing to the associated maldevelopment of the nasal and nasopharyngeal structures.

True mandibular micrognathia of the congenital type is often difficult to explain. Some patients appear clinically to have a severe retrusion of the chin but, by actual measurements, the mandible may be found to be within the normal limits of variation. Such cases may be due to a posterior positioning of the mandible with regard to the skull or to a steep mandibular angle resulting in an apparent retrusion of the jaw. Agenesis of the condyles also results in a true mandibular micrognathia.

The acquired type of micrognathia is of postnatal origin and usually results from a disturbance in the area of the temporomandibular joint. Ankylosis of the joint, for example, may be caused by trauma or by infection of the mastoid, of the middle ear, or of the joint itself. Since the normal growth of the mandible depends to a considerable extent on normally developing condyles as well as on muscle function, it is not difficult to understand how condylar ankylosis may result in a deficient mandible.

The clinical appearance of mandibular micrognathia is characterized by severe retrusion of the chin, a steep mandibular angle, and a deficient chin button (Fig. 1-3).

Micrognathia may be caused by or may be a feature of several conditions (Table 1-8).

Macrognathia

Macrognathia refers to the condition of abnormally large jaws. An increase in size of both jaws is frequently proportional to a generalized increase in size of the entire skeleton, e.g. in pituitary gigantism. More commonly only the jaws are affected, but macrognathia may be associated with certain other conditions, such as:

- Paget's disease of bone, in which overgrowth of the cranium and maxilla or occasionally the mandible occurs,
- Acromegaly, in which there is progressive enlargement of the mandible owing to hyperpituitarism in the adult, or
- Leontiasis ossea, a form of fibrous dysplasia in which there is enlargement of the maxilla.

Cases of mandibular protrusion or prognathism, uncomplicated by any systemic condition, are a rather common clinical occurrence (Fig. 1-4). The etiology of this protrusion is unknown, although some cases follow hereditary patterns. In many instances the prognathism is due to a disparity in the size of the maxilla in relation to the mandible. In other cases the mandible is measurably larger than normal. The angle between the ramus and the body also appears to influence the relation of the mandible to the maxilla, as does the actual height of the ramus. Thus prognathic patients tend to have long rami which form a less steep angle with the body of the mandible. The length of the ramus, in turn, may be associated with the growth of the condyle. It may be reasoned, therefore, that excessive condylar growth predisposes to mandibular prognathism.

General factors which conceivably would influence and tend to favor mandibular prognathism are as follows:

- Increased height of the ramus
- Increased mandibular body length
- Increased gonial angle
- Anterior positioning of the glenoid fossa
- Decreased maxillary length
- Posterior positioning of the maxilla in relation to the cranium
- Prominent chin button
- Varying soft-tissue contours.

Surgical correction of such cases is feasible. Ostectomy, or resection of a portion of the mandible to decrease its length, is now an established procedure, and the results are usually excellent from both a functional and a cosmetic standpoint.

Facial Hemihypertrophy
(Hyperplasia)

Hemihyperplasia is a rare developmental anomaly characterized by asymmetric overgrowth of one or more body parts. Although the condition is known more commonly as hemihypertrophy, it actually represents a hyperplasia of the tissues rather than a hypertrophy. Hemihyperplasia can be an isolated finding, but it also may be associated with a variety of malformation syndromes (Table 1-9). Almost all cases of isolated hemihyperplasia are sporadic.

Source: HE Hoyme et al, 1998.

Hoyme et al (1998) provided an anatomic classification of hemihyperplasia:

- Complex hemihyperplasia is the involvement of half of the body (at least one arm and one leg); affected parts may be contralateral or ipsilateral,
- Simple hemihyperplasia is the involvement of a single limb, and
- Hemifacial hyperplasia is the involvement of one side of the face.

Etiology. The cause is unknown, but the condition has been variously ascribed to vascular or lymphatic abnormalities; CNS disturbances; and chromosomal abnormalities.

Clinical Features. Patients affected by facial hemihypertrophy exhibit an enlargement which is confined to one side of the body, unilateral macroglossia and premature development, and eruption as well as an increased size of dentition. Familial occurrence has been reported on a few occasions, according to the excellent review of the condition by Rowe, who described four additional cases. Of all reported cases, females are affected somewhat more frequently than males (63% versus 37%), according to the review by Ringrose. There is an almost equal involvement of the right and left sides.

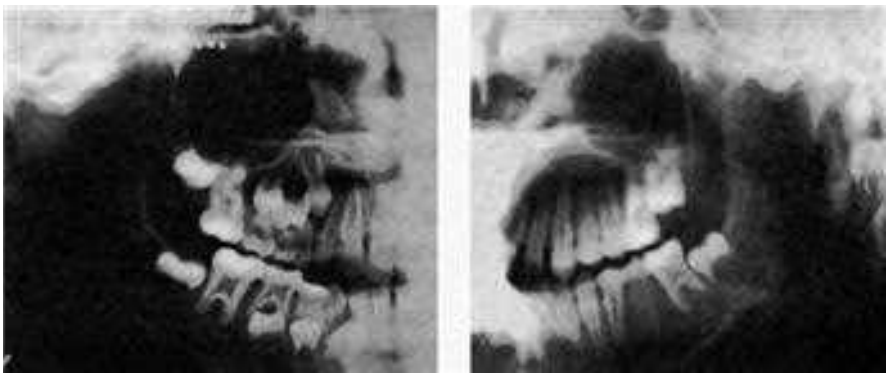
Oral Manifestations. The dentition of the hypertrophic side, according to Rowe, is abnormal in three respects: crown size, root size and shape, and rate of development. Rowe has also pointed out that not all teeth in the enlarged area are necessarily affected in a similar fashion. There is little information about the effects on the deciduous dentition, but the permanent teeth on the affected side are often enlarged, although not exceeding a 50% increase in size. This enlargement may involve any tooth, but seems to occur most frequently in the cuspid, premolars, and first molar. The roots of the teeth are sometimes proportionately enlarged but may be short.

Characteristically, the permanent teeth on the affected side develop more rapidly and erupt before their counterparts on the uninvolved side (Fig. 1-5). Coincident to this phenomenon is premature shedding of the deciduous teeth. The bone of the maxilla and mandible is also enlarged, being wider and thicker, sometimes with an altered trabecular pattern.

The tongue is commonly involved by the hemihypertrophy and may show a bizarre picture of enlargement of lingual papillae in addition to the general unilateral enlargement and contralateral displacement. In addition, the buccal mucosa frequently appears velvety and may seem to hang in soft, pendulous folds on the affected side.

Histologic Features. Tissue examination has been infrequently reported but is generally uninformative. In those cases reported, true muscular hypertrophy was not found.

Treatment and Prognosis. There is no specific treatment for this condition other than attempts at cosmetic repair. Cosmetic surgery is advised after cessation of growth. Effect on life expectancy is not certain, but in some cases patients have lived a normal life span. Periodic abdominal ultrasound/MRI is recommended to rule out tumors.



A B

Figure 1-5. Facial hemihypertrophy.
The difference in the eruption pattern of the teeth on each side is apparent. The teeth on the affected side, where all deciduous teeth have already been lost, are not appreciably larger than those on the unaffected side *(Courtesy of Dr John B Wittgen)*.

Differential Diagnosis. There are certain diseases of the jaws, such as neurofibromatosis and fibrous dysplasia of the jaws, that may give the clinical appearance of facial hemihypertrophy, but these can usually be differentiated readily by the lack of effect on tooth size and rate of eruption.

Facial Hemiatrophy

(Parry-Romberg syndrome, Romberg-Parry syndrome, progressive facial hemiatrophy, progressive hemifacial atrophy)

Hemifacial atrophy remains almost as much an enigma today as it was when first reported by Romberg in 1846. Hemifacial atrophy, originally described by Parry and Henoch and Romberg consists of slowly progressive atrophy of the soft tissues of essentially half the face, which is characterized by progressive wasting of subcutaneous fat, sometimes accompanied by atrophy of skin, cartilage, bone and muscle. Although the atrophy is usually confined to one side of the face and cranium, it may occasionally spread to the neck and one side of the body and it is accompanied usually by contralateral Jacksonian epilepsy, trigeminal neuralgia, and changes in the eyes and hair. Evidence of a mendelian basis is lacking. Lewkonia and Lowry reported the case of a 16-year-old boy who developed facial changes at age seven and had localized scleroderma on one leg and the trunk. The presence of antinuclear antibodies in his serum suggested that the Parry-Romberg syndrome may be a form of localized scleroderma. Hemifacial atrophy is a form of localized scleroderma and is supported by its concurrence with scleroderma.

Hemifacial atrophy is a rare condition that occurs sporadically although some familial distribution has been found. The majority of cases are sporadic with no definite inheritance being proven in the literature.

Etiology. The etiology has been the subject of considerable debate. Wartenburg considered the primary factor to be a cerebral disturbance leading to increased and unregulated activity of sympathetic nervous system, which in turn produced the localized atrophy through its trophic functions conducted by way of sensory trunks of the trigeminal nerve. Other workers suggested extraction of teeth, local trauma, infection and genetic factors could also be a cause. In a paper published in 1973, Poswillo attributed the development of facial deformities to the disruption of the stapedial artery. Poswillo fed pregnant rats with triazine and pregnant monkeys with thalidomide and showed the consistent maldevelopment of first and second branchial arch structures. Robinson, in 1987, supported Poswillo's theory by demonstrating carotid flow abnormalities in two and defects related to vascular disruption in a third child with craniofacial microsomia.

Clinical Features. Hemifacial atrophy is a syndrome with diverse presentation. The most common early sign is a painless cleft, the 'coup de sabre,' near the midline of the face or forehead. This marks the boundary between normal and atrophic tissue. A bluish hue may appear in the skin overlying atrophic fat.

The affected area extends progressively with the atrophy of the skin, subcutaneous tissue, muscles, bones, cartilages, alveolar bone and soft palate on that side of the face. In addition to facial wasting that may include the ipsilateral salivary glands and hemiatrophy of the tongue, unilateral involvement of the ear, larynx, esophagus, diaphragm, kidney and brain have been reported.

It starts in the first decade and lasts for about three years before it becomes quiescent. The final deformity varies widely, burning itself out in some patients with minimal atrophy, while in others progressing to marked atrophy.

Neurological disorders are found in 15% of patients, while ocular findings occur in 10–40%, the most common being enophthalmos.

Rarely, one half of the body may be affected. This condition may be accompanied by pigmentation disorders, vitiligo, pigmented facial nevi, contralateral Jacksonian epilepsy, contralateral trigeminal neuralgia and ocular complications.

The disease occurs more frequently in women; female to male ratio is 3 : 2. It has a slight predilection for the left side and appears in the first or second decades of life. It progresses over a period of two and 10 years, and atrophy appears to follow the distribution of one or more divisions of the trigeminal nerve. The resulting facial flattening may be mistaken for Bell's palsy (Fig. 1-6).

Figure 1-6. Facial hemiatrophy.

Oral Manifestations. Dental abnormalities include incomplete root formation, delayed eruption and severe facial asymmetry, resulting in facial deformation and difficulty with mastication. Hemiatrophy of the lips and the tongue is reported, as are dental effects. Foster has reported that growth of the teeth may be affected just as other tissues are involved. Eruption of teeth on the affected side may also be retarded.

Differential Diagnosis. Post-traumatic fat atrophy, hemifacial microsomia (first and second branchial arch syndrome), Goldenhar's syndrome, and partial lipodystrophy which is; however, always bilateral.

Treatment and Prognosis. There is no specific treatment for the condition. It has been found that, typically, the disease will be progressive for a period of several years and then remain unchanged for the remainder of the patient's life.

ABNORMALITIES OF DENTAL ARCH RELATIONS

In the preceding sections the conditions discussed are those in which there is an actual or apparent abnormal variation in size of one or both jaws. Of far greater importance than a simple disparity in size is the disparity in relation of one jaw to the other and the difficulties in occlusion and function that result.

A great many different types of malocclusion exist, and many classifications have been evolved in an attempt to unify methods of treatment. The classification of Angle, proposed in 1899, is the most universally known and used. That classification, with the approximate percentage occurrence as determined by Angle in a large group of orthodontic patients, is as follows:

Class I. Arches in normal mesiodistal relations 69.0%.

Class II. Mandibular arch distal to normal in its relation to the maxillary arch.
Division 1. Bilaterally distal, protruding maxillary incisors 9.0.
Subdivision. Unilaterally distal, protruding maxillary incisors 3.5.
Division 2. Bilaterally distal, retruding maxillary incisors 4.0.
Subdivision. Unilaterally distal, retruding maxillary incisors 10.0.

Class III. Mandibular arch mesial to normal in its relation to the maxillary arch.
Division. Bilaterally mesial 3.5.
Subdivision. Unilaterally mesial 1.0.

Since these abnormal jaw relations constitute a separate course of study, no further allusion to this subject will be made here.

DEVELOPMENTAL DISTURBANCES OF LIPS AND PALATE

Congenital Lip and Commissural Pits and Fistulas

Congenital lip pits and fistulas are malformations of the lips, often following a hereditary pattern, that may occur alone or in association with other developmental anomalies such as various oral clefts. Both Taylor and Lane and McConnel and his associates have emphasized that in 75–80% of all cases of congenital labial fistulas, there is an associated cleft lip or cleft palate, or both. The association of pits of the lower lip and cleft lip and/or cleft palate, termed van der Woude's syndrome, has been reviewed by Cervenka and his associates.

Commissural pits are an entity probably very closely related to lip pits, but occur at the lip commissures, lateral to the typical lip pits. Everett and Wescott have described this entity and noted that it is also frequently hereditary, possibly a dominant characteristic following a Mendelian pattern, and may be associated with other congenital defects.

Etiology. Many theories of the etiology of congenital lip pits have been offered, but none has been universally accepted. Pits may result from notching of the lip at an early stage of development, with fixation of the tissue at the base of the notch, or from failure of complete union of the embryonic lateral sulci of the lip, which persist and ultimately develop into the typical pits.

Commissural pits are also difficult to explain, but they occur at the site of the horizontal facial cleft and may represent defective development of this embryonic fissure.

Clinical Features. The lip pit or fistula is a unilateral or bilateral depression or pit that occurs on the vermilion surface of either lip but far more commonly on the lower lip (Fig. 1-7A). In some cases a sparse mucous secretion may exude from the base of this pit. The lip sometimes appears swollen, accentuating the appearance of the pits.

Commissural pits appear as unilateral or bilateral pits at the corners of the mouth on the vermilion surface (Fig. 1-7B). An actual fistula may be present from which fluid may be expressed. Whether this tract, either in lip or commissural fistulas, represents a true duct is not clear. Interestingly, in several cases preauricular pits have been reported in association with commissural pits.

A

B

Figure 1-7. (A) Congenital lip pits. (B) Congenital commissural pits.
(Courtesy of Dr Spencer Lilly, Meenakshi Ammal Dental College, Chennai).

Treatment. Surgical excision of these various pits has been recommended but primarily for academic information, since the pits are harmless and seldom manifest complications.

van der Woude Syndrome

(Cleft lip syndrome, lip pit syndrome, dimpled papillae of the lip)

van der Woude syndrome is an autosomal dominant syndrome typically consisting of a cleft lip or cleft palate and distinctive pits of the lower lips. The degree to which individuals carrying the gene are affected is widely variable, even within families. These variable manifestations include lip pits alone, missing teeth, or isolated cleft lip and palate of varying degrees of severity. Other associated anomalies have also been described.

Etiology. The most prominent and consistent feature of van der Woude syndrome is orofacial anomalies. They are due to an abnormal fusion of the palate and lips, at days 30–50 postconception. The van der Woude syndrome can be caused by deletions in chromosome band **1q32,** and linkage analysis has confirmed this chromosomal locus as the disease gene site. The gene has been localized to chromosome band **1q32**. Further studies have raised the possibility that the degree of phenotypic expression of a gene defect at this locus may be influenced by a second modifying gene that has been mapped to chromosome band **17p11**.

Clinical Features. In general, van der Woude syndrome affects about 1 in 100,000–200,000 people. About 1–2% of patients with cleft lip or palate have van der Woude syndrome. The van der Woude syndrome affects both genders equally and no difference among them have been reported. The severity of the van der Woude syndrome varies widely, even within families. About 25% of individuals with the van der Woude syndrome have no findings or minimal ones, such as missing teeth or trivial indentations in the lower lips. Others have severe clefting of the lip or palate. The hallmark of the van der Woude syndrome is the association of cleft lip and/or palate with distinctive lower lip pits. This combination is seen in about 70% of those who are overtly affected but in less than half of those who carry the gene. The cleft lip and palate may be isolated. They may take any degree of severity and may be unilateral or bilateral. Submucous cleft palate is common and may be easily missed on physical examination. Hypernasal voice and cleft or bifid uvula are clues to this diagnosis. It is possible as well that a bifid uvula is an isolated finding in certain individuals with the van der Woude syndrome. The lower lip pits seen in this syndrome are fairly distinctive (Fig. 1-8). The pits are usually medial, on the vermilion portion of the lower lip. They tend to be centered on small elevations in infancy, but are simple depressions in adults. These pits are often associated with accessory salivary glands that empty into the pits, sometimes leading to embarrassing visible discharge. Occasionally lip pits may be the only manifestation of the syndrome. Affected individuals may have maxillary hypodontia; missing maxillary incisors or missing premolars. Again, this may be the only manifestation of the syndrome. Although infrequently reported, other oral manifestations include syngnathia (congenital adhesion of the jaws); narrow, high, arched palate; and ankyloglossia (short glossal frenulum or tongue-tie).

Extraoral Manifestations. The reported incidence of extraoral manifestations are rare but include limb anomalies, popliteal webs, and brain abnormalities. Accessory nipples, congenital heart defects, and Hirschsprung disease have also been reported. It is uncertain whether these extraoral manifestations are unassociated additional anomalies or infrequently expressed aspects of van der Woude syndrome.

Treatment. Along with a thorough orofacial examination, a thorough general physical examination helps to determine if

Figure 1-8. Bilateral lip pits.

there are other associated anomalies of the cardiovascular system, genitourinary system, limbs, or other organ systems. Examination and genetic counseling by a pediatric geneticist (dysmorphologist) is suggested for families that may be affected by the van der Woude syndrome. This should include an examination of as many potentially affected family members (probands) as possible. Surgical repair of the cleft lip and palate or other anomalies may be required, when planning surgical intervention, imaging studies of affected areas, such as CT scanning of the oropharynx, may be appropriate. Even among those less severely affected, surgical excision of lip pits is often performed, either to alleviate discomfort or for cosmetic reasons (e.g. improving the appearance of lip pits or reducing mucous discharge).

Cleft Lip and Cleft Palate

The term cleft lip and palate is commonly used to represent two types of malformation, i.e., cleft lip with or without cleft palate (CL/P) and cleft palate (CP). Cleft lip and palate are common congenital malformations. The reported incidence of clefts of the lip and palate varies from 1 in 500 to 1 in 2500 live births depending on geographic origin, racial and ethnic background and socioeconomic status. In general, Asian population have the highest frequencies, often at 1 in 500 or higher, with Caucasian population intermediate, and African-derived population the lowest at 1 in 2500.

An understanding of the normal human maxillofacial development is necessary before a discussion of cleft lip and palate. During the fourth week of gestation, the maxillary processes emerge from the first branchial arch on each side and the nasal placodes form from the frontal prominence. By the fifth week, all the primordia for the lip and palate are present. The medial, lateral nasal and the frontonasal processes are formed from the nasal placodes and the maxillary processes continue to enlarge. During the seventh week the medial nasal, frontonasal and maxillary processes fuse to form the primary palate, which becomes the medial portion of the upper lip, alveolus and the anterior part of hard palate up to the incisive foramen. When the primary palate is completely formed, the maxillary processes enlarge intraorally to form the palatine processes. During the 8th week of gestation, the palatal shelves fill up the space on both sides of the tongue. During the 9th and 10th weeks, the mandibular arch enlarges and the tongue drops. The palatal shelves transpose horizontally and fuse with each other and with the anterior part of the palate. Palatal fusion occurs anteroposteriorly and the process is completed by the 11th to 12th weeks (Shapiro, 1976).

Failure in the fusion of the nasal and maxillary processes leads to the cleft of the primary palate, which can be unilateral or bilateral. The degree of cleft can vary from a slight notch on the lip to complete cleft of the primary palate. Cleft of the secondary palate is medial. It varies from bifid uvula to complete cleft palate up to the incisive foramen. When it is associated with the primary palate, a complete uni- or bilateral cleft lip and palate is formed.

Etiology. It has been clearly established by Fogh-Andersen and confirmed by numerous other investigators that two separate and distinct entities exist:

- Cleft lip with or without associated cleft palate, and
- Isolated cleft palate.

Heredity is undoubtedly one of the most important factors to be considered in the etiology of these malformations. However, there is increasing evidence that environmental factors are important as well. According to Fogh-Andersen, slightly less than 40% of the cases of cleft lip with or without cleft palate are genetic in origin, whereas slightly less than 20% of the cases of isolated cleft palate appear to be genetically derived. Most investigations indicate that the inheritance pattern in cleft lip with or without cleft palate is different from that in isolated cleft palate. The mode of transmission of the defect is uncertain. This has been discussed by Bhatia, who pointed out that the possible main modes of transmission are either by a single mutant gene, producing a large effect, or by a number of genes (polygenic inheritance), each producing a small effect which together create this condition. It should be pointed out that cytogenetic studies have failed to reveal visible alterations in chromosomal morphology of the affected individuals.

Bixler more recently has expanded upon this concept and reiterated that there are two forms of clefts. The most common is hereditary, its nature being most probably *polygenic* (determined by several different genes acting together). In other words, when the total genetic liability of an individual reaches a certain minimum level, the threshold for expression is reached and a cleft occurs. Actually, it is presumed that every individual carries some genetic liability for clefting, but if this is less than the threshold level, there is no cleft. When the individual liabilities of two parents are added together in their offspring, a cleft occurs if the threshold value is exceeded. However, even though this is the most common form of cleft, the threshold value is sufficiently high that it is a low-risk type. The second form of cleft is **monogenic** or **syndromic** and is associated with a variety of other congenital anomalies. Since these are monogenic, they are of a high-risk type. Bixler has pointed out that, fortunately, the clefting syndromes are rare and probably make up only 5% of all cleft cases even though, according to Cohen, there are now over 300 clefting syndromes reported in the literature.

Although there is insufficient evidence that nutritional disturbances cause cleft palates in human beings, abnormal dietary regimens have caused developmental clefts in animals. Cleft palate has been experimentally produced in newborn rats by feeding diets either deficient or excessive in vitamin A to maternal rats during pregnancy. Riboflavin-deficient diets fed to pregnant rats have also produced offspring with a high incidence of cleft palate. The administration of cortisone to pregnant rabbits has induced similar clefts in their young.

Strean and Peer reported that physiologic, emotional, or traumatic stress may play a significant role in the etiology of human cleft palate, since stress induces increased function of the adrenal cortex and secretion of hydrocortisone. Their study,

based on histories of 228 mothers of children with cleft palate, confirms the experimental findings of cleft palate in animals due to the action of stressor agents or the administration of cortisone. However, Fraser and Warburton have reported data which indicate that neither maternal emotional stress nor the lack of a prenatal nutritional supplement was causally related to the occurrence of cleft lip or cleft palate.

Other factors that have been suggested as possible causes of cleft palate include:

- A defective vascular supply to the area involved
- A mechanical disturbance in which the size of the tongue may prevent the union of parts
- Circulating substances, such as alcohol and certain drugs and toxins
- Infections
- Lack of inherent developmental force.

Despite the numerous clinical and experimental investigations, the etiology of cleft palate in the human being is still largely unknown. It must be concluded; however, that heredity is probably the most important single factor.

Clinical Features. Cleft lip with or without palate is more common in males than in females. Males have also been reported to have more severe defects, whereas the isolated cleft palate is more common in females.

Clefts can be divided into nonsyndromic and syndromic forms. Syndromic forms of clefts include those cases that have additional birth defects like lip pits or other malformations, whereas nonsyndromic clefts are those cases wherein the affected individual has no other physical or developmental anomalies and no recognized maternal environmental exposures. At present, most studies suggest that about 70% of cases of cleft lip with or without palate and 50% of isolated cleft palate are nonsyndromic. The remaining syndromic cases can be subdivided into chromosomal anomalies, teratogens and uncategorized syndromes.

Cleft lip can occur as a unilateral (on the left or right side) or as a bilateral anomaly. The line of cleft always starts on the lateral part of the upper lip and continues through the philtrum to the alveolus between the lateral incisor and the canine tooth. The clefting anterior to the incisive foramen (i.e. lip and alveolus) is also defined as a cleft of primary palate. Cleft lip may occur with a wide range of severity, from a notch located on the left or right side of the lip to the most severe form, bilateral cleft lip and alveolus that separates the philtrum of the upper lip and premaxilla from the rest of the maxillary arch. When cleft lip continues from the incisive foramen further through the palatal suture in the middle of the palate, a cleft lip with palate (either unilateral or bilateral) is present (Figs. 1-9, 1-10). A wide range of severity may be observed. The cleft line may be interrupted by skin or mucosa bridges, hard (bone) bridges, or both, corresponding to a diagnosis of an **incomplete cleft**. This occurs in unilateral and bilateral CLP.

Isolated cleft palate is etiologically and embryologically different from cleft lip with or without cleft palate. Several subtypes of isolated cleft palate can be diagnosed based on severity. The uvula is the place where the minimal form of clefting of the palate is observed (Fig. 1-11). A more severe form is a cleft of the soft palate. A complete cleft palate constitutes a cleft of the hard palate, soft palate, and cleft uvula. The clefting posterior to the incisive foramen is defined as a cleft of secondary palate.

Classification of CLP

Various classification schemes have been devised in the last 70 years, but few have received widespread clinical acceptance. Four of the more accepted schemes are depicted:

Davis and Ritchie classification. Each of the following subgroups is further subdivided into the extent of the cleft (1/3, 1/2, etc.):

- Group I: Clefts anterior to the alveolus (unilateral, median, or bilateral CL)
- Group II: Postalveolar clefts (CP alone, soft palate alone, soft palate and hard palate, or submucous cleft).

Veau classification. The Veau classification system is illustrated in:

- Group I (A): Defects of the soft palate only
- Group II (B): Defects involving the hard palate and soft palate
- Group III (C): Defects involving the soft palate to the alveolus, usually involving the lip
- Group IV (D): Complete bilateral clefts.

Kernahan and Stark symbolic classification. This classification highlights the anatomic and embryonic importance of the incisive foramen formed during weeks 4–7 GA. The secondary palate forms the roof of the mouth from the incisive foramen to the uvula during weeks 7–12 GA.

This system provides a graphic classification scheme using a Y-configuration, which can be divided into 9 areas:

- Areas 1 and 4: Lip
- Areas 2 and 5: Alveolus
- Areas 3 and 6: Palate between the alveolus and the incisive foramen
- Areas 7 and 8: Hard palate
- Area 9: Soft palate.

International confederation of plastic and reconstructive surgery classification. This system uses an embryonic framework to divide clefts into 4 groups, with further subdivisions to denote unilateral or bilateral cases.

- Group I: Defects of the lip or alveolus
- Group II: Clefts of the secondary palate (hard palate, soft palate, or both)
- Group III: Any combination of clefts involving the primary and secondary palates.

A **median maxillary anterior alveolar cleft** is a relatively common defect, occurring in approximately 1% of the population, according to Stout and Collett, but this is unrelated to cleft lip or cleft palate. This type of cleft has been discussed by Gier and Fast, who suggested that it might be due to precocious limitation of the growth of the primary ossification centers on either side of the midline at the primary palate, or to their subsequent failure to fuse. In addition, Miller and his coworkers have suggested that at least some cases may represent an incomplete manifestation of the median cleft-face syndrome (hypertelorism, median cleft of the premaxilla and palate, and cranium bifidum occultum). This syndrome has no clinical manifestations and is usually detected only on routine intraoral radiographic examination (Fig. 1-12).

Clinical Significance. Most cases of cleft lip can be surgically repaired with excellent cosmetic and functional results. It is customary to operate before the patient is one month old or when he has regained his original birth weight and is still gaining.

Both the physical and psychologic effects of cleft palate on the patient are of considerable concern. Eating and drinking are difficult because of regurgitation of food and liquid through the nose. The speech problem is also serious and tends to increase the mental trauma suffered by the patient.

Most individuals with CL, CP, or both, require the coordinated care of providers in many fields of medicine and dentistry, as well as those in speech pathology, otolaryngology, audiology, genetics, nursing, mental health, and social medicine.

Treatment. Treatment of CLP anomalies requires years of specialized care. Although successful treatment of the cosmetic and functional aspects of orofacial cleft anomalies is now

Figure 1-12. Median maxillary anterior alveolar cleft.
All degrees of severity of the cleft may occur *(Copyright by the American Dental Association. Reprinted by permission and by courtesy of Dr Arthur S Miller. From AS Miller, JN Greeley and DL Catena: Median maxillary anterior alveolar cleft: report of three cases. J Am Dent Assoc, 79: 896, 1969).*

possible, it is still challenging, lengthy, costly, and dependent on the skills and experience of a medical team. This especially applies to surgical, dental, and speech therapies. Undoubtedly, closure of the CL is the first major procedure that tremendously changes children's future development and ability to thrive. Variations occur in timing of the first lip surgery; however, the most usual time occurs at approximately three months of age. Pediatricians used to strictly follow a rule of 'three 10s' as a necessary requirement for identifying the child's status as suitable for surgery (i.e. 10 lb, 10 mg/L of hemoglobin, and age 10 weeks). Although pediatricians are presently much more flexible, and some surgeons may well justify a neonatal lip closure, the rule of three 10s is still very useful.

Anatomical differences predispose children with CLP and with isolated CP to ear infections. Therefore, ventilation tubes are placed to ventilate the middle ear and prevent hearing loss secondary to otitis media with effusion (OME). In multidisciplinary teams with significant participation of an otolaryngologist, the tubes are placed at the initial surgery and at the second surgery routinely. The hearing is tested after the first placement when ears are clear with tubes. If no cleft surgery is planned early, placing the tubes by age six months and monitoring hearing with repeated testing is recommended. Complications include eardrum perforation and otorrhea, particularly in patients with open secondary palates in which closure is planned for a later date.

Cheilitis Glandularis

(Actinic cheilitis, squamous cell carcinoma)

Cheilitis glandularis (CG) is a clinical diagnosis that refers to an uncommon and poorly understood inflammatory disorder of the lip. The condition is characterized by progressive enlargement and eversion of the lower labial mucosa that results in obliteration of the mucosal-vermilion interface. With externalization and chronic exposure, the delicate labial mucous membrane is secondarily altered by environmental influences, leading to erosion, ulceration, and crusting. Most significantly, susceptibility to actinic damage is increased. Therefore, CG can be considered a potential predisposing factor for the development of actinic cheilitis and squamous cell carcinoma.

Etiology. CG is an unusual clinical manifestation of cheilitis that evolves in response to one or more diverse sources of chronic irritation. Lip enlargement is attributable to inflammation, hyperemia, edema, and fibrosis. Surface keratosis, erosion, and crusting develop consequent to long-standing actinic exposure, unusual repeated manipulations that include self-inflicted biting or other factitial trauma, excessive wetting from compulsive licking, drying (sometimes associated with mouth-breathing, atopy, eczema, and asthma), and any other repeated stimulus that could serve as a chronic aggravating factor.

Clinical Features. In 1870, von Volkman introduced the term cheilitis glandularis. He described a clinically distinct, deeply suppurative, chronic inflammatory condition of the lower lip characterized by mucopurulent exudates from the ductal orifices of the labial minor salivary glands. In 1914, Sutton proposed that the characteristic lip swelling was attributable to a congenital adenomatous enlargement of the labial salivary glands. This remained the prevailing hypothesis until 1984 when Swerlick and Cooper reported five new cases and a retrospective analysis of all cases of CG reported until that time. Their studies revealed no evidence to support the assertion that salivary gland hyperplasia is responsible for CG.

Cheilitis glandularis is a chronic progressive condition. Patients typically present for diagnostic consultation within 3–12 months of onset. Complaints vary according to the nature and the degree of pain, the enlargement and the loss of elasticity of the lip, and the extent of evident surface change. Asymptomatic lip swelling initially occurs with clear viscous secretion expressible from dilated ductal openings on the mucosal surface. Some patients report periods of relative quiescence interrupted by transient or persistent painful episodes associated with suppurative discharge. A burning discomfort or a sensation of rawness referable to the vermilion border may be reported. This is associated with atrophy, speckled leukoplakic change, erosion, or frank ulceration with crusting. CG affects the lower lip almost exclusively. In more suppurative cases, application of gentle pressure can elicit mucopurulent exudate. Prolonged exposure to the external environment results in desiccation and disruption of the labial mucous membrane, predisposing it to inflammatory, infectious, and actinic influences. This is an uncommon condition. CG has been associated with a heightened risk for the development of squamous cell carcinoma. In many cases, dysplastic (premalignant) surface epithelial change is evident, and frank carcinomas have been reported in 18–35% of cases. The disorder appears to favor adult males; however, cases have been reported in both genders. The condition most frequently occurs between the fourth and seventh decades of life; however, the age range is wide. The risk of dysplasia and carcinoma increases with age, especially in fair-skinned individuals with sun-damaged skin. This is because the characteristic eversion of the lower lip results in long-term chronic exposure of the thinner, more vulnerable labial mucosa to actinic influence.

Classification. CG had historically been subclassified into three types, now believed to represent evolving stages in the severity of a single progressive disorder.

- In the **simple type,** multiple, painless, papular surface lesions with central depressions and dilated canals are seen.
- The **superficial (suppurative) type** (also referred to as **Baelz disease**) consists of painless, indurated swelling of the lip with shallow ulceration and crusting.
- CG of the **deep suppurative type** (CG apostematosa, CG suppurativa profunda, myxadenitis labialis) comprises a deep-seated infection with formation of abscesses, sinus tracts and fistulas, and potential for scarring.

The latter two types of CG have the highest association with dysplasia and carcinoma, respectively.

Histologic Findings. Lip biopsy is indicated to rule out specific granulomatous diseases that predispose to lip enlargement and aid in establishing a definitive diagnosis. A

representative incisional biopsy specimen should consist of a wedge (or punch) of lip tissue that includes surface epithelium and is of adequate depth to ensure inclusion of several submucosal salivary glands. The term cheilitis glandularis is a provisional descriptive designation rather than a definitive diagnosis. It refers to a constellation of clinical findings that can reflect a broad scope of possible histologic changes; therefore, no consistent or pathognomonic features of this disorder are seen at the microscopic level. Instead, a diverse array of possible alterations can be seen in both the surface epithelium and the submucosal tissues. These findings best enable the clinician to presumptively determine the etiology and the nature of individual cases.

The minor salivary glands may appear normal under the microscope, or they may exhibit various changes indicative of nonspecific sialadenitis. These changes can include atrophy or distention of acini, ductal ectasia with or without squamous metaplasia, chronic inflammatory infiltration and replacement of glandular parenchyma, and interstitial fibrosis. Suppuration and sinus tracts may be present in cases that involve bacterial infection. Other possible histologic findings include stromal edema, hyperemia, surface hyperkeratosis, erosion, or ulceration.

Differential Diagnosis. Differential diagnoses of this condition include actinic keratosis, atopic dermatitis, cheilitis granulomatosa (Miescher-Melkersson-Rosenthal syndrome), sarcoidosis and squamous cell carcinoma.

Treatment. The approach to treatment is based on diagnostic information obtained from histopathologic analysis, the identification of likely etiologic factors responsible for the condition, and attempts to alleviate or eradicate those causes. In cases with acute or chronic suppuration, bacterial culture and sensitivity testing is indicated for selection of appropriate antibiotic therapy. Given the relatively small number of reported cases of CG, neither sufficient nor reliable data exist with regard to medical approaches to the condition. Therefore, treatment varies accordingly for each patient. In cases where a history of chronic sun exposure exists (especially if the patient is fair skinned or the everted lip surface is chronically eroded, ulcerated, or crusted), biopsy is strongly recommended to rule out actinic cheilitis or carcinoma.

Cheilitis Granulomatosa
(Miescher-Melkersson-Rosenthal syndrome)

Cheilitis granulomatosa is a chronic swelling of the lip due to granulomatous inflammation. Miescher cheilitis is the term used when the granulomatous changes are confined to the lip. Miescher cheilitis is generally regarded as a monosymptomatic form of the Melkersson-Rosenthal syndrome, although the possibility remains that these may be two separate diseases. Melkersson-Rosenthal syndrome is the term used when cheilitis occurs with facial palsy and plicated tongue. Melkersson-Rosenthal syndrome is occasionally a manifestation of Crohn's disease or orofacial granulomatosis.

Figure 1-13. Cheilitis granulomatosa.

Etiology. The cause is unknown. A genetic predisposition may exist in Melkersson-Rosenthal syndrome; siblings have been affected, and a plicated tongue may be present in otherwise unaffected relatives. Crohn's disease, sarcoidosis, and orofacial granulomatosis may present in a similar clinical fashion, and with identical histologic findings. Dietary or other antigens are the most common identified causes of orofacial granulomatosis. Contact antigens are sometimes implicated.

Clinical Features. Cheilitis granulomatosa is episodic with nontender swelling and enlargement of one or both lips (Fig. 1-13). Occasionally, similar swellings involve other areas, including the periocular region. The first episode of edema typically subsides completely in hours or days. After recurrent attacks, swelling may persist and slowly increase in degree, eventually becoming permanent. Recurrences can range from days to years. Attacks sometimes are accompanied by fever and mild constitutional symptoms (e.g. headache, visual disturbance).

The earliest manifestation is sudden diffuse or occasionally nodular swellings of the lip or the face involving (in decreasing order of frequency) the upper lip, the lower lip, and one or both cheeks. The forehead, the eyelids, or one side of the scalp may be involved (less common). The upper lip is involved slightly more often than the lower lip, and it may feel soft, firm, or nodular on palpation. Once chronicity is established, the enlarged lip appears cracked and fissured with reddish brown discoloration and scaling. The fissured lip becomes painful and eventually acquires the consistency of firm rubber. Swelling may regress very slowly after some years. Regional lymph nodes are enlarged (usually minimally) in 50% of patients. A fissured or plicated tongue is seen in 20–40% of patients. Its presence from birth (in some patients) may indicate a genetic susceptibility. Patients may lose the sense of taste and have decreased salivary gland secretion. Facial palsy of the lower motor-neuron type occurs in about 30% of patients. Facial palsy may precede attacks of edema by months or years, but it more commonly develops later. Facial palsy is intermittent at first, but it may become permanent. It can be unilateral or bilateral, partial or complete. Other cranial nerves

(e.g. olfactory, auditory, glossopharyngeal, hypoglossal) are occasionally affected. Poorly defined association of psychiatric and neurologic features are reported. Autonomic disturbances may occur. In granulomatous cheilitis, normal lip architecture is eventually altered by the presence of lymphedema and noncaseating granulomas in the lamina propria. The frequency is unknown; the condition is rare. Morbidity depends on whether underlying organic disease, such as Crohn's disease or sarcoidosis, is present. There is no racial and sexual predilection. The age of onset is usually young adulthood.

Differential Diagnosis. Differential diagnoses include insect bites and sarcoidosis. Serum angiotensin-converting enzyme test, chest radiography or gallium or positron emission tomography (PET) scanning may be performed to help exclude sarcoidosis. Gastrointestinal tract endoscopy and radiography may be used to help exclude Crohn's disease.

Histologic Features. The histologic features of cheilitis granulomatosa and the swellings of the syndrome are rather characteristic, consisting of a chronic inflammatory cell infiltrate — particularly peri- and para-vascular aggregations of lymphocytes, plasma cells, and histiocytes—and focal noncaseating granuloma formation with epithelioid cells and Langhans type giant cells. The microscopic findings are suggestive of sarcoidosis, but as yet there is insufficient evidence to relate cheilitis granulomatosa with sarcoid.

Treatment. Patch tests may be used to help exclude reactions to metals, food additives, or other oral antigens. Some cases may be associated with such sensitivities. If found, avoidance of the implicated allergen is recommended. This condition can be conservatively managed by intralesional corticosteroid injections, nonsteroidal anti-inflammatory agents, mast cell stabilizers, clofazimine and tetracycline (used for anti-inflammatory activity). Surgery and radiation have been reported to be used.

HEREDITARY INTESTINAL POLYPOSIS SYNDROME

(Peutz-Jeghers syndrome, intestinal hamartomatous polyps in association with mucocutaneous melanocytic macules)

The Peutz-Jeghers syndrome is an autosomal dominantly inherited disorder characterized by intestinal hamartomatous polyps in association with mucocutaneous melanocytic macules. A 15-fold elevated relative risk of developing cancer exists in this syndrome over that of the general population; cancer primarily is of the GI tract, including the pancreas and luminal organs, and of the female and male reproductive tracts and the lung. The syndrome was named after Peutz, who noted a relationship between the intestinal polyps and the mucocutaneous macules in 1921, and after Jeghers, who is credited with the definitive descriptive reports in 1944 and later in 1949.

Etiology. The cause of the Peutz-Jeghers syndrome appears to be a germline mutation of the **STK11** (serine threonine kinase 11) gene in most cases, located on band **19p13.3**. Penetrance of the gene is variable, causing varied phenotypic manifestations among patients with Peutz-Jeghers syndrome (e.g. inconsistent number of polyps, differing presentation of the macules) and allowing for a variable presentation of cancer. Because the signaling pathway of the *STK11* gene product currently is not identified, the mechanism of hamartomatous polyp formation and mucocutaneous pigmentation is not known. In cancer formation, *STK11* inactivation appears to occur early and might be followed by interruption of the APC/β-catenin and p53 pathways, but this has not been fully elucidated. *STK11* may be a tumor suppressor gene in that its overexpression can induce a growth arrest of a cell at the G1 phase of the cell cycle and that somatic inactivation of the unaffected allele of *STK11* often is observed in polyps and cancers from patients with the Peutz-Jeghers syndrome.

Clinical Features. The Peutz-Jeghers syndrome has been described in all races. The occurrence of cases in males and females is about equal. The average age at diagnosis is 23 years in men and 26 years in women. The affected individuals usually have a positive family history of the Peutz-Jeghers syndrome. The principal causes of morbidity stem from the intestinal location of the polyps (i.e. small intestine, colon, stomach). Morbidity includes small intestinal obstruction and intussusception (43%), abdominal pain (23%), hematochezia (14%), and prolapse of a colonic polyp (7%), and these typically occur in the second and third decades of life.

The presenting complaints include repeated bouts of abdominal pain in patients younger than 25 years, unexplained intestinal bleeding in a young patient, or menstrual irregularities in females (due to hyperestrogenism from sex cord tumors with annular tubules). Cutaneous pigmentation (1–5 mm macules) of the perioral region crossing the vermilion border (94%), perinasal, and perioral areas is seen; pigmentation may also be present on the fingers and toes, on the dorsal and ventral aspects of the hands and feet, and around the anus and genitalia. This pigmentation may fade after puberty. Mucous membrane pigmentation primarily affects the buccal mucosa (66%) and the intestinal mucosa rarely. Other manifestations of this syndrome include precocious puberty, prolapse of tissue from the rectum, rectal mass (rectal polyp), testicular mass, gynecomastia and growth acceleration (due to Sertoli cell tumor).

Histologic Features. Characteristic pathology of Peutz-Jeghers polyps includes extensive smooth muscle arborization throughout the polyp, with the appearance of pseudoinvasion because some of the epithelial cells, usually from benign glands, are surrounded by the smooth muscle.

Treatment. Surgical treatment for cancers detected by surveillance has been recommended.

Labial and Oral Melanotic Macule

The oral mucosa is usually not pigmented despite the fact that it has the same density of melanocytes as the skin. Occasional patients; however, will show a focal area of melanin

deposition, either as a response to local chronic conditions (mechanical trauma, tobacco smoking, chronic autoimmune mucositis), racial background (the darker a person's skin color the more likely they are to have oral pigmentation), or systemic medications, especially chloroquine. Moreover, certain syndromes and systemic diseases have oral pigmentation as part of their spectrum.

Most focal melanin deposits of the oral mucosa which are not associated with race or an appropriate syndrome are innocuous surface discolorations called oral melanotic macule (focal melanosis). This entity represents not only a focal increase in melanin deposition but a concomitant increase in the number of melanocytes. Unlike the cutaneous ephelis (freckle), the oral melanotic macule is neither dependent on sun exposure, nor does it show the elongated rete ridges of actinic lentigo. Some authorities have questioned the purported lack of an association with actinic irradiation for melanotic macule located on the vermilion border, preferring to consider the lesion at this site to be a distinct entity called labial melanotic macule. Melanotic macules are found in the mouths of 1 of every 1,000 adults.

Clinical Features. The oral melanotic macule has a 2:1 female predilection with an average age of 43 years at the time of diagnosis, although it can develop at any age. One-third of lesions occur on the vermilion border of the lower lip, but the buccal mucosa, gingiva and palate are other sites of common occurrence. Almost one fifth of the lesions are multiple.

The typical macule is a well-demarcated, uniformly tan to dark brown, asymptomatic, round or oval discoloration less than 7 mm in diameter. The lesion is not thickened and has the same consistency as surrounding mucosa. It tends to have an abrupt onset and seldom enlarges after diagnosis.

A special case of oral melanosis, called **smoker's melanosis** is found on the gingival or buccal mucosa in heavy smokers. It has an adult onset and is often associated with a concomitant superficial white/gray keratosis. The keratosis may become thick enough to mimic *leukoplakia,* although it is not known whether or not it is a true precancer. Both the pigmentation and the keratosis diminish or disappear once the tobacco habit is stopped.

While the melanotic macule is an innocuous lesion, it must be remembered that focal oral and oropharyngeal pigmentation might represent an internal malignancy (usually lung), an oral manifestation of a systemic disease or one facet of a genetic syndrome.

Histologic Features. The oral melanotic macule is characterized by an otherwise normal stratified squamous epithelium with abundant melanin deposits within the keratinocytes of the basal and parabasal layers. Deposits may also be seen within subepithelial stroma (melanin incontinence), perhaps within macrophages or melanophages. There is no underlying inflammatory response. The melanin can be distinguished from iron deposits with melanin stains or by the loss of brown color after bleaching. Brown formalin deposits can be differentiated by their association with erythrocytes rather than with basal layer epithelial cells.

Treatment and Prognosis. No treatment is required for oral melanotic macule except for esthetic considerations. The intraoral melanotic macule has no malignant transformation potential, but an early melanoma could have a similar clinical appearance. For this reason, pigmented macular lesions of recent onset, large size, irregular pigmentation, unknown duration, or with a history of recent enlargement should be excised and examined histopathologically.

DEVELOPMENTAL DISTURBANCES OF ORAL MUCOSA

Fordyce's Granules
(Fordyce's disease)

This is not a disease of the oral mucosa, as the name might indicate, but rather a developmental anomaly characterized by heterotopic collections of sebaceous glands at various sites in the oral cavity. It has been postulated that the occurrence of sebaceous glands in the mouth may result from inclusion in the oral cavity of ectoderm having some of the potentialities of skin in the course of development of the maxillary and mandibular processes during embryonic life. A complete review of Fordyce's granules was published by Miles, and a superb investigation of the sebaceous glands of the lips and oral cavity was carried out by Sewerin.

Clinical Features. Fordyce's granules appear as small yellow spots, either discretely separated or forming relatively large plaques, often projecting slightly above the surface of the tissue (Fig. 1-14). They are found most frequently in a bilaterally symmetrical pattern on the mucosa of the cheeks opposite the molar teeth but also occur on the inner surfaces of the lips, in the retromolar region lateral to the anterior faucial pillar, and occasionally on the tongue, gingiva, frenum, and palate. Ectopic sebaceous glands have been discussed in an excellent review by Guiducci and Hyman and are recognized to occur,

Figure 1-14. Fordyce's granules.

Figure 1-15. Fordyce's granules.
Heterotopic collections of sebaceous glands.

besides in the oral cavity, in the esophagus, the female genitalia including the cervix uteri, the male genitalia, the nipples, the palms and soles, the parotid gland, the larynx, and the orbit.

Studies by Halperin and coworkers, confirmed by Miles, have indicated that the oral condition is present in approximately 80% of the population, with apparently no significant differences in occurrence between the genders or races. Fewer children than adults exhibit Fordyce's granules, probably because the sebaceous glands and hair system do not reach maximal development until puberty. Nevertheless, Miles has reported that large numbers of sebaceous glands in the cheeks and lips may sometimes be found in children long before the age of puberty. Because of the high incidence of these glands in the oral cavity, Knapp has suggested that they be regarded as sebaceous nevi rather than ectopic glandular tissue.

Histologic Features. These heterotopic collections of sebaceous glands are identical with those seen normally in the skin, but are unassociated with hair follicles, although a single hair follicle and hair shaft growing from the gingiva—an extremely rare occurrence—has been reported recently by Baughman (Fig. 1-15). The glands are usually superficial and may consist of only a few or a great many lobules, all grouped around one or more ducts which open on the surface of the mucosa. These ducts may show keratin plugging.

Treatment. These glands are innocuous, have no clinical or functional significance, and require no treatment. However, very rarely a benign sebaceous gland adenoma may develop from these intraoral structures, such as in the case involving the buccal mucosa reported by Miller and McCrea. Sewerin has also reported the occasional development of keratin-filled pseudocysts from the ducts of these sebaceous glands.

Focal Epithelial Hyperplasia
(Heck's disease)

One of the most contagious of the oral papillary lesions is focal epithelial hyperplasia or Heck's disease, another HPV-induced epithelial proliferation first described in 1965 in Native Americans. The level of contagion is exemplified by the fact that in some isolated population up to 40% of children have been affected. Today, it is known to exist in numerous populations and ethnic groups and to be produced by one of the subtypes of the human papillomavirus, HPV-13, and possibly HPV-32. Where the infection is endemic among children, adults seem to have minimal evidence of residual oral lesions and so the lesions are presumed to eventually disappear on their own.

Focal epithelial hyperplasia is somewhat different from other HPV infections in that it is able to produce extreme acanthosis or hyperplasia of the prickle cell layer of the epithelium with minimal production of surface projections or induction of connective tissue proliferation. The mucosa may be 8–10 times thicker than normal.

Clinical Features. Heck's disease primarily occurs in children, but lesions may occur in young and middle-aged adults. There is no gender predilection. Sites of greatest involvement include the labial, buccal and lingual mucosa, but gingival and tonsillar lesions have also been reported.

Individual lesions are broad-based or so slightly elevated as to present as well demarcated plaques. Lesions are frequently papillary in nature, but relatively smooth-surfaced, flat-topped lesions are more commonly seen. Papules and plaques are usually the color of normal mucosa, but may be pale or, rarely, white. Hyperplastic lesions are small (0.3–1.0 cm), discrete, and well-demarcated, but they frequently cluster so closely together that the entire mucosal area takes on a **cobblestone** or **fissured appearance.**

Histologic Features. Epithelial hyperplasia in this disease presents microscopically as an abrupt and sometimes considerable focal acanthosis of the oral epithelium. The thickened mucosa extends upward, not down into underlying connective tissues, hence the lesional rete ridges are at the same depth as the adjacent normal rete ridges. The ridges themselves are widened, often confluent and sometimes club-shaped; they are not long and thin as in *psoriasis* and other diseases. Some superficial keratinocytes show a koilocytic change similar to that seen in other HPV infections, while occasionally others demonstrate a collapsed nucleus which resembles a mitotic figure (mitosoid cell). These presumably result from viral alteration of the cells. Virus-like particles have been noted ultrastructurally within both cytoplasm and nuclei of cells within the spinous layer, and this layer is positive for HPV antigen with *in situ* hybridization.

The lesion is usually easily differentiated from squamous papilloma, verruca vulgaris and condyloma by its lack of pronounced surface projections; the presence of mitosoid cells, and the lack of connective tissue cores in the surface projections, when present. The sessile nature of focal epithelial hyperplasia also serves to separate it from the former two lesions, although this is not a guaranteed distinction.

Focal epithelial hyperplasia also tends to lack the pronounced elongation of thin rete ridges seen in keratoacanthoma and pseudoepitheliomatous hyperplasia, and it lacks the central keratin-filled core of the keratoacanthoma. It also lacks the subepithelial foamy or granular histiocyte-like cells required for the diagnosis of verruciform xanthoma.

Treatment and Prognosis. Conservative excisional biopsy may be required to establish the proper diagnosis, but additional treatment is unnecessary, except perhaps for esthetic reasons relating to visible labial lesions. Spontaneous regression has been reported after months or years, and the disease is rather rare in adults. No case of focal epithelial hyperplasia has been reported to transform into carcinoma. It should be remembered that focal epithelial hyperplasia may be an oral manifestation of AIDS.

DEVELOPMENTAL DISTURBANCES OF GINGIVA

Hereditary gingival fibromatosis is a benign, idiopathic condition affecting both arches. It affects males and females equally and is usually autosomal dominant. The gingiva are markedly enlarged, asymptomatic, nonhemorrhagic, nonexudative. It may be an isolated finding or associated with other syndromes (see below). A relationship with growth hormone deficiency has been suggested. The condition is either of a nodular form or, more commonly, a symmetric form. Onset of the condition usually begins with eruption of the permanent teeth. This condition predisposes one to malpositioning of the teeth, retention of deciduous teeth, esthetic and functional problems. Treatment is gingivectomy in one or several appointments. Recurrence is possible after some years.

Fibromatosis Gingivae

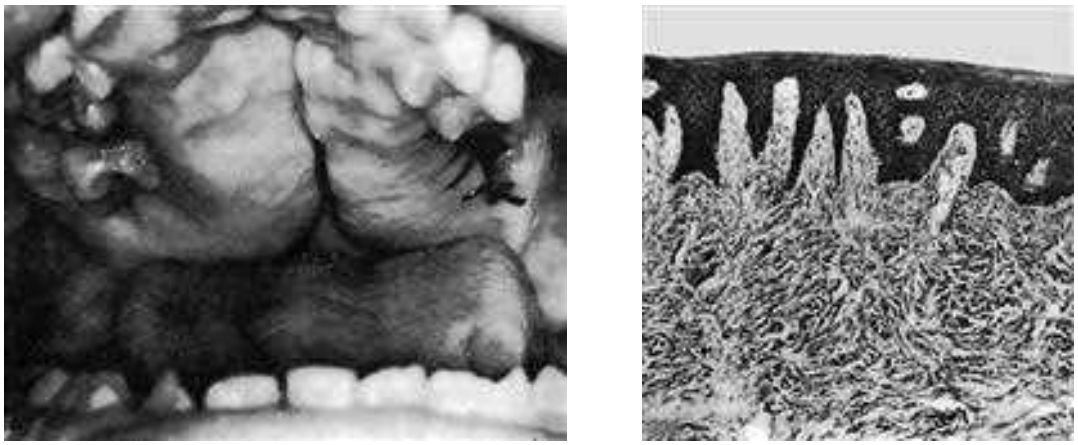
(Elephantiasis gingivae, hereditary gingival fibromatosis, congenital macrogingivae)

Fibromatosis gingivae is a diffuse fibrous overgrowth of the gingival tissues, described for many years under a variety of terms. In the majority of reported cases, the condition was hereditary, being transmitted through a dominant autosomal gene. Zackin and Weisberger have reviewed this condition and presented a family of 11 affected children and 10 normal children from six marriages over four generations, while Emerson has reported the pedigree of a family over four generations in which nine marriages between affected and unaffected persons resulted in seven affected and all 11 normal offsprings. But many cases have appeared to be sporadic, with no familial background. Occasionally other abnormalities have been reported in association with fibromatosis gingivae, but of these, only hypertrichosis has been noted more than a few times. Even this association, in terms of total number of reported cases, is rare.

Clinical Features. This condition is manifested as a dense, diffuse, smooth, or nodular overgrowth of the gingival tissues of one or both arches, usually appearing about the time of eruption of the permanent incisors. It has been reported; however, in even very young children and, in a few instances, at birth (Fig. 1-16A). The tissue is usually not inflamed, but is of normal or even pale color, and it is often so firm and dense that it may prevent the normal eruption of teeth. It is not painful and shows no tendency for hemorrhage. The extent of the tissue overgrowth may be such that the crowns of the teeth are nearly hidden even though they are fully erupted with respect to the alveolar bone (Fig. 1-17).

Histologic Features. The microscopic picture of the tissue in fibromatosis gingivae is similar to that of any fibrous hyperplasia. The epithelium may be somewhat thickened with elongated rete pegs, although the bulk of the tissue is composed of dense fibrous connective tissue. The bundles of collagen fibers are coarse and show few interspersed fibroblasts or blood vessels. Inflammation is an unrelated and variable finding (Fig. 1-16B).

Treatment and Prognosis. When tooth eruption is impeded, surgical removal of the excessive tissue and exposure of the teeth are indicated. The cosmetic appearance may also require surgical excision. The lesion sometimes recurs. It has been reported that tooth extraction alone will cause the tissues to shrink almost to normal and that recurrences can be prevented by this means.



A B

Figure 1-16. Fibromatosis gingivae.
(A) The palatal vault is nearly filled with a dense fibrous mass of tissue. The apparent midline cleft extends only to the bone and is not a true cleft. The maxillary gingiva is also involved. **(B)** The photomicrograph reveals that the mass is made up only of a dense mass of fibrous connective tissue covered by normal epithelium.

Figure 1-17. Fibromatosis gingivae.
The firm fibrous tissue mass has covered all but the incisal edges and the tips of the cusps of the maxillary teeth.

Figure 1-18. Congenital short lingual frenum of the tongue with microglossia.

Retrocuspid Papilla

The retrocuspid papilla, first described by Hirshfeld in 1933 but not reported until 1957, is a small, elevated nodule located on the lingual mucosa of the mandibular cuspids.

Clinical Features. This soft, well-circumscribed, sessile, mucosal nodule, commonly bilateral, is located lingual to the mandibular cuspid, between the free gingival margin and the mucogingival junction.

It is exceedingly common in children, occurring in 99% of those between the ages of eight and 16 years, according to the original report of Hirshfeld, but decreases in incidence with age, occurring in 38% of those between the ages of 25 and 39 years and in 19% of those between the ages of 60 and 80 years. Thus there appears to be regression of the structure with maturity. In addition, most studies have found a greater occurrence bilaterally than unilaterally. A study by Berman and Fay, who have reviewed the studies dealing with the retrocuspid papilla, reported from their own data that the structure was consistently more common in females than in males.

Histologic Features. The structure appears as an elevated mucosal tag often showing mild hyperorthokeratosis or hyperparakeratosis, with or without acanthosis. The underlying connective tissue is sometimes highly vascularized and may exhibit large stellate fibroblasts as well as occasional epithelial rests.

Treatment. Because of its frequency of occurrence, the retrocuspid papilla is often considered to be a 'normal' anatomic structure which regresses with age and requires no treatment.

DEVELOPMENTAL DISTURBANCES OF TONGUE

Aglossia and Microglossia Syndrome

This malformation is very rare, since the first publication which was attributed by Gaillard and Nogué to Antoine De Jussieu in 1718, to present till date there have been less than 35 cases reported (Grinspan, 1976). This anomaly is almost always associated to malformations in the extremities, especially the hands and feet, cleft palate and dental agenesia. Aglosia syndrome is, in reality, a microglossia with extreme glossoptosis. What is commonly observed is a rudimentary, small tongue. As a consequence of the lack of muscular stimulus between the alveolar arches, these do not develop transversely and the mandible does not grow in an anterior direction, producing as a result a severe dentoskeletal malocclusion (Fig. 1-18). This syndrome shows no predilection for gender and has no genetic implications. Its etiology must be searched for in some sort of fetal cell traumatism in the first few weeks of gestation. Neither language nor swallowing are sensibly affected by this condition.

Macroglossia

(Tongue hypertrophy, prolapsus of the tongue, enlarged tongue, pseudomacroglossia)

Macroglossia, meaning large tongue, has been a documented anatomical anomaly for several centuries. The earliest known written description of tongue lesions comes from the Egyptian Papyrus Ebers, originally thought to be from around 1550 BC. Obviously, tongue lesions have since been categorized by their etiologies. Macroglossia has an extensive list of possible causes. Its treatment has been largely surgical in the modern era.

Although the exact incidence of macroglossia is unknown (because the etiologies are too numerous to quantify), some congenital syndromes often express macroglossia in their phenotypes, most commonly Down syndrome (1 per 700 live births) and **Beckwith-Wiedemann syndrome** (0.07 per 1,000 live births). In Beckwith-Wiedemann syndrome, 97.5% of patients have macroglossia.

Reports on the etiology of macroglossia are extensive. Historically, Virchow described it as a form of elephantiasis. In the last 100 years, Butlin and Spencer attributed it to the dilation of lymphatics, muscle hypertrophy, or inflammation. Because of the large number of possible etiologies, multiple classification schemes have been used to list the causes.

The two broadest categories under the heading of macroglossia are **true macroglossia** and **pseudomacroglossia.**

Physical examination of the oral cavity and head morphology is helpful to deduce true macroglossia from pseudomacroglossia. Severe retrognathia and unusually small maxillary and/or mandibular size may indicate the latter. In addition, check tongue tone and mobility to rule out simple

Figure 1-19. Macroglossia.

atonia or hypotonia indicating poor posturing of the tongue—as is commonly observed in Down syndrome (Fig. 1-19).

In addition to the oral cavity and airway, assess other features in the patient that may indicate congenital or systemic syndromes. Certain vitamin deficiencies may present with angular stomatitis, nonpitting edema of the lower extremities may indicate hypothyroidism, and unusual body morphologies may indicate the early signs of diseases-like acromegaly.

Treatment. The goal of nearly all surgery is to return the patient to an anatomically and physiologically normal condition; and this applies to macroglossia as well. The goal is to reduce tongue size and thereby improve function. Those main functions include articulation, mastication, deglutition, protection of the airway, and gustation. Of these, only gustation is not often improved with surgical intervention.

Ankyloglossia or Tongue-tie

Ankyloglossia, or tongue-tie as it is more commonly known, is said to exist when the inferior frenulum attaches to the bottom of the tongue and subsequently restricts free movement of the tongue. At one time, such restriction was believed to cause speech problems and it was routine to clip the membranous frenulum (frenulectomy) to free the tongue tip. Ankyloglossia occurs in approximately 1.7% of all neonates without preference for either gender and is reported to be transitory. With growth, the frenulum lengthens so normal tongue function is established. The criterion for diagnosis is based upon observation of lingual mobility; no current specific indications for surgery are emphasized in either the dental or medical literature reviewed. Simple incision of the frenulum may result in the development of scar tissue and further restriction of tongue movement (Schuller and Schleuning, 1994). Some authors indicate that if the tongue is able to touch the lower incisor teeth or just beyond the lower teeth, articulation will not be adversely affected. In some cases the frenulum is reported to tear spontaneously during infancy. Tongue-tie can cause feeding problems in infants; if this is the case, feeding difficulties are usually noticed early in an infant's life. Feeding difficulties may be a reason to consider early surgery to cut the lingual frenulum and loosen the tongue. In some children, tongue-tie may also cause speech defects, especially articulation of the sounds: l, r, t, d, n, th, sh, and z. Preventing speech defects or improving a child's articulation may be another reason to consider surgical intervention. The tongue is remarkably able to compensate; however, many children have no speech impediments due to ankyloglossia. Tongue-tie may contribute to dental problems as well, causing a persistent gap between the mandibular incisors.

Treatment. Frenulectomy is recommended.

Cleft Tongue

A completely cleft or bifid tongue is a rare condition that is apparently due to lack of merging of the lateral lingual swellings of this organ. A partially cleft tongue is considerably more common and is manifested simply as a deep groove in the midline of the dorsal surface (Figs. 1-20, 1-21). The partial cleft results because of incomplete merging and failure of groove obliteration by underlying mesenchymal proliferation. Interestingly, it is often found as one feature of the oral-facial-digital syndrome in association with thick, fibrous bands in the lower anterior mucobuccal fold eliminating the sulcus and with clefting of the hypoplastic mandibular alveolar process.

Figure 1-20. Cleft tongue.
(Courtesy Dr N Gururaj, CSI Dental College, Madurai, Tamil Nadu).

Figure 1-21. Bifidness of the tip of tongue.

Pseudomacroglossia includes any of the following conditions, which force the tongue to sit in an abnormal position:

- Habitual posturing of the tongue
- Enlarged tonsils and/or adenoids displacing tongue
- Low palate and decreased oral cavity volume displacing tongue
- Transverse, vertical, or anterior/posterior deficiency in the maxillary or mandibular arches displacing the tongue
- Severe mandibular deficiency (retrognathism)
- Neoplasms displacing the tongue
- Hypotonia of the tongue

True macroglossia can be subdivided into two main subcategories, congenital causes and acquired causes:

- **Congenital causes**
  - Idiopathic muscle hypertrophy
  - Gland hyperplasia
  - Hemangioma
  - Lymphangioma
  - Down syndrome
  - Beckwith-Wiedemann syndrome
  - Behmel syndrome
  - Lingual thyroid
  - Gargoylism
  - Transient neonatal diabetes mellitus
  - Trisomy 22
  - Laband syndrome
  - Lethal dwarfism of Blomstrand
  - Mucopolysaccharidoses
  - Skeletal dysplasia of Urbach
  - Tollner syndrome
  - Autosomal dominant inheritance
  - Microcephaly and hamartoma of Wiedemann
  - Ganglioside storage disease type I
- **Acquired causes** (categories have been assigned to simplify the list, but there can be overlap of a particular etiology into more than one of these categories)
- Metabolic/endocrine
  - Hypothyroidism
  - Cretinism
  - Diabetes
- Inflammatory/infectious
  - Syphilis
  - Amebic dysentery
  - Ludwig angina
  - Pneumonia
  - Pemphigus vulgaris
  - Rheumatic fever
  - Smallpox
  - Typhoid
  - Tuberculosis
  - Actinomycosis
  - Giant cell arteritis
  - Candidiasis
  - Scurvy
  - Pellagra
- Systemic/medical conditions
  - Uremia
  - Myxedema
  - Hypertrophy
  - Acromegaly
  - Neurofibromatosis
  - Iatrogenic macroglossia
- Traumatic
  - Surgery
  - Hemorrhage
  - Direct trauma (e.g. biting)
  - Intubation injury
  - Radiation therapy
- Neoplastic
  - Lingual thyroid
  - Lymphangioma
  - Hemangioma
  - Carcinoma
  - Plasmacytoma
- Infiltrative
  - Amyloidosis
  - Sarcoidosis

It is of little clinical significance except that food debris and microorganisms may collect in the base of the cleft and cause irritation.

Fissured Tongue

(Scrotal tongue, lingua plicata)

Fissured tongue is a condition frequently seen in the general population and it is characterized by grooves that vary in depth and are noted along the dorsal and lateral aspects of the tongue (Fig. 1-22). Although a definitive etiology is unknown, a polygenic mode of inheritance is suspected because the condition is seen clustering in families who are affected. Patients are usually asymptomatic, and the condition is initially noted on routine intraoral examination as an incidental finding. Fissured tongue is also seen in **Melkersson-Rosenthal syndrome** and **Down syndrome** and in frequent association with benign migratory glossitis (geographic tongue).

Melkersson-Rosenthal syndrome is a rare condition consisting of a triad of persistent or recurring lip or facial swelling, intermittent seventh (facial) nerve paralysis (Bell's palsy), and a fissured tongue. The etiology of this condition is also unknown. The orofacial swelling usually manifests as pronounced lip enlargement. It may or may not affect both lips,

Figure 1-22. Large fissured tongue.

and it may be tender or erythematous. Histologic examination of this tissue exhibits characteristic noncaseating granulomatous inflammation. Therapy for these lesions is often intralesional steroid injections. The facial paralysis is indistinguishable from Bell's palsy, and it may be an inconsistent and intermittent finding with spontaneous resolution. The presence of fissured tongue in association with these other features is diagnostic of the condition.

This condition affects only the tongue and is a finding in Melkersson-Rosenthal syndrome, which consists of a triad of fissured tongue, cheilitis granulomatosa, and cranial nerve VII paralysis (Bell's palsy).

Clinical Features. The prevalence worldwide varies by geographic location and has been reported to be as high as 21%. Fissured tongue is a totally benign condition and is considered by most to be a variant of normal tongue architecture. No predilection for any particular race appears to exist. Some reports have shown a slight male predilection. Although fissured tongue may be diagnosed initially during childhood, it is diagnosed more frequently in adulthood. The prominence of the condition appears to increase with increasing age.

The lesions are usually asymptomatic unless debris is entrapped within the fissure or when it occurs in association with geographic tongue (a common finding). On clinical examination, fissured tongue affects the dorsum and often extends to the lateral borders of the tongue. The depth of the fissures varies but has been noted to be up to 6 mm in diameter. When particularly prominent, the fissures or grooves may be interconnected, separating the tongue dorsum into what may appear to be several lobules. Although a specific etiology has not been elicited, a polygenic or autosomal dominant mode of inheritance is suspected because this condition is seen with increased frequency in families with an affected proband.

Histologic Features. A biopsy is rarely performed on a fissured tongue because of its characteristic diagnostic clinical appearance; however, histologic examination has shown an increase in the thickness of the lamina propria, loss of filiform papillae of the surface mucosa, hyperplasia of the rete pegs, neutrophilic microabscesses within the epithelium, and a mixed inflammatory infiltrate in the lamina propria.

Treatment. No definitive therapy or medication is required.

Median Rhomboid Glossitis

Embryologically the tongue is formed by two lateral processes (lingual tubercles) meeting in the midline and fusing above a central structure from the first and second branchial arches, the tuberculum impar. The posterior dorsal point of fusion is occasionally defective, leaving a rhomboid-shaped, smooth erythematous mucosa lacking in papillae or taste buds. This median rhomboid glossitis (central papillary atrophy, posterior lingual papillary atrophy) is a focal area of susceptibility to recurring or chronic atrophic candidiasis, prompting a recent shift towards the use of **posterior midline atrophic candidiasis** as a more appropriate diagnostic term.

The latter term has certain difficulties; however, because not all cases improve with antifungal therapy or show initial evidence of fungal infection. The erythematous clinical appearance; moreover, is due primarily to the absence of filiform papillae, rather than to local inflammatory changes, as first suggested in 1914 by Brocq and Pautrier. The lesion is found in one of every 300–2,000 adults, depending on the rigor of the clinical examinations. It is seldom biopsied unless the red discoloration is confused with precancerous erythroplakia or its surface shows pronounced nodularity.

Clinical Features. Median rhomboid glossitis presents in the posterior midline of the dorsum of the tongue, just anterior to the V-shaped grouping of the circumvallate papillae (Fig. 1.23A, B). The long axis of the rhomboid or oval area of red depapillation is in the anteroposterior direction. Most cases are not diagnosed until the middle age of the affected patient, but the entity is, of course, present in childhood. There appears to be a 3 : 1 male predilection.

Those lesions with atrophic candidiasis are usually more erythematous but some respond with excess keratin production, and therefore, show a white surface change. Infected cases may also demonstrate a midline soft palate erythema in the area of routine contact with the underlying tongue involvement; this is commonly referred to as a **kissing lesion.**

Lesions are typically less than 2 cm in greatest dimension and most demonstrate a smooth, flat surface, although it is not unusual for the surface to be lobulated. Occasional lesions are located somewhat anterior to the usual location. None have been reported posterior to the circumvallate papillae.

Prior to biopsy, the clinician should be certain that the midline lesion does not represent a lingual thyroid, as it may be the only thyroid tissue present in the patient's body. Differential diagnoses include the gumma of tertiary syphilis, the granuloma of tuberculosis, deep fungal infections, and granular cell tumor.

Histologic Features. Median rhomboid glossitis shows a smooth or nodular surface covered by atrophic stratified squamous epithelium overlying a moderately fibrosed stroma

A B

Figure 1-23 (A, B) Median rhomboid glossitis.
(Courtesy of Dr S Rohini, Ambattur, Chennai).

with somewhat dilated capillaries. Fungiform and filiform papillae are not seen, although surface nodules may mimic or perhaps represent anlage of these structures. A mild to moderately intense chronic inflammatory cell infiltrate may be seen within subepithelial and deeper fibrovascular tissues.

Chronic candida infection may result in excess surface keratin or extreme elongation of rete processes and premature keratin production with individual cells or as epithelial pearls (dyskeratosis) deep in the processes. Silver staining for fungus will often reveal candida hyphae and spores in the superficial layers of the epithelium. This **pseudoepitheliomatous hyperplasia** may be quite pronounced, and the tangential cutting of such a specimen may result in the artifactual appearance of cut rete processes as unconnected islands of squamous epithelium, leading to a mistaken diagnosis of well differentiated squamous cell carcinoma. Because of this difficulty, it is recommended that the patient be treated with topical antifungals prior to biopsy of a suspected median rhomboid glossitis.

Treatment and Prognosis. No treatment is necessary for median rhomboid glossitis, but nodular cases are often removed for microscopic evaluation. Recurrence after removal is not expected, although those cases with pseudoepitheliomatous hyperplasia should be followed closely for at least a year after biopsy to be certain of the benign diagnosis. Antifungal therapy (topical troches or systemic medication) will reduce clinical erythema and inflammation due to candida infection. This therapy, as stated earlier, should ideally be given prior to the biopsy, in order to reduce the candida-induced pseudoepitheliomatous hyperplasia features. Some lesions will disappear entirely with antifungal therapy.

Benign Migratory Glossitis
(Geographic tongue)

Benign migratory glossitis is a psoriasiform mucositis of the dorsum of the tongue. Its dominant characteristics is a constantly changing pattern of serpiginous white lines surrounding areas of smooth, depapillated mucosa. The changing appearance has led some to call this the wandering rash of the tongue, with the depapillated areas have reminded others of continental outlines on a globe, hence the use of the popular term geographic tongue (Fig. 1-24). As with psoriasis, the etiology of benign migratory glossitis is unknown, but it does seem to become more prominent during conditions of psychological stress and it is found with increased frequency (10%) in persons with psoriasis of the skin. The great majority of those with oral involvement; however, lack psoriatic skin involvement. Approximately 1–2% of the population are affected, although most cases are so mild that they are never formally diagnosed.

Histologic Features. All of the microscopic features of psoriasis are present in benign migratory glossitis and migratory stomatitis, but these will not be obvious unless the biopsy is

Figure 1-24. Benign migratory glossitis.
(Courtesy of Dr Spencer Lilly, Meenakshi Ammal Dental College, Chennai).

taken from a prominent serpiginous line at the periphery of a depapillated patch. A thickened layer of keratin is infiltrated with neutrophils, as are lower portions of the epithelium to a lesser extent. These inflammatory cells often produce small microabscesses, called **Monro's abscesses,** in the keratin and spinous layers. Rete ridges are typically thin and considerably elongated, with only a thin layer of epithelium overlying connective tissue papillae. When rete ridges are not elongated, the pathologist should consider **Reiter's syndrome** as a diagnostic possibility. Chronic inflammatory cells can be seen in variable numbers within the stroma and silver or PAS staining will often demonstrate candida hyphae or spores in the superficial layers of the epithelium. There is no liquefactive degeneration of basal cells, as seen in lichenoid lesions, and there is no ulceration except in cases of Reiter's syndrome.

Treatment and Prognosis. No treatment is usually necessary for benign migratory glossitis and stomatitis. Symptomatic lesions can be treated with topical prednisolone and a topical or systemic antifungal medication can be tried if a secondary candidiasis is suspected. Occasional symptomatic cases respond well to topical tetracycline or systemic, broad-spectrum antibiotics, but this should not be expected.

Hairy Tongue

(Lingua nigra, lingua villosa, lingua villosa nigra, black hairy tongue)

Hairy tongue (lingua villosa) is a commonly observed condition of defective desquamation of the filiform papillae that results from a variety of precipitating factors (Fig. 1-25). The condition is most frequently referred to as **black hairy tongue** (lingua villosa nigra); however, hairy tongue may also appear brown, white, green, pink, or any of a variety of hues depending on the specific etiology and secondary factors (e.g. use of colored mouthwashes, breath mints, candies).

Figure 1-25. Hairy tongue.
(Courtesy of Dr S Rohini, Ambattur, Chennai)

Etiology. The basic defect in hairy tongue is the hypertrophy of filiform papillae on the dorsal surface of the tongue, usually due to a lack of mechanical stimulation and debridement. This condition often occurs in individuals with poor oral hygiene (e.g. lack of toothbrushing, eating a soft diet with no roughage that would otherwise mechanically debride the dorsal surface of the tongue). Contributory factors for hairy tongue are numerous and include tobacco use and coffee or tea drinking. These factors account for the various colors associated with the condition.

Clinical Features. Normal filiform papillae are approximately 1 mm in length, whereas filiform papillae in hairy tongue are more than 15 mm in length. Hairy tongue has been reported with greater frequency in males, patients infected with human immunodeficiency virus (HIV), and those who are HIV negative and use intravenous drugs. Hairy tongue is rarely symptomatic, although overgrowth of *Candida albicans* may result in glossopyrosis (burning tongue). Patients frequently complain of a tickling sensation in the soft palate and the oropharynx during swallowing. In more severe cases, patients may actually complain of a gagging sensation. Retention of oral debris between the elongated papillae may result in halitosis. No racial predilection is associated with hairy tongue. Because hairy tongue is usually asymptomatic, the history is often irrelevant. In most cases, lesions are noted as part of an intraoral examination, although patients may complain of a tickling or gagging sensation. The tongue has a thick coating in the middle, with a greater accentuation towards the back. Bacterial and fungal overgrowth play a role in the color of the tongue. The only complication associated with hairy tongue is an occasional candidal overgrowth, which often results in an uncomfortable glossopyrosis (burning tongue). Altered taste sensation is a rare complication.

Differential Diagnosis. This condition has to be differentiated from candidiasis, leukoplakia, oral lichen planus and oral hairy leukoplakia. Culture of the tongue's dorsal surface may be taken if a superimposed oral candidiasis or other specific oral infection is suspected. Distinguishing between oral hairy leukoplakia and hairy tongue is important if patients are found or suspected to be HIV positive. This can be accomplished by a simple mucosal punch biopsy and appropriate immunostaining of the specimen for the presence of Epstein-Barr virus, the causative agent of oral hairy leukoplakia. However, in most cases, the diagnosis is made retrospectively on the basis of the clinical response to mechanical debridement.

Histologic Features. Histopathologic findings in hairy tongue consist of elongated filiform papillae, with mild hyperkeratosis and occasional inflammatory cells. Debris accumulation among the papillae and candidal pseudohyphae is not unusual finding. No other specific microscopic findings are associated with this entity.

Treatment. The treatment of hairy tongue is variable. In many cases, brushing of the tongue with a toothbrush or

using a commercially available tongue scraper is sufficient to remove elongated filiform papillae and retard the growth of additional ones. Surgical removal of the papillae by using electrodesiccation, carbon dioxide laser, or even scissors is the treatment of last resort when less complicated therapies prove ineffective. The prognosis for hairy tongue is excellent. If the precipitating factors cannot be adequately controlled or compensated for, patients may have to make tongue brushing or scraping part of their daily oral hygiene regimen.

Lingual Varices

(Lingual or sublingual varicosities)

A varix is a dilated, tortuous vein, most commonly a vein which is subjected to increased hydrostatic pressure but poorly supported by surrounding tissue. Varices involving the lingual ranine veins are relatively common, appearing as red or purple shotlike clusters of vessels on the ventral surface and lateral borders of the tongue as well as in the floor of the mouth. However, varices also do occur in other oral sites such as the upper and lower lip, buccal mucosa, and buccal commissure.

There has been no direct association established between these varicosities and other specific organic diseases. However, Kleinman has concluded that these varicosities represent an aging process and that, when they occur prior to 50 years of age, they may indicate premature aging. In his study, lingual varicosities were not related to cardiac pulmonary disease. In an investigation of 1,751 persons (755 males and 996 females) ranging in age from 7 to 99 years, Ettinger and Manderson found that 68% of the persons over 60 years of age had sublingual varices. In this study, there appeared to be a significant relationship between the presence of leg varicosities and sublingual varices.

Thrombosis of any of these varices is a relatively frequent occurrence, as indicated in a report of 12 such cases by Weathers and Fine, but is apparently of little clinical significance.

Lingual Thyroid Nodule

The thyroid gland develops in the embryo from the ventral floor of the pharynx by means of an endodermal invagination or diverticulum. The tongue forms at the same time from this pharyngeal floor and is anatomically associated with the thyroid gland by connection through the thyroglossal tract, the lingual remnant of which is known as the foramen caecum.

The lingual thyroid is an anomalous condition in which follicles of thyroid tissue are found in the substance of the tongue, possibly arising from a thyroid anlage that failed to 'migrate' to its predestined position or from anlage remnants that became detached and were left behind. Baughman has reviewed and discussed in detail the various theories on the development of lingual thyroglossal remnants and the lingual thyroid nodule.

Etiology. The benign enlargement of lingual thyroid tissue is thought to be due in some cases to functional insufficiency of the chief thyroid gland in the neck, since some patients with such a lingual lesion are without a demonstrable main thyroid gland. Other cases of lingual thyroid nodules occur in patients residing in goitrous areas, but it is not certain that the condition is a form of goiter. In addition, it has been suggested that the failure of the primitive thyroid anlage to descend is the cause of the majority of cases of nongoitrous sporadic cretinism.

Clinical Features. The incidence of this benign condition is not known, since a routine autopsy seldom includes an examination of the base of the tongue. Montgomery, in an exceptionally complete and thorough review of the entire subject of the lingual thyroid, analyzed 144 acceptable previously reported cases, pointing out that these represented only cases showing hypertrophy of the lingual thyroid tissue. Though information is inadequate about racial and geographic distribution of lingual thyroid nodules, a difference in gender incidence does appear to be significant. Of 135 cases in which the gender was recorded, 118 patients were female and only 17 were male. The majority of patients had their onset of symptoms relatively early in life, chiefly during puberty, adolescence, and early maturity, though cases have been recorded as early as birth and as late as the seventh decade.

In contrast, Sauk carried out a study to determine the frequency with which ectopic thyroid tissue occurred in the tongue of 'normal' persons, i.e. those without a definite symptomatic mass for which treatment was sought. In a series of 200 consecutive necropsies, ectopic thyroid tissue was found in 10% of the cases, with an equal distribution between the sexes. Nearly identical data have been reported by Baughman in his own investigation of 184 tongues from human cadavers. Since the condition is more often clinically apparent in females, Sauk suggested that hormonal factors may be involved in the genesis of symptoms. Most cases appear to arise in females during puberty, adolescence, pregnancy, or menopause.

The lingual thyroid may be manifested clinically as a nodular mass in or near the base of the tongue in the general vicinity of the foramen caecum and often, but not always, in the midline (Fig. 1-26). This mass, which more commonly appears as deeply situated rather than as a superficial exophytic lesion, tends to have a smooth surface. In some cases it may appear vascular, while in others the color of the mucosa is not atypical. The size of the lesion in many of the reported

Figure 1-26. Lingual thyroid nodule.
(Courtesy of Dr Ronald A Baughman).

cases has been approximated 2–3 cm in diameter. The chief symptoms of the condition may vary, but the presenting complaint is often dysphagia, dysphonia, dyspnea, hemorrhage with pain, or a feeling of tightness or fullness in the throat.

Histologic Features. The benign lingual thyroid nodules may present a variety of microscopic patterns, but in the majority of cases they resemble either normal thyroid tissue or thyroid tissue of an embryonal or fetal type. In some instances the nodules exhibit colloid degeneration or goiter.

Great care must be taken to distinguish these lesions from lesions derived from accessory salivary glands in the same location. Both the lingual thyroid and these salivary glands may give rise to adenomas and adenocarcinomas in the tongue.

Treatment. Care must be exercised in handling the lingual thyroid lesion. It has been emphasized by Hung and his associates that a careful physical examination should be performed to demonstrate the presence of a normally located thyroid gland in patients presenting with midline masses in the lingual or sublingual area. If the thyroid gland cannot be palpated, a scintiscan with a tracer dose of radioactive iodine, ^{131}I, should be carried out to determine whether there is a normally located thyroid gland and if the lingual mass is ectopic thyroid. It is usually recommended that a patient with an ectopic thyroid gland should have a trial of replacement thyroid hormone therapy before excision is contemplated, since this will often decrease the size of the lesion and make surgery unnecessary. Occasionally, the clinical manifestations of the lesion and its size necessitates surgical excision.

DEVELOPMENTAL DISTURBANCES OF ORAL LYMPHOID TISSUE

Reactive Lymphoid Aggregate
(Reactive lymphoid hyperplasia)

The lingual tonsil, one of the largest oral lymphoid aggregates, is located on the posterior portion of the tongue on the dorsolateral aspect. It is typically surrounded by a crypt lined by stratified squamous epithelium. It frequently becomes inflamed and enlarged so that it is clinically evident. Such enlargement is usually bilateral but, if unilateral, may easily be mistaken clinically for early carcinoma. This reactive lingual tonsil has often been called 'foliate papillitis,' referring to the vestigial foliate papilla in this area.

Similar reactive hyperplasia may occur in the lymphoid aggregates in the other locations mentioned previously, the buccal mucosa being especially common. This presents clinically as a firm nodular submucosal mass which may be tender. Since this lymphoid tissue may be the site for the development of lesions of the malignant lymphoma group, early microscopic diagnosis is essential whenever the lesions do not regress in a short period of time.

Hyperplastic lymphoid polyps have also been described as polypoid structures composed entirely of lymphoid tissue. They are reported to occur on the gingiva, buccal mucosa, tongue, and floor of the mouth.

Lymphoid Hamartoma
(Angiofollicular lymph node hyperplasia, angiomatous lymphoid, Castleman tumor, giant benign lymphoma, hamartoma of lymphatics, giant lymph node hyperplasia)

Castleman's disease is a rare disorder characterized by noncancerous benign growths that may develop in the lymph node tissue throughout the body (i.e. systemic disease of plasma cell type). Most often, they occur in the chest, stomach, and/or neck (i.e. localized disease of hyaline vascular type). Less common sites include the armpit (axilla), pelvis, and pancreas. Usually the growth represents abnormal enlargement of the lymph nodes normally found in these areas (lymphoid hamartoma). There are two main types of Castleman's disease: **hyaline vascular type** and **plasma cell type.** The hyaline vascular type accounts for approximately 90% of the cases. Most individuals exhibit no symptoms of this form of the disorder (asymptomatic) or they may develop noncancerous growths in the lymph nodes. The plasma cell type of Castleman's disease may be associated with fever, weight loss, skin rash, early destruction of red blood cells, leading to unusually low levels of circulating red blood cells (hemolytic anemia), and/or abnormally increased amounts of certain immune factors in the blood (hypergammaglobulinemia).

A third type of Castleman's disease has been reported in the medical literature. This type may affect more than one area of the body (**multicentric** or **generalized Castleman's disease**). Many individuals with multicentric Castleman's disease may exhibit an abnormally large liver and spleen (hepatosplenomegaly). Researchers' opinions in the medical literature differ as to whether multicentric Castleman's disease is a distinct entity or a multicentric form of the plasma cell type of Castleman's disease. The exact cause of Castleman's disease is not known. Some researchers speculate that increased production of interleukin-6 (IL-6) may be involved in the development of Castleman's disease. IL-6 is a substance produced by structures within the lymph nodes.

Angiolymphoid Hyperplasia with Eosinophilia
(Epithelioid hemangioma, histiocytoid hemangioma, pseudopyogenic granuloma, papular angioplasia, inflammatory angiomatous nodules)

Angiolymphoid hyperplasia with eosinophilia (ALHE) is an uncommon idiopathic condition that presents with isolated or grouped plaques or nodules in the skin of the head and neck. Most patients present with lesions in the periauricular region, forehead, or scalp.

A distinct pathologic entity, ALHE is marked by a proliferation of blood vessels with distinctive large endothelial cells. These blood vessels are accompanied by a characteristic inflammatory infiltrate that includes eosinophils. The lesion is benign but may be persistent and difficult to eradicate. Whether ALHE represents a benign neoplasm or an unusual reaction to varied stimuli, including trauma, remains unclear. While ALHE shows some similarity to **Kimura disease,** it is a distinct condition.

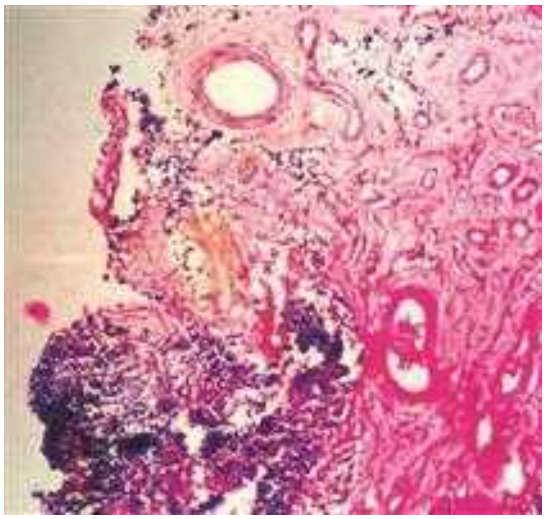


Figure 1-27. Angiolymphoid hyperplasia.
H and E section showing irregular clusters of blood vessels and intermixed lymphocytes and eosinophils in this example of ALHE.

Etiology. ALHE is idiopathic. Whether this condition is a neoplastic or reactive state is uncertain; a reactive cause is favored.

Clinical Features. Although ALHE may be a benign tumor, numerous factors suggest that it is an unusual reactive process. The condition may be multifocal. ALHE has occurred following various forms of trauma or infection. Hyperestrogenic states (e.g. pregnancy, oral contraceptive use) may foster lesion growth. Additionally, the distinctive inflammatory infiltrate in ALHE appears to be an intrinsic (not secondary) component of the lesion. Approximately 20% of patients have blood eosinophilia. Although frequency is unknown, cases have been reported worldwide. ALHE is uncommon but not rare; it may be more common in Japan than in other countries. ALHE can persist for years, but serious complications (e.g. malignant transformation) do not occur. ALHE is seen most commonly in Asians, followed by Caucasians. Although less commonly, blacks too can develop ALHE. ALHE is somewhat more common in females; however, a male predominance has been noted in selected Asian studies. ALHE presents most commonly in patients aged 20–50 years, with mean onset of 30–33 years. This condition is rare in elderly patients and in the non-Asian pediatric population.

Patients with ALHE typically present with an expanding nodule or group of nodules, usually in the vicinity of the ear. The lesion(s) may be associated with pain or pruritus. Uncommon symptoms include pulsation and spontaneous bleeding.

ALHE typically appears as dome-shaped, smooth-surfaced papules or nodules. Approximately 85% of lesions occur in the skin of the head and neck; most of them are on or near the ear or on the forehead or scalp. The lesions range from erythematous to brown in color and may be eroded or crusted. Approximately 80% of patients present with isolated lesions, while the remaining patients usually demonstrate grouped papules or nodules in a single region. Rarely, the lesions may be pulsatile. Most lesions are 0.5–2 cm in diameter, with a range of 0.2–8 cm. Larger nodules tend to be deeply centered within the subcutis.

Differential Diagnosis. Granuloma faciale, insect bites, pyogenic granuloma (lobular capillary hemangioma), angiosarcoma, hemangioendothelioma and hemangioma.

Histologic Features. The clinical presentation of papules around the ears may suggest ALHE, but a biopsy is required to establish the diagnosis. ALHE shows characteristic histologic features, including a proliferation of small blood vessels, many of which are lined by enlarged endothelial cells with uniform ovoid nuclei and intracytoplasmic vacuoles. These distinctive endothelial cells have been described as having a cobblestone appearance. In addition, a perivascular and interstitial infiltrate composed primarily of lymphocytes and eosinophils is present. Eosinophils typically comprise 5–15% of the infiltrate. Rarely, they can account for as much as 50% of the infiltrate. Occasionally, the infiltrate is devoid of eosinophils. Lymphoid aggregates with or without follicle formation are typical.

Treatment. Treatment is not mandatory. Intralesional corticosteroids and irradiation have been employed but are not very effective. Surgical removal of the lesions has demonstrated the best results, however, they may recur.

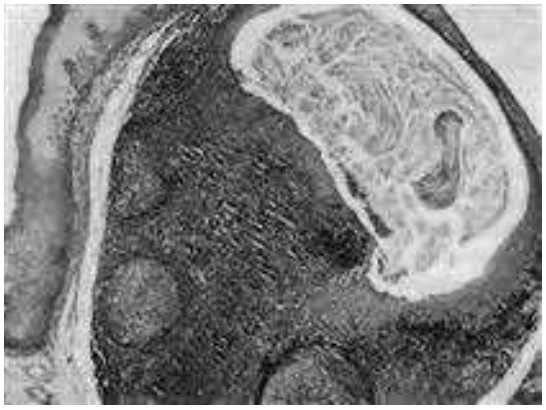
Lymphoepithelial Cyst

The oral lymphoepithelial cyst develops within a benign lymphoid aggregate or accessory tonsil of the oral or pharyngeal mucosa. The surface of such aggregates may be indented with tonsillar crypts, as are the much larger pharyngeal tonsils of the lateral pharyngeal walls. The crypts may become obstructed by keratin or other debris, or the surface opening may become constricted during episodes of inflammatory hyperplastic responses. Certain cases develop a complete disunion of the crypt epithelium from the surface epithelium, resulting in a subepithelial cyst lined by the old crypt epithelium. This cyst was first reported by Parmentier in 1857 as hydatid cyst. Outside of the head and neck region, lymphoepithelial cyst is found most frequently in the pancreas and testis.

A similar but much larger cervical lymphoepithelial cyst (**branchial cleft cyst**) most probably develops from entrapped salivary duct epithelium in the lymph nodes of the lateral neck, rather than from the branchial cleft. These are discussed in a separate section of the present book. Another similar cyst, the **parotid cyst,** is found in major salivary glands, especially in AIDS patients, although it often lacks a surrounding lymphoid aggregate in Chapter 3 on Tumors of the Salivary Gland.

Clinical Features. Oral lymphoepithelial cyst presents as a movable, painless submucosal nodule with a yellow or yellow-white discoloration. Occasional cysts are transparent. Almost all cases are less than 0.6 cm in diameter at the time of diagnosis, which is usually during the teen years or the third decade of life. Approximately half of all intraoral examples are found on the oral floor (Fig. 1-28A), but the lateral and ventral tongue are not uncommon sites of occurrence, nor is the soft

A



B

Figure 1-28. Oral lymphoepithelial cyst.
An elevated nodule in the floor of the mouth **(A)**. Histologically exhibited a keratin-filled epithelium-lined cyst in a lymphoid aggregate **(B)**. *(Courtesy of Dr Joseph A Regezi).*

palate, especially the mucosa above the pharyngeal tonsil. Of course, this cyst may also occur within the pharyngeal tonsils themselves. Occasional superficial cysts rupture to release a foul-tasting, cheesy, keratinaceous material.

This cyst has a clinical appearance similar to that of an epidermoid cyst or a dermoid cyst of the oral/pharyngeal mucosa, but its growth potential is much less than the other cysts. The lymphoepithelial cyst never occurs on the alveolar mucosa, hence, can easily be distinguished from a gingival cyst of adults or from an unruptured **parulis** or **'pus pocket'** at the terminus of a fistula (extending from the apical or lateral region of an abscessed tooth).

Histologic Features. The lymphoepithelial cyst is lined by atrophic and often degenerated stratified squamous epithelium, usually lacking rete processes and usually demonstrating a minimal granular cell layer. Orthokeratin is seen to be sloughing from the epithelial surface into the cystic lumen, often completely filling the lumen and sometimes showing dystrophic calcification. Rarely, mucus-filled goblet cells may be seen within the superficial layers of the epithelium, and occasional cysts will demonstrate an epithelium-lined communication with the overlying mucosal surface. The cyst is entrapped within a well-demarcated aggregate of mature lymphocytes. The aggregate or 'tonsil' will have a variable number of germinal centers, sometimes none at all. The lymphoid aggregate may be hyperplastic.

This combination of epithelium-lined cyst with lymphoid aggregates is unique enough to make the diagnosis an easy one (Fig. 1-28B), but the pathologist must differentiate this lesion from the Warthin tumor (papillary cystadenoma lymphomatosum). The latter lesion is lined not by squamous epithelium but by a bilayered cuboidal, columnar or oncocytic ductal epithelium. It is almost always found in the parotid gland, but rare oral examples have been reported.

Occasional cysts have very small lumina with degenerated epithelial linings and may mimic metastatic deposits of well differentiated squamous cell carcinoma. Deeper sections will reveal the true nature of the benign lesion.

Treatment and Prognosis. No treatment is usually necessary for the oral lymphoepithelial cyst unless its location is such that it is constantly being traumatized. Most lesions are, however, removed by conservative surgical excision in order to arrive at a definitive diagnosis. There is no malignant potential to this lesion but the lymphoid stroma, as with all lymphoid tissues, can become involved with an extranodal lymphoma.

DEVELOPMENTAL DISTURBANCES OF SALIVARY GLANDS

Aplasia
(Agenesis)

Any one or group of salivary glands may be absent, unilaterally or bilaterally. Aplasia becomes manifest with the development of xerostomia and its sequelae. A diagnosis of salivary gland aplasia is made after exclusion of the common causes of xerostomia medications, Sjögren's syndrome and radiation. The CT scan or MRI will indicate the gland's absence and its replacement by fat and fibrous tissue. Scintiscanning with a radioisotope will confirm the initial diagnosis. The absence of the salivary duct orifice/papilla is an additional clue.

Aplasia occurs for unknown reasons as an isolated finding or in conjunction with other developmental defects such as *hemifacial microsomia,* the *LADD syndrome* (see below) and *mandibulofacial dysostosis (Treacher Collins).* In the more severe cases, the ensuing xerostomia causes clinical problems. Salivary loss leads to increased caries, burning sensations, oral infections, taste aberrations and difficulty with denture retention.

Hemifacial microsomia, a relatively frequent entity (1 in 3,500 births), is characterized by an asymmetric mild to severe underdevelopment of the craniofacial skeleton, the external ear, and facial soft tissues including the parotid gland. It involves structures derived from the first and second branchial arches. The majority of cases occur sporadically but rare familial cases have been reported.

LADD is a hereditary autosomal dominant syndrome. The lacrimal (**L**) apparatus usually demonstrates occlusion of the lacrimal puncta, nasolacrimal duct obstruction with overflow of tears (epiphora), lacrimal sac inflammation (dacrocystitis) and lacrimal gland aplasia. The auricles (**A**) are deformed with the ear having a cup-shaped appearance. There is some hearing loss. Dentally (**D**), peg-shaped teeth, hypodontia, and enamel hypoplasia are noted. Various combinations of salivary gland agenesis, with varying degrees of xerostomia, are present. Digital (**D**) deformities are manifested by deviation of the fingers medially or laterally (clinodactyly).

Mandibulofacial dysostosis is familial in origin. Patients have a symmetric notching of the lower eyelids with the eyes slanting downward at the lateral borders. Maldevelopment of the mandible and maxilla, a defective development of the malar bones results in bird-like appearance and often salivary aplasia are seen.

Treatment. Treatment for salivary gland agenesis is supportive and directed at relieving xerostomia and its effects. Salivary substitutes, frequent mouth washes, comprehensive dental care, fluoride therapy, and good oral hygiene all play a role in successful management.

Xerostomia
(Dry mouth)

Xerostomia is not a disease but can be a symptom of certain diseases. It can produce serious negative effects on the patient's quality of life, affecting dietary habits, nutritional status, speech, taste, tolerance to dental prosthesis and increased susceptibility to dental caries. The increase in dental caries can be devastating in many patients and therefore special care must be made to control this condition.

Etiology. A convenient way of classifying the causes of xerostomia is as temporary or permanent.

Temporary Causes

Psychological. Anxiety and depression are well recognized as causes of reduced salivary flow, as many students become aware at examination times! However, these psychological problems are often treated with drugs, which may be salivary inhibitors.

Duct calculi. A blockage of the duct of a major salivary gland, commonly the submandibular, can produce dryness on the affected side, together with pain and swelling in the gland, especially on stimulation. If untreated, the obstruction may lead to progressive fibrosis of the gland and permanent xerostomia.

Sialoadenitis. Inflammation of the salivary glands can cause reduced secretion. Acute infections include mumps and postoperative parotitis, while chronic conditions include swellings related to nutritional deficiency and hypersensitivity to iodine. However, many cases of intermittent swelling of the salivary glands are idiopathic and are described as 'chronic nonspecific sialadenitis' and may be associated with duct calculi.

Drug therapy. A wide variety of drugs may cause xerostomia. Anticholinergic and sympathomimetic agents may be implicated and this group includes tricyclic antidepressants, bronchodilators and antihistamines. Diuresis produced by drugs or alcohol can result in dehydration and xerostomia. In most cases function recovers after the drug is withdrawn. **Zyban,** a newly introduced drug to aid smoking cessation can cause xerostomia and since the demand for the drug is likely to be high, its use may become a common etiological factor.

Permanent Causes

Salivary gland aplasia. Congenital absence of one or more of the major salivary glands is a rare but recognized condition of unknown etiology.

Sjögren's syndrome. This combination of dry mouth, dry eyes, and often rheumatoid arthritis, mainly affects women over 40 years of age and is often accompanied by a mild fever. About half of the patients with this syndrome also present with, or go on to develop swellings of the major salivary glands, which display similar histology to Mikulicz's disease.

Other systemic disorders. Xerostomia is associated with diabetes mellitus, probably as a consequence of polyurea, as well as Parkinson's disease, cystic fibrosis and sarcoidosis. It has been reported in cases of vitamin A, riboflavin and nicotinic acid deficiencies and anemia.

Radiotherapy. One of the most dramatic and distressing causes of xerostomia is therapeutic radiography for head and neck tumors. The effect on the glands of the irradiated side is often rapid and profound. Postradiation glandular atrophy is partly due to a reduction in the vascularity of the gland and partly to the direct effect of the X-rays on the highly specialized and sensitive secretory epithelial cells. While recovery of function can occur after several months, in many cases a permanent xerostomia develops. Radiation does not appear to damage the teeth or periodontal tissues directly, the effect on the dentition resulting solely from the reduction in salivary flow.

Surgical desalivation. Surgery or physical trauma to the salivary gland duct may result in damage to the gland, duct, blood or nerve supply and impair secretion.

Clinical Features. It is important to establish whether the dryness is continual or intermittent, whether it is accompanied by pain or swelling, if unilateral or bilateral and whether there is any relevant history of anxiety, stress or depression, a systemic disorder, irradiation, trauma, surgery or medication. The patient's occupation, diet and domestic situation are often relevant.

Unilateral dryness with pain or discomfort and swelling in the affected gland on stimulation is often an indication of a duct calculus. Sjögren's syndrome commonly produces bilateral swelling, often constant and accompanied by the other symptoms of the syndrome, and in many cases lymph node enlargement. A punch biopsy of labial glands and by serological tests may be needed to confirm the diagnosis. As well as looking for evidence of enlargement of salivary glands and lymph nodes and unilateral dryness, the palpation of the floor of the mouth for evidence of submandibular duct calculi and examination of the major duct openings,

as inflammation or swelling of the orifice may indicate the presence of a distally placed calculus. These are often revealed by simple radiography.

While the more dramatic forms of xerostomia are not common, a more typical case of nonspecific xerostomia is a postmenopausal woman, living alone with few family or other social contacts, surviving on a low income and a marginally inadequate diet, and wearing old ill-fitting dentures. The combination of atrophy of the oral mucosa due to hormonal changes and a mild chronic candidosis and reduced salivary flow due to age and depression for which she might have medication, together with a marginal iron deficiency anemia, is sufficient to produce a degree of discomfort which a cursory oral examination will not reveal.

All degrees of xerostomia exist. In some cases, the patient complains of a dry or burning sensation but the mucosa appears normal. In other cases there is a complete lack of saliva.

When the deficiency of saliva is pronounced, there may be severe alterations in the mucous membranes, and the patient may have extreme discomfort. The mucosa will appear dry and atrophic, sometimes inflamed or, more often, pale and translucent. The tongue may manifest the deficiency by atrophy of the papillae, inflammation, fissuring, and cracking and in severe cases by areas of denudation. Soreness, burning, and pain of the mucous membrane and tongue are common symptoms. Xerostomia, in all its aspects, has been discussed by Bertram.

Clinical Significance. Aside from annoyance to the patient, there is one feature of the condition that is serious. In many cases, chronic xerostomia predisposes to rampant dental caries and subsequent loss of teeth. Moreover, patients with xerostomia have difficulty with artificial dentures. Dental appliances are extremely disagreeable against dry mucosa and cannot be tolerated by some patients.

Treatment. The basic principles of management are first to eliminate or address any etiological factors such as drugs, calculi and emotional problems. It is also advisable to promote salivary stimulation by using sugar-free chewing gum which is effective and convenient. Salivary substitutes can also be given. The relief that can be given to many sufferers is limited. However, patience and consideration, especially towards the elderly, is as important as clinical intervention. Regular review to monitor the condition of teeth, gingivae and mucosa and to give support and reinforcement of preventive measures is advised.

Hyperplasia of Palatal Glands

An unusual localized hyperplasia or hypertrophy of minor accessory salivary glands in the palate has been described by Giansanti and his associates, although they have also accepted the view that this lesion may represent a benign adenoma of these glands. The cause of this focal enlargement is unknown although, according to these investigators, the following have been reported to result in salivary gland enlargement: (1) endocrine disorders, (2) gout, (3) diabetes mellitus, (4) menopause, (5) hepatic disease, (6) starvation, (7) alcoholism, (8) inflammation, (9) benign lymphoepithelial lesion, (10) Sjögren's syndrome, (11) adiposity, hyperthermia, oligomenorrhea, and parotid swelling syndrome, (12) aglossia-adactylia syndrome, (13) Waldenstrom's macroglobulinemia, (14) uveoparotid fever, (15) Felty's syndrome, (16) certain drugs, and (17) the aging process.

A series of 10 cases has been reported recently by Arafat and her associates. They could also find no associated abnormalities and had to consider the cases idiopathic. Interestingly, one of their cases involved the glands of the retromolar area rather than the palate.

Clinical Features. Palatal gland hyperplasia presents as a small localized swelling, measuring from several millimeters to 1 cm or more in diameter, usually on the hard palate or at the junction of the hard and soft palates. The lesion has an intact surface and is firm, sessile, and normal in color. It is usually asymptomatic and the patient may be unaware of the lesion. Too few cases have been reported to determine whether there is any age or gender predilection.

Histologic Features. The mass appears microscopically as closely packed collections of normal-appearing mucous acini with the usual intermingling of normal ducts. There is no inflammation, no spillage of mucin, and no fibrosis.

Treatment. Because hyperplasia of palatal glands cannot be differentiated clinically from a small salivary gland neoplasm in this area, it is essential that they be excised for microscopic examination. No further treatment is necessary and the condition is not reported to recur.

Atresia

Congenital occlusion or absence of one or more of the major salivary gland ducts is an exceedingly rare condition. When it does occur, it may result in the formation of a retention cyst or produce a relatively severe xerostomia. Such a case has been reported by Foretich and his associates.

Aberrancy

Because of the widespread distribution of normal accessory salivary glands in the oral cavity, it is difficult to define the condition of aberrancy. Since such accessory glands may be found in the lips, palate, buccal mucosa, floor of the mouth, tongue, and retromolar area, aberrancy may be construed as simply that situation in which these glands are found farther than normal from their usual location. In any event, there is no clinical significance to be attached to aberrant salivary glands other than that they may be the site of development of a retention cyst or neoplasm.

Occasional cases have been reported in the literature of salivary gland tissue present within the body of the mandible. It has been found, in many instances, that this glandular tissue anatomically communicated with the normal submaxillary or sublingual gland, generally through a stalk or pedicle of tissue which perforated the lingual cortical plate. For this reason, this

aberrancy of salivary gland tissue probably represents only an extreme example of the condition known as the 'developmental lingual mandibular salivary gland depression' described next.

Developmental Lingual Mandibular Salivary Gland Depression

(Static bone cavity or defect of the mandible, lingual mandibular bone cavity, static bone cyst, latent bone cyst, Stafne cyst or defect)

A Stafne bone cyst is an unusual form of slightly aberrant salivary gland tissue wherein a developmental inclusion of glandular tissue is found within or, more commonly, adjacent to the lingual surface of the body of the mandible within a deep and well-circumscribed depression. The oldest described occurrence of this phenomenon is in a skull dated to the sixth to fourth centuries BC. The phenomenon was first recognized by Stafne in 1942, hence the eponym. However, this cyst has been referred to by many other names, including static bone cavity, defect of the mandible, lingual mandibular bone cavity, static bone cyst, latent bone cyst, and Stafne bone defect. The incidence of occurrence has been reported as 0.1–1.3% in various studies. The general consensus is that this is a congenital defect, although it rarely has been observed in children. These lesions generally may be regarded as developmental rather than pathologic defects. A predilection for males over females seems to exist.

Radiographically, the lesion usually appears as an ovoid radiolucency located between the inferior alveolar canal and the inferior border of the mandible in the region of the second or third molars. It can be differentiated from the traumatic or hemorrhagic bone cyst, which by location almost invariably lies superior to the inferior alveolar canal.

Although the classic Stafne cyst is described in the posterior mandible, an anterior variant presenting as a round or ovoid radiolucency in the area between the central incisors and first premolars exists; however, it is far less common.

Anterior Lingual Depression

It has also been recognized that a similar asymptomatic round or ovoid radiolucency may occur in the anterior segment of the mandible, generally appearing as a rather poorly circumscribed lesion somewhere between the central incisor and the first premolar area. This anterior radiolucency also represents a cavity or depression on the lingual surface of the mandible. It has been reviewed by Miller and Winnick and more recently by Connor. Langlais and his coworkers examined 12 dried mandibles with such anterior depressions and concluded that these might represent either anatomic variants related to the digastric or sublingual fossa or developmental anomalies caused by impingement of the sublingual gland. These are far less common than the posterior lesion (Fig. 1-29).

Complications. A complication occasionally reported in the literature is the development of a true central salivary gland neoplasm from the included salivary gland tissue, but this is rare. This has been discussed in Chapter 3 on Tumors of the Salivary Glands (q.v.) in the section on mucoepidermoid carcinoma.

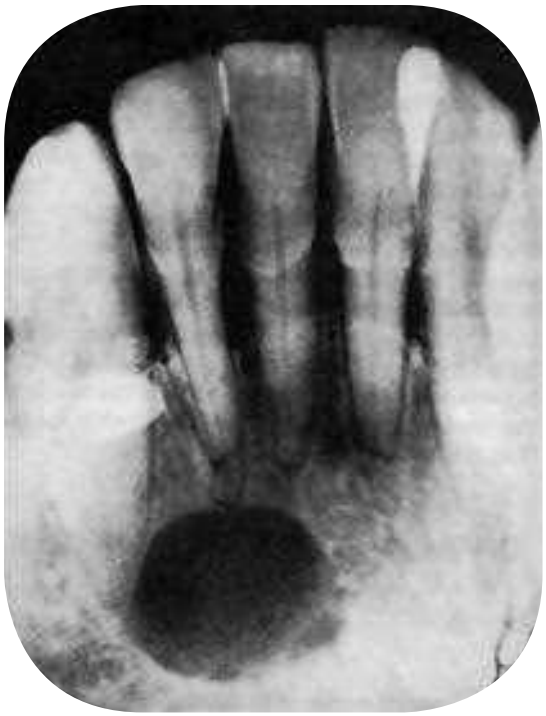


Figure 1-29. Developmental lingual mandibular salivary gland depression of sublingual gland.
(Courtesy of Dr Michael J Freeman).

Treatment. These lesions generally represent benign developmental anomalies that normally do not require any treatment. A complication occasionally reported in the literature is the development of a true salivary gland neoplasm in the tissue associated with one of the cortical defects. Therefore, recording the finding of these lesions and periodically observing them radiographically seem prudent. Clinical or radiographic changes may indicate the need for further investigation.

DEVELOPMENTAL DISTURBANCES IN SIZE OF TEETH

Microdontia

This term is used to describe teeth which are smaller than normal, i.e. outside the usual limits of variation. Three types of microdontia are recognized: (1) true generalized microdontia, (2) relative generalized microdontia, and (3) microdontia involving a single tooth.

In **true generalized microdontia,** all the teeth are smaller than normal. Aside from its occurrence in some cases of pituitary dwarfism, this condition is exceedingly rare. The teeth are reportedly well formed, merely small.

In **relative generalized microdontia,** normal or slightly smaller than normal teeth are present in jaws that are somewhat larger than normal, and there is an illusion of true microdontia.

Since it is well recognized that a person may inherit the jaw size from one parent and the tooth size from the other parent, the role of hereditary factors in producing such a condition is obvious.

Microdontia involving only a single tooth is a rather common condition (Fig. 1-30). It affects most often the maxillary lateral incisor and the third molar. These two teeth are among those that are most often congenitally missing. It is of interest to note; however, that other teeth which are often congenitally absent, the maxillary and mandibular second premolars, seldom exhibit microdontia. Supernumerary teeth; however, are frequently small in size.

One of the common forms of localized microdontia is that which affects the maxillary lateral incisor, a condition that has been called the **'peg lateral'** (Fig. 1-31). Instead of exhibiting parallel or diverging mesial and distal surfaces, the sides converge or taper together incisally, forming a peg-shaped or cone-shaped crown. The root of such a tooth is frequently shorter than usual.

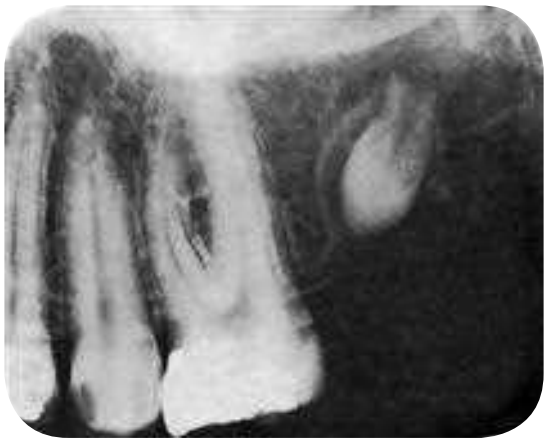

Figure 1-30. Microdontia.
The third molar is small and incompletely formed. The second molar had been previously extracted.

Figure 1-31. Microdontia.
Peg-shaped maxillary lateral incisor *(Courtesy of Dr Gururaj N, CSI Dental College, Madurai, Tamil Nadu).*

Macrodontia

Macrodontia is the opposite of microdontia and refers to teeth that are larger than normal. Such teeth may be classified in the same manner as microdontia.

True generalized macrodontia, the condition in which all teeth are larger than normal, has been associated with pituitary gigantism, but is extremely rare.

Relative generalized macrodontia is somewhat more common and is a result of the presence of normal or slightly larger than normal teeth in small jaws, the disparity in size giving the illusion of macrodontia. As in microdontia, the importance of heredity must be considered.

Macrodontia of single teeth is relatively uncommon, but is occasionally seen. It is of unknown etiology. The tooth may appear normal in every respect except for its size. True macrodontia of a single tooth should not be confused with fusion of teeth, in which, early in odontogenesis, the union of two or more teeth results in a single large tooth.

A variant of this localized macrodontia is the type that is occasionally seen in cases of hemihypertrophy of the face, in which the teeth of the involved side may be considerably larger than those of the unaffected side.

DEVELOPMENTAL DISTURBANCES IN SHAPE OF TEETH

Gemination

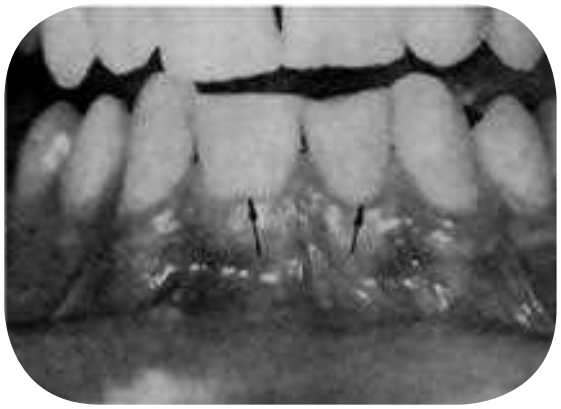
Geminated teeth are anomalies which arise from an attempt at division of a single tooth germ by an invagination, with resultant incomplete formation of two teeth. The structure is usually one with two completely or incompletely separated crowns that have a single root and root canal. It is seen in deciduous as well as permanent dentition, and in some reported cases, appears to exhibit a hereditary tendency. It is not always possible to differentiate between gemination and a case in which there has been fusion between a normal tooth and a supernumerary tooth (Fig. 1-32).

The term 'twinning' has sometimes been used to designate the production of equivalent structures by division resulting in one normal and one supernumerary tooth. These terms, as well as 'fusion' and 'concrescence,' have been discussed by Levitas.

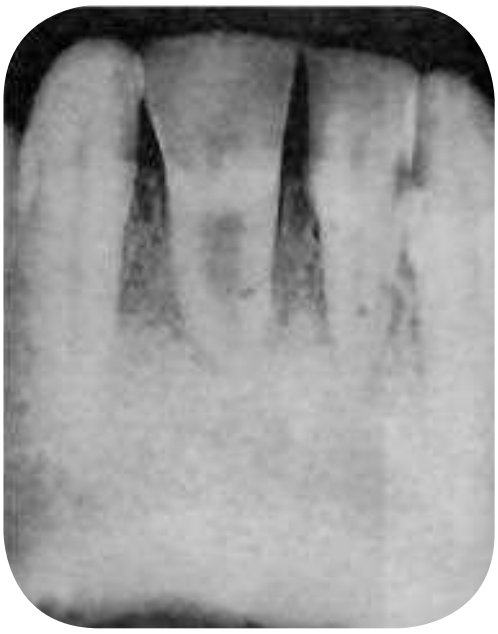
Figure 1-32. Gemination (with unpaired root canals).

Fusion

Fused teeth arise through union of two normally separated tooth germs. Depending upon the stage of development of the teeth at the time of the union, fusion may be either complete or incomplete. It has been thought that some physical force or pressure produces contact of the developing teeth and their subsequent fusion. If this contact occurs early, at least before calcification begins, the two teeth may be completely united to form a single large tooth (Fig. 1-33). If the contact of teeth occurs later, when a portion of the tooth crown has completed its formation, there may be union of the roots only. The dentin; however, is always confluent in cases of true fusion. The tooth may have separate or fused root canals, and the condition is common in the deciduous as well as in the permanent dentition. In fact, Grahnen and Granath have reported that fusion of teeth is more common in the deciduous than in the permanent dentition.



A



B

(A) There has been complete fusion between the mandibular left central and lateral incisors and the right central and lateral incisors. **(B)** The intraoral radiograph showing a common pulp chamber and root canal in each pair of fused teeth.

Figure 1-34. Fusion of right lower central and a supernumerary tooth.
(Courtesy of Dr Spencer Lilly, Meenakshi Ammal Dental College, Chennai).

In addition to affecting two normal teeth, fusion may also occur between a normal tooth and a supernumerary tooth such as the mesiodens or the distomolar (Fig. 1-34). In some cases the condition has been reported to show a hereditary tendency.

The possible clinical problems related to appearance, spacing, and periodontal conditions brought about by fused teeth have been discussed by Mader, who has also reported several illustrative cases.

Concrescence

Concrescence of teeth is actually a form of fusion which occurs after root formation has been completed. In this condition, teeth are united by cementum only. It is thought to arise as a result of traumatic injury or crowding of teeth with resorption of the interdental bone so that the two roots are in approximate contact and become fused by the deposition of cementum between them. Concrescence may occur before or after the teeth have erupted, and although it usually involves only two teeth, there is at least one case on record of union of three teeth by cementum.

The diagnosis can frequently be established by radiographic examination. Since with fused teeth the extraction of one may result in the extraction of the other, it is desirable that the dentist be forewarned of the condition and advices the patient.

Dilaceration

The term 'dilaceration' refers to an angulation, or a sharp bend or curve, in the root or crown of a formed tooth (Fig. 1-35). The condition is thought to be due to trauma during the period in which the tooth is forming, with the result that the position of the calcified portion of the tooth is changed and the remainder of the tooth is formed at an angle. The curve or bend may occur anywhere along the length of the tooth, sometimes at the cervical portion, at other times midway along the root or even just at the apex of the root, depending upon the amount of root formed when the injury occurred. It has been emphasized by van Gool that such an

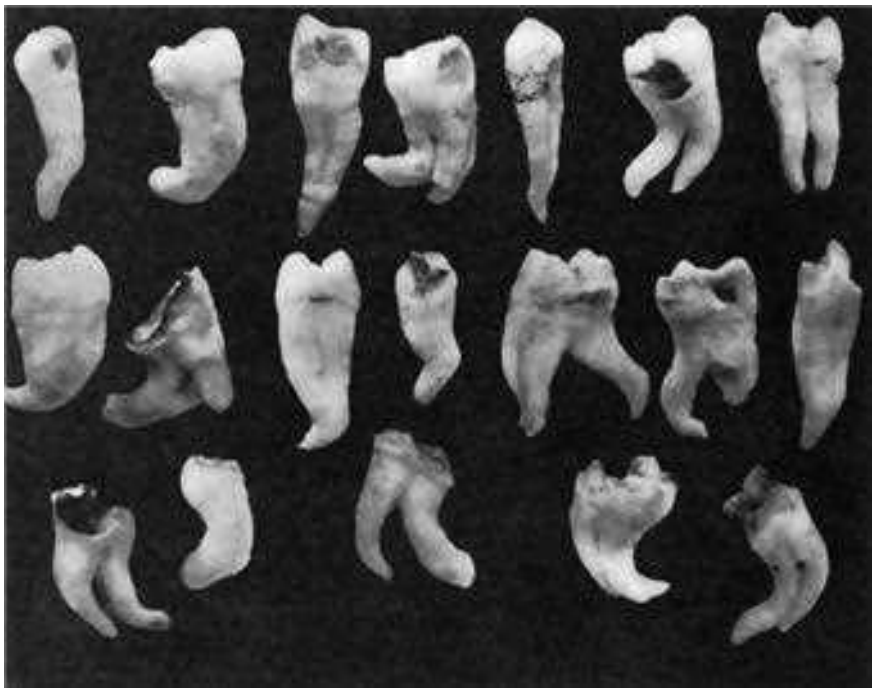

Figure 1-35. Dilaceration.
Examples of various types of curves and angles involving roots of teeth.

injury to a permanent tooth, resulting in dilaceration, often follows traumatic injury to the deciduous predecessor in which that tooth is driven apically into the jaw. He has discussed this condition in detail, reporting 18 such cases.

Since dilacerated teeth frequently present difficult problems at the time of extraction if the operator is unaware of the condition, the need for preoperative radiographs before any surgical procedures are carried out is self-evident.

Talon Cusp

The talon cusp, an anomalous structure resembling an eagle's talon, projects lingually from the cingulum areas of a maxillary or mandibular permanent incisor. This cusp blends smoothly with the tooth except that there is a deep developmental groove where the cusp blends with the sloping lingual tooth surface (Fig. 1-36). It is composed of normal enamel and dentin and contains a horn of pulp tissue.

This anomaly has been discussed by Mellor and Ripa, who have emphasized the problems it poses for the patient in terms of esthetics, caries control, and occlusal accommodation. They have recommended prophylactically restoring the groove to prevent caries. If there is occlusal interference, it should be removed but exposure of the pulp horn, necessitating endodontic therapy, is almost certain to occur. Fortunately, this anomaly is quite uncommon among the general population. However, it has been reported by Gardner and Girgis that it appears to be more prevalent in persons with the **Rubinstein-Taybi syndrome** (developmental retardation, broad thumbs and great toes, characteristic facial features, delayed or incomplete descent of testes in males, and stature, head

Figure 1-36. Talon cusp.
(Courtesy of Dr Spencer Lilly D, Meenakshi Ammal Dental College, Chennai).

circumference, and bone age below the fiftieth percentile). The talon cusp has not been reported as an integral part of any other syndrome, although Mader, in his thorough review, suggested that it may be associated with other somatic and odontogenic anomalies.

Dens in Dente

(Dens invaginatus, dilated composite odontome)

The 'dens in dente' is a developmental variation which is thought to arise as a result of an invagination in the surface of tooth crown before calcification has occurred (Fig. 1-37). Several causes of this condition have been proposed. These include an increased localized external pressure, focal growth

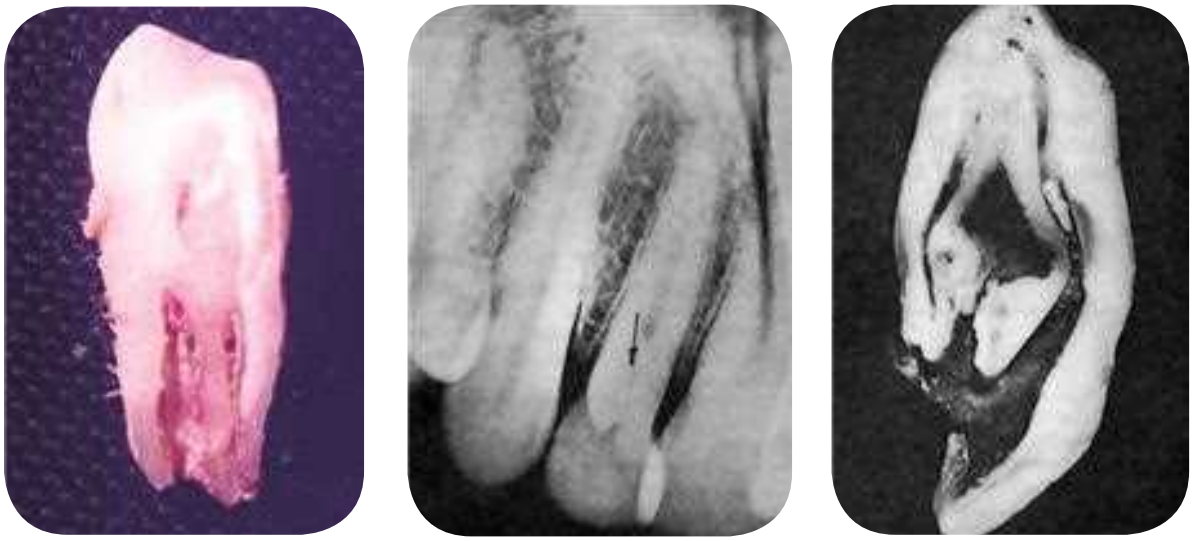

Figure 1-37. Dens in dente.
(A) Dens invaginatus. **(B)** A slight invagination may be seen in the lingual pit area of the maxillary lateral incisor on the radiograph. **(C)** The ground section of tooth represents a severe form of 'dens in dente' and illustrates how the anomaly may resemble a tooth within a tooth (*Courtesy of Dr Twinkle S Prasad*).

retardation, and focal growth stimulation in certain areas of the tooth bud.

The permanent maxillary lateral incisors are the teeth most frequently involved, and in the majority of cases the 'dens in dente' appears to represent simply an accentuation in the development of the lingual pit (Fig. 1-37A). The maxillary central incisors are sometimes involved, and the condition is frequently bilateral. Oehlers has presented an excellent discussion of this condition and emphasized that not only are posterior teeth sometimes affected but also an analogous form of invagination occasionally occurs in the roots of teeth. This radicular variety of 'dens in dente' has been discussed by Bhatt and Dholakia, who pointed out that the radicular invagination usually results from an infolding of Hertwig's sheath and takes its origin within the root after development is complete.

The cases that have been reported in the literature indicate that the condition is fairly common and that an extremely wide range in degree of variation can exist. The term 'dens in dente,' originally applied to a severe invagination that gave the appearance of a tooth within a tooth, is actually a misnomer, but it has continued in usage (Fig. 1-37B). In the mild form, there is a deep invagination in the lingual pit area, which may not be evident clinically. Radiographically, it is recognized as a pear-shaped invagination of enamel and dentin with a narrow constriction at the opening on the surface of the tooth and closely approximating the pulp in its depth. Food debris may become packed in this area with resultant caries and infection of the pulp, occasionally even before the tooth has completely erupted. The more severe forms of 'dens in dente' may exhibit an invagination that extends nearly to the apex of the root, and these present a bizarre radiographic picture (Fig. 1-38),

Figure 1-38. Dens in dente.
A nearly complete invagination in a maxillary lateral incisor.

reflecting a severe disturbance in the normal anatomic and morphologic structure of the teeth.

It is important to realize that this condition, particularly in its mild form, is fairly common. The clinical studies of Amos have shown that if the minor invaginations are included, the incidence may be as high as 5% of all patients examined (Table 1-10). The more severe forms; however, are much less common.

Table 1-10: Investigations on the prevalence of dens invaginatus

Author/Country	Year	Sample	Frequency
Muhlreiter(Austria)	1873	500 extracted lateral maxillaryincisors (histological investigation)	2.8% of teeth

To prevent caries, pulp infection, and premature loss of the tooth, the condition must be recognized early and the tooth prophylactically restored. Fortunately, the defect may be recognized radiographically even before the teeth erupt.

Dens Evaginatus

(Occlusal tuberculated premolar, Leong's premolar, evaginated odontome, occlusal enamel pearl)

The dens evaginatus is a developmental condition that appears clinically as an accessory cusp or a globule of enamel on the occlusal surface between the buccal and lingual cusps of premolars, unilaterally or bilaterally, although it has been reported to occur rarely on molars, cuspids, and incisors (Fig. 1-39). It has been thought to develop only in persons of Mongoloid ancestry: Chinese, Japanese, Filipinos, Eskimos, and American Indians. Its prevalence in a group of 2,373 Chinese schoolchildren in Singapore, reported by Yip, was 2.2%. However, Palmer has reported a series of cases in Caucasians in England.

The pathogenesis of the lesion is thought to be the proliferation and evagination of an area of the inner enamel epithelium and subjacent odontogenic mesenchyme into the dental organ during early tooth development. Thus, it has been considered to be the antithesis of the mechanism of development of the dens in dente or dens invaginatus.

The clinical significance of the condition is similar to that of the talon cusp, which it may physically resemble. This 'extra' cusp may contribute to incomplete eruption, displacement of teeth and/or pulp exposure with subsequent infection following occlusal wear or fracture. This phenomenon has been discussed by Senia and Regezi, who have reported periapical infection of caries-free premolars affected by dens evaginatus.

Figure 1-39. Dens evaginatus.

Taurodontism

The term 'taurodontism' was originated by Sir Arthur Keith in 1913 to describe a peculiar dental anomaly in which the body of the tooth is enlarged at the expense of the roots. The term means 'bull-like' teeth and its usage is derived from the similarity of these teeth to those of ungulate or cud-chewing animals. Shaw further classified taurodont teeth into hypotaurodont, mesotaurodont, and hypertaurodont forms, with hypertaurodontism being the extreme form in which the bifurcation or trifurcation occurs near the apices of the roots and hypotaurodontism being the mildest form.

A variety of possible causes of taurodontism have been enumerated by Mangion as follows: (1) a specialized or retrograde character, (2) a primitive pattern, (3) a mendelian recessive trait, (4) an atavistic feature, and (5) a mutation resulting from odontoblastic deficiency during dentinogenesis of the roots. Hammer and his associates believe that the taurodont is caused by failure of Hertwig's epithelial sheath to invaginate at the proper horizontal level. The heritability of this condition requires further study, although after finding 11 cases of taurodontism among members of three families, Goldstein and Gottlieb have stated that the condition appears to be genetically controlled and familial in nature.

This condition is of anthropologic interest in as much as it has been found commonly in fossil hominids, especially in the Neanderthal man, with a very high prevalence during the neolithic period. At one time it was thought to be confined to these early populations, but it is now known to be widespread in many modern races. Hammer and his associates have discussed these anthropologic aspects in detail, while Blumberg and his coworkers have carried out a biometric study of the condition. A case of taurodontism occurring concomitantly with amelogenesis imperfecta has been reported by Crawford. In addition, it has been reported that many patients with the Klinefelter syndrome (males whose sex chromosome constitution includes one or more extra X chromosomes) exhibit taurodontism, but it is not a constant feature of this syndrome. For this reason, Gardner and Girgis have recommended that male patients exhibiting taurodontism should have chromosomal studies performed, especially if there is any nonspecific diagnosis of mental retardation and if the patient has a tall, thin appearance with long arms and legs and a prognathic jaw.

Clinical Features. Taurodontism may affect either the deciduous or permanent dentition, although permanent tooth involvement is more common. The teeth involved are almost invariably molars, sometimes only a single tooth, at other times several molars in the same quadrant. The condition may be unilateral or bilateral or may exhibit any combination of quadrant involvement. The teeth themselves have no remarkable or unusual morphologic clinical characteristics.

Radiographic Features. The unusual nature of this condition is best visualized on the radiograph. Involved teeth frequently tend to be rectangular in shape rather than taper toward the roots. The pulp chamber is extremely large with a much greater apico-occlusal height than normal. In addition, the pulp lacks the usual constriction at the cervical of the tooth and the roots are exceedingly short. The bifurcation or trifurcation may be only a few millimeters above the apices of the roots (Fig. 1-41). This radiographic picture is quite striking and characteristic.

Treatment. No special treatment is necessary for this anomaly.

Supernumerary Roots

This developmental condition is not uncommon and may involve any tooth (Fig. 1-42). Teeth that are normally single-rooted, particularly the mandibular bicuspids and cuspids, often have two roots. Both maxillary and mandibular molars, particularly third molars, also may exhibit one or more supernumerary roots. This phenomenon is of considerable significance in exodontia, for one of these roots may be broken off during extraction and, if unrecognized and allowed to remain in the alveolus, may be the source of future infection.

DEVELOPMENTAL DISTURBANCES IN NUMBER OF TEETH

Anodontia

True anodontia, or congenital absence of teeth, may be of two types, total and partial. Total anodontia, in which all teeth are missing, may involve both deciduous and permanent dentition (Fig. 1-43). This is a rare condition; when it occurs, it is frequently associated with a more generalized disturbance, hereditary ectodermal dysplasia (q.v.).

Induced or false anodontia occurs as a result of extraction of all teeth, while the term pseudoanodontia is sometimes applied to multiple unerupted teeth. The condition under discussion here is a true failure of odontogenesis and should not be confused with false or pseudoanodontia.

True partial anodontia (hypodontia or oligodontia) involves one or more teeth and is a rather common condition (Fig. 1-42). Although any tooth may be congenitally missing, there is a tendency for certain teeth to be missing more frequently than others (Table 1-11). Studies on the frequency of missing third molars have shown this tooth to be congenitally absent in as many as 35% of all subjects examined, with a frequent absence of all four third molars in the same person (Table 1-12). Other studies have shown that the maxillary lateral incisors and maxillary or mandibular second premolars are commonly missing, often bilaterally (Fig. 1-44). In severe partial anodontia, the bilateral absence of corresponding teeth may be striking. An outstanding review of this subject has been reported by Graber, who showed that the overall frequency of patients with congenitally missing teeth (excluding third molars) has ranged from 1.6–9.6% in various series of studies in different countries.

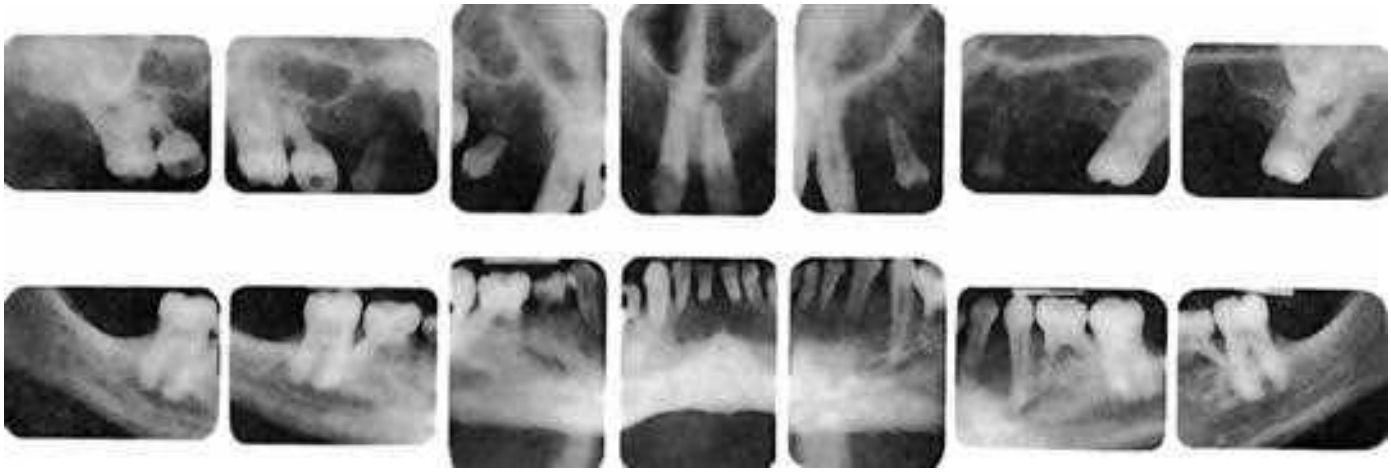

Figure 1-43. Anodontia.
There is congenital absence of nearly all permanent teeth with retention of many deciduous teeth.

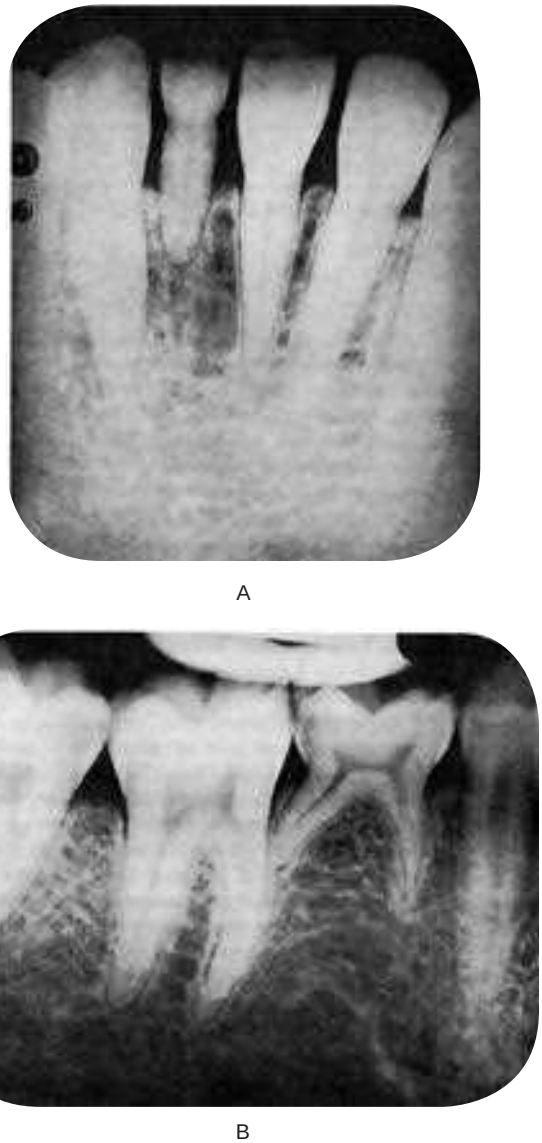
Congenitally missing deciduous teeth are uncommon but, when occurring, usually involve the maxillary lateral incisor. Mandibular lateral incisors and mandibular cuspids may also be missing, according to the study of Grahnen and Granath. Their studies also showed a close correlation between congenitally missing deciduous teeth and their permanent successors; suggesting, at least in some instances, a genetic factor.

Although the etiology of a single missing tooth is unknown, a familial tendency for this defect is present in many instances. Graber, in reviewing congenital absence of teeth, reported the accumulating evidence that it is actually the result of one or more point mutations in a closely linked polygenic system, most often transmitted in an autosomal dominant pattern with incomplete penetrance and variable expressivity. Some investigators believe cases of missing third molars to be an evidence of an evolutionary trend towards fewer teeth. Hereditary ectodermal dysplasia may be associated with partial anodontia, and in these instances the few teeth that are present may be deformed or misshapen, frequently cone-shaped.

Occasionally one sees children with teeth of one quadrant or both quadrants on the same side missing owing to X-ray radiation of the face at an early age. Tooth buds are extremely sensitive to X-ray radiation and may be destroyed completely by relatively low dosages. Teeth already forming and partially calcified may be stunted by X-ray radiation.

Supernumerary Teeth

A supernumerary tooth may closely resemble the teeth of the group to which it belongs, i.e. molars, premolars, or anterior teeth, or it may bear little resemblance in size or shape to the teeth with which it is associated. It has been suggested that supernumerary teeth develop from a third tooth bud arising from the dental lamina near the permanent tooth bud, or



A

B

Figure 1-44. Partial anodontia.
The mandibular permanent left central incisor is congenitally missing. The deciduous incisor is retained **(A)**. There is congenital absence of the mandibular second bicuspid with retention of the deciduous molar **(B)**.

possibly from splitting of the permanent bud itself. Another theory, well supported in the literature, is the hyperactivity theory, which suggests that supernumeraries are formed as a result of local, independent, conditioned hyperactivity of the dental lamina. In some cases there appears to be a hereditary tendency for the development of supernumerary teeth.

A supernumerary tooth is an additional entity to the normal series and is seen in all the quadrants of the jaw. The etiology of supernumerary teeth is not completely understood. The anomaly does not follow a simple mendelian pattern. In a survey of 2,000 schoolchildren, Brook found that supernumerary teeth were present in 0.8% of primary dentition and in 2.1% of permanent dentition. Occurrence may be single or multiple, unilateral or bilateral, erupted or impacted, and in one or both jaws. Multiple supernumerary teeth are rare in individuals with no other associated diseases or syndromes. The conditions commonly associated with an increased prevalence of supernumerary teeth include cleft lip and palate, cleidocranial dysplasia, and Gardner syndrome. Supernumerary teeth associated with cleft lip and palate result from fragmentation of the dental lamina during cleft formation. The frequency of supernumerary permanent teeth in the cleft area in children with unilateral cleft lip or palate or both was found to be 22.2%. The frequency of supernumeraries in patients with cleidocranial dysplasia ranged from 22% in the maxillary incisor region to 5% in the molar region. While there is no significant gender predilection in primary supernumerary teeth, males are affected approximately twice as frequently as females in the permanent dentition.

Classification. Supernumerary teeth are classified according to morphology and location. In the primary dentition, morphology is usually normal or conical. There is a greater variety of forms presenting in the permanent dentition.

Four different morphological types of supernumerary teeth have been described:

- Conical
- Tuberculate
- Supplemental
- Odontome.

Conical. This small peg-shaped conical tooth is supernumerary and most commonly found in the permanent dentition. It develops with root formation ahead of or at an equivalent stage to that of permanent incisors and usually presents as a mesiodens. It may occasionally be found high and inverted into the palate or in a horizontal position. In most cases; however, the long axis of the tooth is normally inclined. The conical supernumerary can result in rotation or displacement of the permanent incisor, but rarely delays eruption.

Tuberculate. The tuberculate type of supernumerary possesses have more than one cusp or tubercle. It is frequently described as barrel-shaped and may be invaginated. Root formation is delayed compared to that of the permanent incisors. Tuberculate supernumeraries are often paired and are commonly located on the palatal aspect of the central incisors. They rarely erupt and are frequently associated with delayed eruption of the incisors.

Supplemental. The supplemental supernumerary refers to a duplication of teeth in the normal series and is found at the end of a tooth series. The most common supplemental tooth is the permanent maxillary lateral incisor, but supplemental premolars and molars also occur. The majority of supernumeraries found in the primary dentition are of the supplemental type and seldom remain impacted.

Odontome. Odontome has been listed as the fourth category of supernumerary teeth by Howard. However, this category is not universally accepted. The term 'odontoma' refers to any tumor of odontogenic origin. Most authorities; however, accept the view that the odontoma represents a hamartomatous malformation rather than a neoplasm. The lesion is composed of more than one type of tissue and consequently has been called a composite odontoma. Two separate types have been described, the diffuse mass of dental tissue which is totally disorganized is known as a **complex composite odontoma,** whereas the malformation which bears some superficial anatomical similarity to a normal tooth is referred to as a **compound composite odontoma.**

Gardner syndrome is an interesting disease complex, reviewed by Fader and his associates and by Duncan and his associates. It is also characterized by the occurrence of multiple impacted supernumerary teeth. This syndrome consists of: (1) multiple polyposis of the large intestine, (2) osteomas of the bones, including long bones, skull, and jaws, (3) multiple epidermoid or sebaceous cysts of the skin, particularly on the scalp and back, (4) occasional occurrence of desmoid tumors, and (5) the impacted supernumerary and permanent teeth (Figs. 1-45, 1-46).

It is due to a single pleiotropic gene and has an autosomal dominant pattern of inheritance, with complete penetrance and variable expression. Indicative of its inheritability is a report by Watne and his associates, who studied 280 patients from 11 families with Gardner syndrome. They found that 126 of the 280, or 45% of the patients at risk, exhibited some part of the syndrome. Significantly, the intestinal polyps in this disease were premalignant, and polyps were found to be present in 85 of the 126 patients. In 41 of the patients, carcinoma of the intestine subsequently developed and only 27% survived. This disease is of interest to the dental profession, since the impacted teeth and osteomas of the jaws may lead to early diagnosis of the entire syndrome.

Predeciduous Dentition

(Premature eruption, natal teeth, neonatal teeth)

Infants occasionally are born with structures which appear to be erupted teeth, usually in the mandibular incisor area. These structures must be distinguished from true deciduous teeth, or the so-called natal teeth described by Massler, which may have erupted by the time of birth. The predeciduous teeth have been described as hornified epithelial structures without roots, occurring on the gingiva over the crest of the ridge, which may be easily removed. Prematurely erupted true deciduous teeth, of course, are not to be extracted. These predeciduous

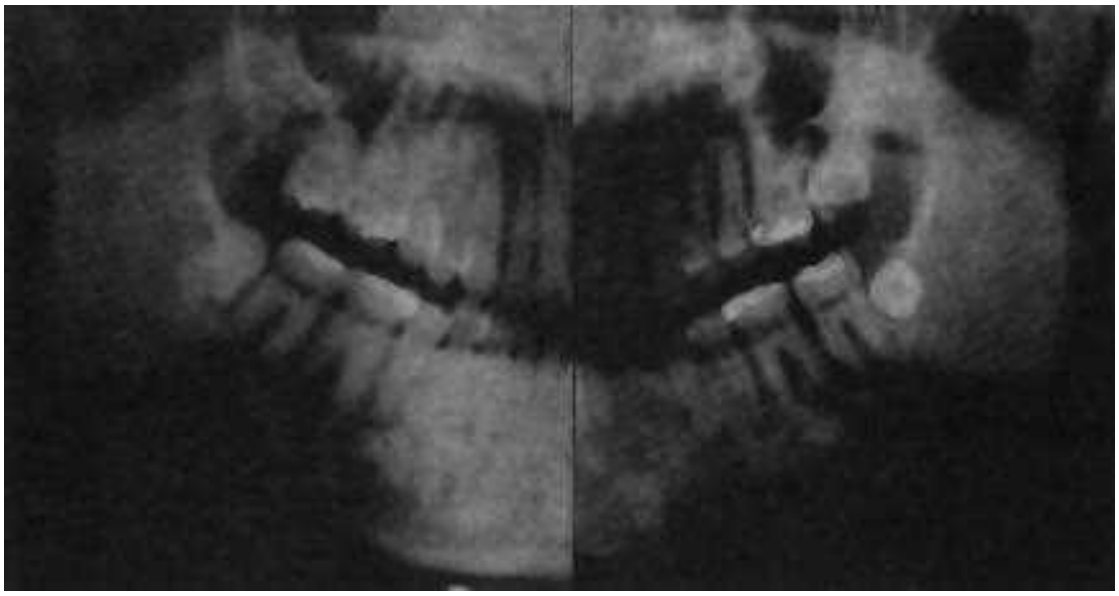


Figure 1-45. Gardner syndrome.
Multiple diffuse osteomas of the maxilla and mandible are present, although the patient does not have supernumerary teeth *(Courtesy of Dr Wesley P Titterington, Dr William M Wade, Jr).*

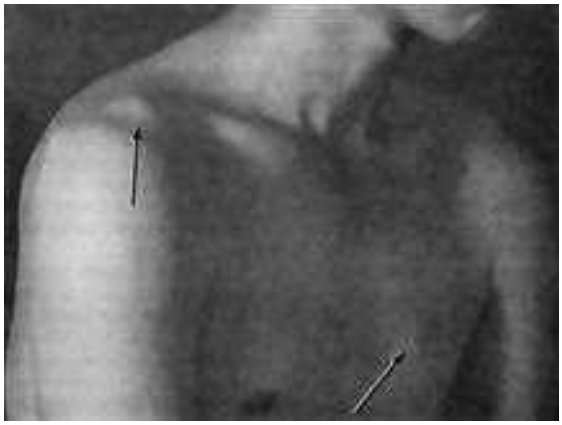

Figure 1-46. Gardner syndrome.
Sebaceous cysts of the skin are present over the shoulder and chest *(Courtesy of Dr Wesley P Titterington, Dr William M Wade, Jr).*

teeth have been thought to arise either from an accessory bud of the dental lamina ahead of the deciduous bud or from the bud of an accessory dental lamina.

The concept of predeciduous teeth has been questioned by Spouge and Feasby; however. They are probably correct in believing that considering predeciduous teeth as an entity is a misinterpretation and that such structures, present at birth, undoubtedly represent only the dental lamina cyst of the newborn (q.v.). This cyst does commonly project above the crest of the ridge, is white in color and is packed within keratin, so that it appears 'hornified' and can be easily removed.

Post Permanent Dentition

A few cases are recorded of persons who have had all their permanent teeth extracted and yet have subsequently erupted several more teeth, particularly after the insertion of a full denture. The majority of such cases are the result of delayed eruption of retained or embedded teeth. A small number of cases; however, do appear to represent examples of a post permanent or third dentition, although it probably would be better to classify these as simply multiple supernumerary unerupted teeth, since they probably develop from a bud of the dental lamina beyond the permanent tooth germ.

DEVELOPMENTAL DISTURBANCES IN STRUCTURE OF TEETH

Amelogenesis Imperfecta

(Hereditary enamel dysplasia, hereditary brown enamel, hereditary brown opalescent teeth)

A complex inheritance pattern gives rise to amelogenesis imperfecta (AI), a structural defect of the tooth enamel. It may be differentiated into three main groups: **hypoplastic (HP), hypocalcified (HC),** and **hypomature (HM),** depending on the clinical presentation of the defects and the likely stage of enamel formation that is primarily affected (Table 1-13). Each main clinical group of AI may be further divided into several subgroups depending on the mode of inheritance, as well as the clinical appearance of the defective enamel, although in some cases, overlapping clinical features may make distinction difficult. The prevalence of this condition has been

Table 1-13: Classification of amelogenesis imperfecta according to Witkop (1989)

Type I	Hypoplastic
IA	Hypoplastic, pitted autosomal dominant
IB	Hypoplastic, local autosomal dominant

IVB	AD Hypoplastic-hypomaturation with taurodontism The gene defect for this AI type is unknown at this time

Source: Modified from the website data of School of Dentistry, University of North Carolina, 2005.

estimated to range from (1 in 718) to (1 in 14,000), depending on the population studied. Hypoplastic AI represents 60–73% of all cases, hypomaturation AI represents 20–40%, and hypocalcification AI represents 7%. Disorders of the enamel epithelium also can cause alterations in the eruption mechanism, resulting in the anterior open bite.

Molecular Genetic Studies. Molecular genetic studies have shown that the etiology of AI is related to the alteration of genes involved in the process of formation and maturation of the enamel (Table 1-14). Although the genetic origin of the autosomal forms is less understood, analysis of X-linked AI has shown the defective gene for this specific AI type to be closely linked to the locus **DXS85 at Xp22**. Interestingly, this also has been identified as the general location of the human gene for **amelogenin,** the principal protein in developing enamel. Information from molecular genetic studies will ultimately lead to identification of the genes involved in normal and pathological enamel formation and provide a basis for definitive diagnostic tests.

Radiographic Features. The overall shape of the tooth may or may not be normal, depending upon the amount of enamel present on the tooth and the amount of occlusal and incisal wear. The enamel may appear totally absent on the radiograph, or when present, may appear as a very thin layer, chiefly over the tips of the cusps and on the interproximal surfaces (Fig. 1-47). In other cases the calcification of the enamel may be so affected that it appears to have the same approximate radiodensity as the dentin, making differentiation between the two difficult (Fig. 1-48).

Histologic Features. The general histologic features of the enamel also parallel the general type of amelogenesis imperfecta that has been diagnosed. There is a disturbance in the differentiation or viability of ameloblasts in the hypoplastic type, and this is reflected in defects in matrix formation up to and including total absence of matrix. In the hypocalcification types there are defects of matrix structure and of mineral deposition. Finally, in the hypomaturation types there are alterations in enamel rod and rod sheath structures.

Treatment. There is no treatment except for improvement of cosmetic appearance. However, in some cases, these teeth do not appear markedly abnormal to the casual observer.

Environmental Enamel Hypoplasia

Enamel hypoplasia may be defined as an incomplete or defective formation of the organic enamel matrix of teeth.

(Courtesy of Dr Bijo Alexander).

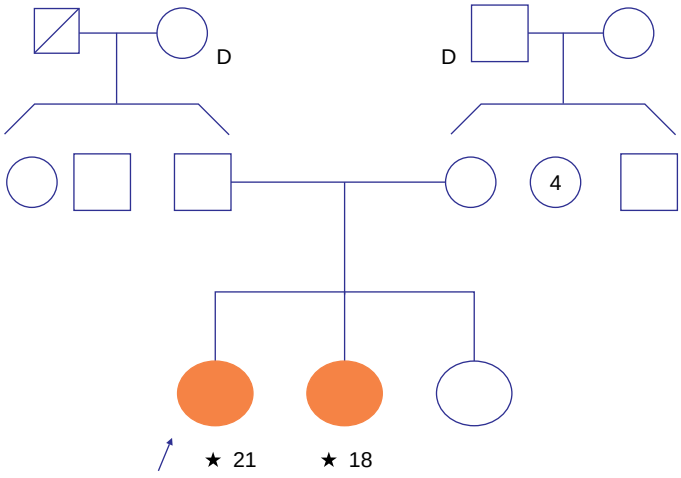

Figure 1-48. Hypocalcified AI with autosomal recessive inheritance pattern.

Two basic types of enamel hypoplasia exist: (1) a hereditary type, described previously under amelogenesis imperfecta, and (2) a type caused by environmental factors. In the hereditary type, both the deciduous and permanent dentitions usually are involved and generally only the enamel is affected. In contrast, when the defect is caused by environmental factors, either dentition may be involved and sometimes only a single tooth; both enamel and dentin are usually affected, at least to some degree.

Many studies, both experimental and clinical, have been carried out in an attempt to determine the cause and nature of environmental enamel hypoplasia. It is known that a number of different factors, each capable of producing injury to the ameloblasts, may give rise to the condition, including: (1) nutritional deficiency (vitamins A, C, and D); (2) exanthematous diseases (e.g. measles, chickenpox, scarlet fever); (3) congenital syphilis; (4) hypocalcemia; (5) birth injury, prematurity, Rh hemolytic disease; (6) local infection or trauma; (7) ingestion of chemicals (chiefly fluoride); and (8) idiopathic causes.

In mild environmental hypoplasia, there may be only a few small grooves, pits, or fissures on the enamel surface (Fig. 1-49). If the condition is more severe, the enamel may exhibit rows of deep pits arranged horizontally across the surface of the tooth (Fig. 1-50). There may be only a single row of such pits or several rows indicating a series of injuries. In the most severe cases, a considerable portion of enamel may be absent, suggesting a prolonged disturbance in the function of the ameloblasts.

Hypoplasia results only if the injury occurs during the time the teeth are developing, or more specifically, during the formative stage of enamel development. Once the enamel has calcified, no such defect can be produced. Thus, knowing the chronologic development of the deciduous and permanent teeth,

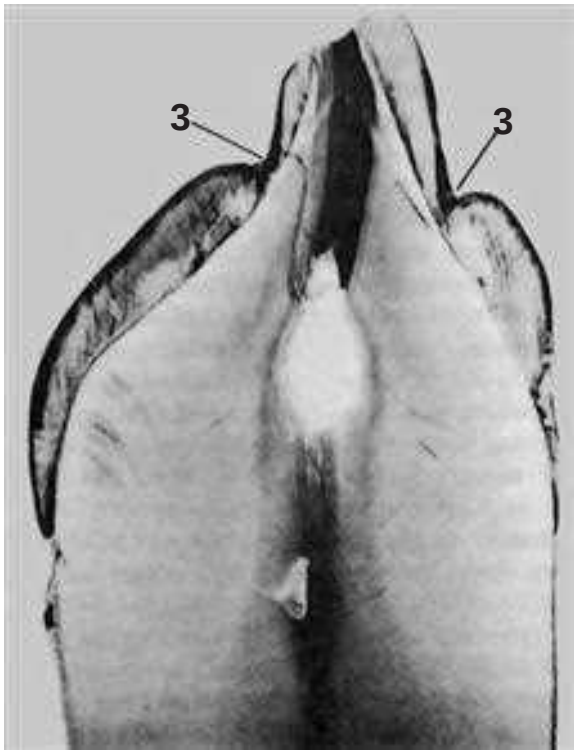

Figure 1-49. Enamel hypoplasia, environmental type.
The ground section of tooth shows a pit like defect on both the labial and lingual surfaces (1).

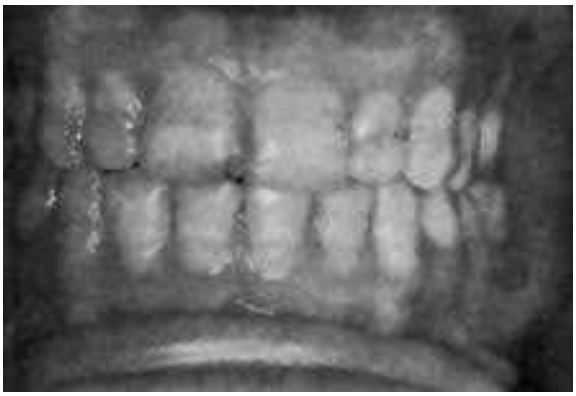

Figure 1-50. Enamel hypoplasia, environmental type.
Several rows of irregular, stained pits cover much of the labial surfaces of the teeth.

it is possible to determine from the location of the defect on the teeth the approximate time at which the injury occurred.

Hypoplasia due to Nutritional Deficiency and Exanthematous Fevers. Some studies have shown that rickets during the time of tooth formation is the most common known cause of enamel hypoplasia. For example, in a series of rachitic children reported by Shelling and Anderson, 43% of teeth showed hypoplasia. At present; however, rickets is not a prevalent disease. Deficiencies of vitamin A and C have also been named as causes.

Some studies have indicated that the exanthematous diseases, including measles, chickenpox and scarlet fever, are etiologic factors, but other investigators have been unable to confirm this finding. In general, it might be stated that any serious nutritional deficiency or systemic disease is potentially capable of producing enamel hypoplasia, since the ameloblasts are one of the most sensitive groups of cells in the body in terms of metabolic function.

The type of hypoplasia occurring from these deficiency or disease states is usually of the pitting variety described above. Since the pits tend to stain, the clinical appearance of the teeth may be very unsightly.

Clinical studies indicate that most cases of enamel hypoplasia involve those teeth that form within the first year after birth, although teeth that form somewhat later may be affected. Thus the teeth most frequently involved are the central and lateral incisors, cuspids, and first molars. Since the tip of the cuspid begins formation before the lateral incisor, some cases involve only the central incisor, cuspid, and first molar. Premolars and second and third molars are seldom affected, since their formation does not begin until about the age of three years or later.

There has been considerable controversy as to whether there is any relation between enamel hypoplasia and dental caries experience, and clinical reports have given conflicting results. It is most reasonable to assume that the two are not related, although hypoplastic teeth do appear to decay at a somewhat more rapid rate once caries has been initiated.

Enamel Hypoplasia due to Congenital Syphilis. The hypoplasia due to congenital syphilis is most frequently not of the pitting variety previously described but instead presents a characteristic, almost pathognomonic, appearance. This hypoplasia involves the maxillary and mandibular permanent incisors and the first molars. The anterior teeth affected are sometimes called 'Hutchinson's teeth,' while the molars have been referred to as 'mulberry molars' (Moon's molars, Fournier's molars).

Characteristically, the upper central incisor is 'screw-driver' shaped, the mesial and distal surfaces of the crown tapering and converging toward the incisal edge of the tooth rather than toward the cervical margin (Fig. 1-51). In addition, the incisal edge is usually notched. The mandibular central and lateral incisors may be similarly involved, although the maxillary lateral incisor may be normal. The cause of the tapering and notching of the maxillary incisor has been explained on the basis of the absence of the central tubercle or calcification center. The crowns of the first molars in congenital syphilis are irregular and the enamel of the occlusal surface and occlusal third of the tooth appears to be arranged in an agglomerate mass of globules rather than in well-formed cusps (Fig. 1-52). The crown is narrower on the occlusal surface than at the cervical margin.

It has been reported by Fiumara and Lessell that between 1958 and 1969 there has been over a 200% increase in reported cases of primary and secondary syphilis in the United States

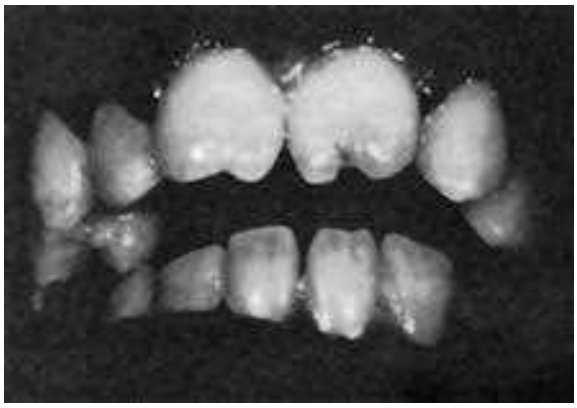

Figure 1-51. Enamel hypoplasia of congenital syphilis (mulberry molars).
The mandibular first molars show many small globular masses of enamel on the occlusal portion of the tooth.

Figure 1-52. Enamel hypoplasia of congenital syphilis (Hutchinson's incisors).
There is characteristic notching of the incisal edges of the maxillary central incisors as well as tapering of the mesial and distal surfaces toward the incisal portion.

and that, consequently, congenital syphilis in children under one year of age increased 117% during the 10–year period from 1960 to 1969. Investigating 271 patients with congenital syphilis, they found that over 63% had Hutchinson's teeth but they pointed out that this may not be the true incidence, since some of the patients had their teeth extracted. In addition, approximately 65% of this group of patients with congenital syphilis also had the characteristic 'mulberry molars.'

Not all patients with congenital syphilis will exhibit these dental findings. Also, occasional patients will appear to have Hutchinson's teeth without having a history of congenital syphilis. Therefore, one must not be hasty in making the diagnosis of syphilis, particularly in the absence of the other conditions of Hutchinson's triad (q.v.).

Enamel Hypoplasia due to Hypocalcemia. Tetany, induced by a decreased level of calcium in the blood, may result from several conditions, the most common being vitamin D deficiency and parathyroid deficiency (parathyroprivic tetany). In tetany the serum calcium level may fall as low as 6–8 mg per 100 ml, and at this level enamel hypoplasia is frequently produced in teeth developing concomitantly. This type of enamel hypoplasia is usually of the pitting variety and thus does not differ from that resulting from a nutritional disturbance or exanthematous disease.

Hypoplasia due to Birth Injuries. The neonatal line or ring, described by Schour in 1936 and present in deciduous teeth and first permanent molars, may be thought of as a type of hypoplasia because there is a disturbance produced in the enamel and dentin, which is indicative of trauma or change of environment at the time of birth. In traumatic births the formation of enamel may even cease at this time. In addition, Miller and Forrester have reported a clinical study with evidence that enamel hypoplasia is far more common in prematurely born children than in normal term infants. In this same study they not only drew attention to the widely recognized staining of teeth in children who had suffered from Rh hemolytic disease at birth (q.v.) but also reported enamel hypoplasia in these cases. Grahnen and Larsson have also shown an increased incidence of enamel hypoplasia in premature children, but interestingly no differences in caries incidence between this group and a control group of children.

Although the literature indicates that most cases of enamel hypoplasia of deciduous teeth involve enamel formed after birth, it is seen also in prenatal enamel. In such instances a gastrointestinal disturbance or some other illness in the mother may be responsible.

Enamel Hypoplasia due to Local Infection or Trauma. A type of hypoplasia occasionally seen is unusual in that only a single tooth is involved, most commonly one of the permanent maxillary incisors or a maxillary or mandibular premolar. There may be any degree of hypoplasia, ranging from a mild, brownish discoloration of the enamel to a severe pitting and irregularity of the tooth crown (Fig. 1-53). These single teeth are frequently referred to as **'Turner's teeth,'** and the condition is called 'Turner's hypoplasia.'

Figure 1-53. Enamel hypoplasia due to local infection (Turner's hypoplasia). The crown of the unerupted bicuspid is extremely irregular, owing to disruption of the forming tooth by infection through the preceding deciduous tooth *(Courtesy of Dr Ralph E McDonald).*

If a deciduous tooth becomes carious during the period when the crown of the succeeding permanent tooth is being formed, a bacterial infection involving the periapical tissue of this deciduous tooth may disturb the ameloblastic layer of the permanent tooth and result in a hypoplastic crown. The severity of this hypoplasia will depend upon the severity of the infection, the degree of tissue involvement, and the stage of permanent tooth formation during which the infection occurred.

A similar type of hypoplasia may follow trauma to a deciduous tooth, particularly when the deciduous tooth has been driven into the alveolus and has disturbed the permanent tooth bud. If this permanent tooth crown is still being formed, the resulting injury may be manifested as a yellowish or brownish stain or pigmentation of the enamel, usually on the labial surface, or as a true hypoplastic pitting defect or deformity. This form of dental injury has been discussed by Via, who has pointed out that a disturbance either in matrix formation or in calcification can occur, depending chiefly upon the stage of tooth formation at the time of injury.

Enamel Hypoplasia due to Fluoride: Mottled Enamel. Mottled enamel is a type of enamel hypoplasia that was first described under that term in this country by GV Black and Frederick S McKay in 1916. Earlier reference to the condition is known in the foreign literature; however. Black and McKay recognized that this lesion exhibited a geographic distribution and even suggested that it was a result of some substance in the water supply, although it was not until some years later that fluorine was shown to be the causative agent.

Etiology. It is now recognized that the ingestion of fluoride-containing drinking water during the time of tooth formation may result in mottled enamel. The severity of the mottling increases with an increasing amount of fluoride in the water. Thus there is little mottling of any clinical significance at a level below 0.9–1.0 part per million of fluoride in the water, whereas it becomes progressively evident above this level.

Pathogenesis. This type of hypoplasia is due to a disturbance of the ameloblasts during the formative stage of tooth development. The exact nature of the injury is not known, but since there is histologic evidence of cell damage, it is

Table 1-15: Distribution (percentage) of dental mottling by age groups

Age group (in yrs.)	Vellore		Dharmapuri		Krishnagiri		Salem		Erode		Pooled	
	n	(%)	n	(%)	n	(%)	n	(%)	n	(%)	n	(%)

Source: Kumar RH et al. J Human Ecology 21 (1): 27– 32, 2007.

likely that the cell product, the enamel matrix, is defective or deficient. It also has been shown that, with somewhat higher levels of fluoride, there is interference with the calcification process of the matrix.

Epidemiologic studies have reported that not all children born and reared in an area of endemic fluorosis exhibit the same degree of mottling even though they all have used the same water supply. Furthermore, a few persons may exhibit mild mottling even when exposed to a very low concentration of fluoride (Table 1-15). These findings may be related to individual variation in total water consumption and thus to total fluoride intake.

Clinical Features. Depending upon the level of fluoride in the water supply, there is a wide range of severity in the appearance of mottled teeth, varying from: (1) questionable changes characterized by occasional white flecking or spotting of the enamel (Fig. 1-54A), through (2) mild changes manifested by white opaque areas involving more of the tooth surface area (Fig. 1-54B), to (3) moderate and severe changes showing pitting and brownish staining of the surface (Fig. 1-54C), and even (4) a corroded appearance of the teeth (Fig. 1-54D). Those teeth which are moderately or severely affected may show a tendency for wear and even fracture

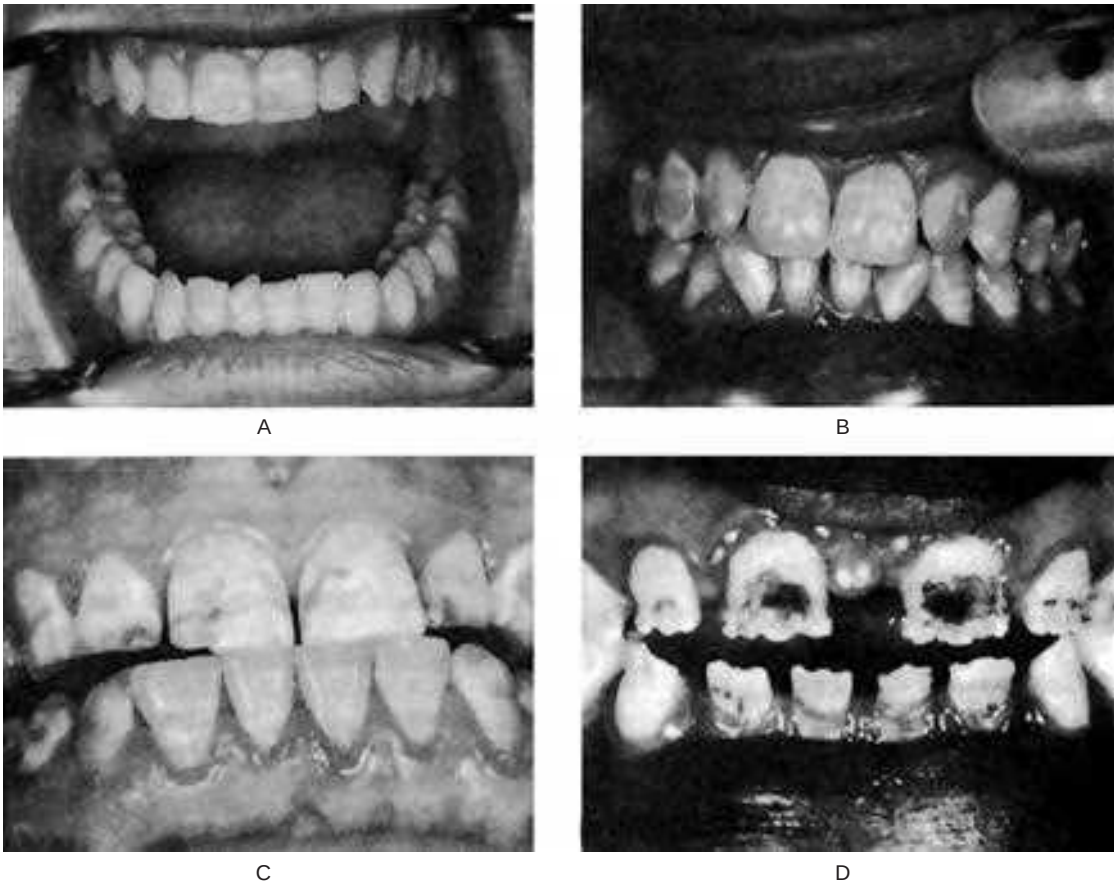

Figure 1-54. Enamel hypoplasia due to excessive fluoride (mottled enamel).
There is **(A, B)** flecking of the enamel surface by white opaque spots, **(C)** involvement of most of the tooth surface by opaque white areas, and **(D)** severe pitting and staining of the tooth surface.

of the enamel. Early studies actually noted the difficulty of retaining restorations in such teeth.

Geographic Distribution. Mottled enamel has been reported in many parts of the world, including Europe, Africa, and Asia as well as the United States. In this country, persons in at least 400 areas in 28 states have shown dental evidence of endemic fluorosis, and undoubtedly more communities remain to be reported. Most of the areas affected are west of the Mississippi River, the largest single area being the Texas Panhandle, but there are numerous communities east of the Mississippi River in which fluorosis is present, the most notable being in Illinois.

The well-known relation between mottled enamel (or actually fluoride intake) and dental caries will be discussed in Chapter 9 on Dental Caries.

Treatment. Mottled enamel frequently becomes stained an unsightly brown color. For cosmetic reasons, it has become the practice to bleach the affected teeth with an agent such as hydrogen peroxide. This is frequently effective, but the procedure must be carried out periodically, since the teeth continue to stain.

Hypoplasia due to Idiopathic Factors. Although numerous factors have been reported as being possibly responsible for causing enamel hypoplasia, clinical studies have shown that, even with careful histories, the majority of cases are of unknown origin. Since the ameloblast is a sensitive type of cell and easily damaged, it is likely that in those cases in which the etiology cannot be determined, the causative agent may have been some illness or systemic disturbance so mild that it made no impression on the patient and was not remembered. Even relatively severe cases of enamel hypoplasia arise with no pertinent past medical history to account for their occurrence.

DENTINOGENESIS IMPERFECTA

Dentinogenesis imperfecta is an autosomal dominant condition affecting both deciduous and permanent teeth. Affected teeth are gray to yellowish-brown and have broad crowns with constriction of the cervical area resulting in a **'tulip'** shape. Radiographically, the teeth appear solid, lacking pulp chambers and root canals. Enamel is easily broken leading to exposure of dentin that undergoes accelerated attrition. The gene maps to **chromosome number 4.** It encodes a protein called **dentin sialophosphoprotein (DSPP).** This protein constitutes about 50% of the noncollagenous component of dentin matrix. It is not known how the mutant protein causes near obliteration of the pulp. A clinically and radiographically indistinguishable dental condition is seen sometimes in patients with osteogenesis imperfecta. Dentin defect associated with osteogenesis imperfecta was earlier listed as dentinogenesis imperfecta type I (**Sheilds classification**). Extensive studies have proven that dentinogenesis imperfecta is clearly a disorder distinct from osteogenesis imperfecta hence the following **revised classification** is proposed.

Dentinogenesis imperfecta I: Dentinogenesis imperfecta without osteogenesis imperfecta (opalescent dentin): this corresponds to dentinogenesis imperfecta type II of Shields classification.

Dentinogenesis imperfecta II: Brandywine type dentinogenesis imperfecta: this corresponds to dentinogenesis imperfecta type III of Shields classification.

There is no substitute in the present classification for the category designated as DI type I of the previous classification (Shields).

Dentinogenesis imperfecta II is even more rare and paradoxically characterized by too little rather than too much dentin resulting in 'shell teeth.' Dentinogenesis imperfecta II may be an allelic variant of dentinogenesis imperfecta I (a different mutation in the same gene), both genes map to the same region on chromosome number 4.

Dentinogenesis Imperfecta I

(Opalescent dentin, dentinogenesis imperfecta without osteogenesis imperfecta, opalescent teeth without osteogenesis imperfecta, dentinogenesis imperfecta, Shields type II, Capdepont teeth)

Dentinogenesis imperfecta II is caused by mutation in the **DSPP** gene (**gene map locus 4q21.3**), encoding **dentin phosphoprotein** and **dentin sialoprotein.** Dentinogenesis imperfecta is an entity clearly distinct from osteogenesis imperfecta with opalescent teeth, and affects only the teeth. There is no increased frequency of bone fractures in this disorder. The frequency may be 1 in 6,000–8,000 children. Witkop and Rao (1971) preferred the term opalescent dentin for this condition as an isolated trait, reserving dentinogenesis imperfecta for the trait when it is combined with osteogenesis imperfecta. The teeth are blue-gray or amber brown and opalescent. On dental radiographs, the teeth have bulbous crowns, roots that are narrower than normal, and pulp chambers and root canals that are smaller than normal or completely obliterated. The enamel may split readily from the dentin when subjected to occlusal stress. Sauk et al (1976) noted an increase in glycosaminoglycans in EDTA soluble dentin in the teeth from patients with this disorder as compared to controls, and less glycosaminoglycan in EDTA insoluble residue.

Shields et al (1973) proposed that the variety of dentinogenesis imperfecta (dentinogenesis imperfecta type III) described in the Brandywine isolate by Hursey et al (1956) was distinct from dentinogenesis imperfecta type II.

A deficiency of dentin sialophosphoprotein had been suggested as a causative factor in dentinogenesis imperfecta. Zhang et al (2001) studied a Chinese family with dentinogenesis imperfecta Shields type II. Affected members in three generations showed discoloration and severe attrition of their teeth, with obliterated pulp chambers.

Dentinogenesis Imperfecta II

(Shields type III, Brandywine type dentinogenesis imperfecta)

This disorder was found in the Brandywine triracial isolate in southern Maryland. The crowns of the deciduous and permanent teeth wear rapidly after eruption and multiple pulp exposures may occur. The dentin is amber and smooth

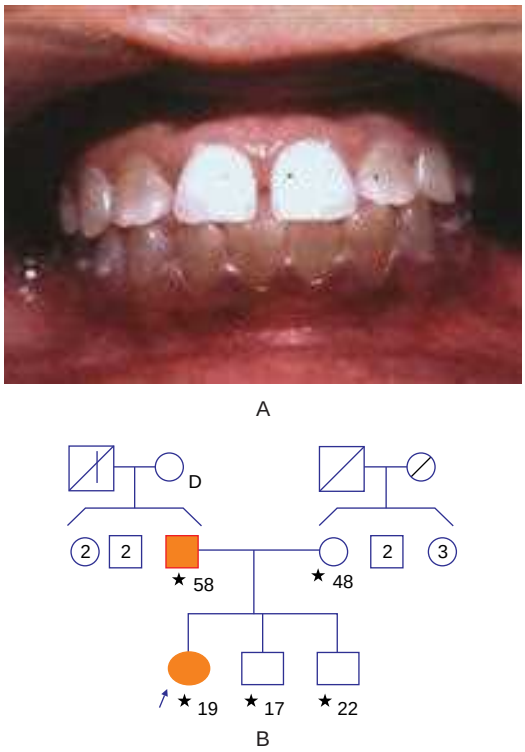

Figure 1-55. Dentinogenesis imperfecta type II with autosomal dominant inheritance pattern.

(Fig. 1-55). Radiographs of the deciduous dentition show very large pulp chambers and root canals, at least during the first few years, although they may become reduced in size with age. The permanent teeth have pulpal spaces that are either smaller than normal or completely obliterated. Patients with Shields type III, or the Brandywine type, do not have stigmata of osteogenesis imperfecta. This disorder may be a separate mutation from dentinogenesis imperfecta I. Shields et al (1973) stated that multiple pulp exposures and markedly enlarged pulp chambers in the deciduous teeth do not occur in DGI-1; however, Witkop (1975) suggested that the two disorders are the same. Recent studies are consistent with the hypothesis that DGI-1 and DGI-2 are allelic or the result of mutations in two tightly linked genes. MacDougall (1998) provided information on the intervals separating four genes that map to this same region, all four of which are involved in dental development: **DSPP, DMP-1, IBSP,** and **SPP1.** MacDougall et al (1999) stated that the manifestations of DGI-2 can differ from those of DGI-1 by the presence of multiple pulp exposures, normal nonmineralized pulp chambers and canals, and a general appearance of **'shell teeth.'** They illustrated the amber discoloration of the teeth, attrition, and fractured enamel, as well as the classic 'shell teeth' appearance on radiographs.

Histologic Features. The histologic appearance of the teeth in dentinogenesis imperfecta I emphasizes the fact that this is purely a mesodermal disturbance. The appearance of the enamel is essentially normal except for its peculiar shade, which is actually a manifestation of the dentinal disturbance. The dentin, on the other hand, is composed of irregular tubules, often with large areas of uncalcified matrix (Fig. 1-56). The tubules tend to be larger in diameter and thus less numerous than normal in a given volume of dentin (Fig. 1-57). In some areas there may be complete absence of tubules. Cellular inclusions, probably odontoblasts, in the dentin are not uncommon, and as pointed out previously, the pulp chamber is usually almost obliterated by the continued deposition of dentin. The odontoblasts have only limited ability to form well-organized dentinal matrix, and they appear to degenerate readily, becoming entrapped in this matrix.

The histopathology of the teeth in type III has not been adequately documented.

Chemical and Physical Features. Chemical analysis explains many of the abnormal features of the teeth of dentinogenesis imperfecta I. Their water content is greatly increased, as much as 60% above normal, while the inorganic content is less than that of normal dentin. As might be expected, the density, X-ray absorption, and hardness of the dentin are also low. In fact, the micro-hardness of the dentin closely approximates that of cementum, thus explaining the rapid attrition of affected teeth. There is no significant information available on teeth in type III.

Treatment. The treatment of patients with dentinogenesis imperfecta is directed primarily towards preventing the loss of enamel and subsequent loss of dentin through attrition. Cast metal crowns on the posterior teeth and jacket crowns on the anterior teeth have been used with considerable success, although care must be taken in the preparation of the teeth for such restorations. Caution must also be exercised in the use

of partial appliances which exert stress on the teeth, because the roots are easily fractured. Experience has further shown that fillings are not usually permanent because of the softness of the dentin.

Dentin Dysplasia
(Rootless teeth)

Dentin dysplasia is a rare disturbance of dentin formation characterized by normal enamel but atypical dentin formation with abnormal pulpal morphology.

At one time this was thought to be a single disease entity, but it now has been separated by Shields and his associates into type I (dentin dysplasia) and type II (anomalous dysplasia of dentin). However, Witkop has suggested that as a guide to the clinician, these conditions be referred to as **radicular dentin dysplasia (type I)** *and* **coronal dentin dysplasia (type II).** It has been found that type I is by far the more common.

The first description of the disease was that of Ballschmiede, who in 1920 reported the spontaneous exfoliation of multiple teeth in seven children of one family and called this phenomenon 'rootless teeth.' The first concise description of the disease was published in 1939 by Rushton, who was also the first to designate it as 'dentin dysplasia.'

Etiology. Dentin dysplasia, both type I and type II, appears to be a hereditary disease, transmitted as an autosomal dominant characteristics. Nothing is known of the mutation rate, but it must be extremely low.

Clinical Features

Type I (radicular). Both dentitions are affected, although the teeth appear clinically normal in morphologic appearance and color. Occasionally there may be a slight amber translucency. The teeth generally exhibit a normal eruption pattern, although delayed eruption has been reported in a few cases. However, the teeth characteristically exhibit extreme mobility and are commonly exfoliated prematurely or after only minor trauma as a result of their abnormally short roots.

Type II (coronal). Both dentitions are also affected in this form of dentin dysplasia, although the involvement of each dentition is different clinically, radiographically, and histologically. The deciduous teeth have the same yellow, brown, or bluish-gray opalescent appearance as seen in dentinogenesis imperfecta. However, the clinical appearance of the permanent dentition is normal.

Radiographic Features

Type I (radicular). In both dentitions, the roots are short, blunt, conical, or similarly malformed (Fig. 1-58). In the deciduous teeth, the pulp chambers and root canals are usually completely obliterated, while in the permanent dentition, a crescent-shaped pulpal remnant may still be seen in the pulp chamber. This obliteration in the permanent teeth commonly occurs pre-eruptively. Of significant interest is the discovery of periapical radiolucencies representing granulomas, cysts, or abscesses involving apparently otherwise intact teeth.

Type II (coronal). The pulp chambers of the deciduous teeth become obliterated as in type I and in dentinogenesis imperfecta. This does not occur before eruption. The permanent teeth; however, exhibit an abnormally large pulp chamber in the coronal portion of the tooth, often described as **'thistle-tube'** in shape, and within such areas radiopaque foci resembling pulp stones may be found. Periapical radiolucencies do not occur unless for an obvious reason.

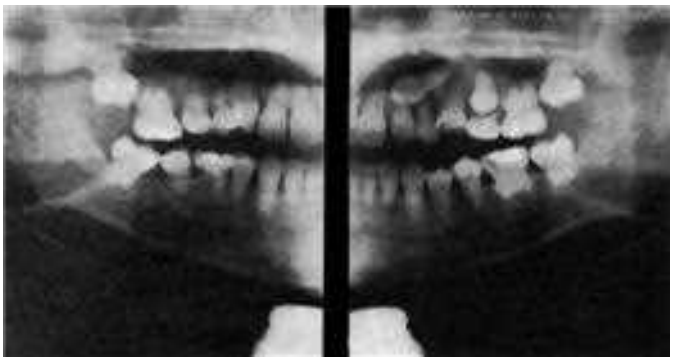

Figure 1-58. Dentinal dysplasia, type I (radicular).
The exceptionally short roots and obliteration of pulp chambers and root canals are clearly evident.*(Courtesy of Dr Arthur S Miller; from AS Miller and K Brookreson: Pa, Dent J, 37: 134, 1970).*

Histologic Features

Type I (radicular). A portion of the coronal dentin is usually normal. Apical to this may be areas of tubular dentin, but most of that which obliterates the pulp is calcified tubular dentin, osteodentin, and fused denticles. Normal dentinal tubule formation appears to have been blocked so that new dentin forms around obstacles and takes on the characteristic appearance described as ***'lava flowing around boulders'*** (Fig. 1-59). Electron microscopic studies by Sauk and his coworkers have suggested that this pattern of 'cascades of dentin' results from repetitive attempts to form root structure. Interestingly, the dentin itself is histologically normal but is simply disoriented.

Figure 1-59. Dentin dysplasia, type I (radicular).
The atypicality of root dentin and dentin filling the pulp chamber is seen in this ground section of tooth *(Courtesy of Dr Richard K Wesley and George Wysocki. From Oral Surg, 41: 516, 1976).*

Type II (coronal). The deciduous teeth exhibit amorphous and atubular dentin in the radicular portion, while coronal dentin is relatively normal. The permanent teeth also show relatively normal coronal dentin, but the pulp has multiple pulp stones or denticles.

Excellent scanning electron microscopic studies of both types I and II dentin dysplasia have been reported by Melnick and his associates, and these have added appreciably to our knowledge of the atypical structure of this dentin.

Treatment and Prognosis. There is no treatment for the disease, and its prognosis depends upon the occurrence of periapical lesions necessitating tooth extraction as well as upon the exfoliation of teeth due to increased mobility.

Regional Odontodysplasia
(Odontodysplasia, odontogenic dysplasia, odontogenesis imperfecta, ghost teeth)

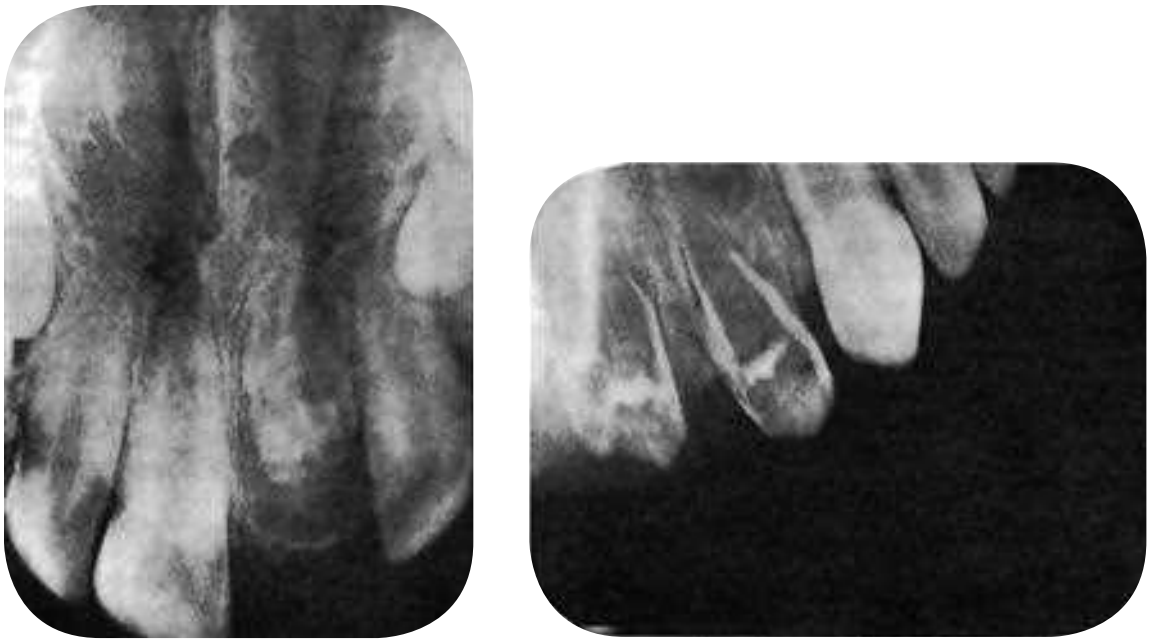
This is an unusual dental anomaly in which one or several teeth in a localized area are affected in an unusual manner. Apparently the maxillary teeth are involved more frequently than the mandibular, the most frequently affected teeth being the maxillary permanent central incisor, lateral incisor, and cuspid. In the mandible, the same three anterior teeth are most often affected. The deciduous teeth as well as the permanent may be involved.

The etiology of this disease is unknown inasmuch as there is no history of trauma or systemic illness. It has been suggested that the condition may represent a somatic mutation, although the possibility has also been raised that it could be due to a latent virus residing in the odontogenic epithelium, which subsequently becomes active during the development of the tooth. In an excellent review of cases in the literature and a discussion of the condition, Walton and his coworkers observed that in three cases of regional odontodysplasia that they reported, all three patients had vascular nevi of the overlying facial skin as infants. They reported similar involvement in three additional cases in the literature, and these findings suggested to them that local vascular defects are involved in the pathogenesis of the condition. An early comprehensive account was also reported by Rushton.

Clinical Features. The teeth affected by odontodysplasia exhibit either a delay or a total failure in eruption. Their shape is markedly altered, being generally very irregular in appearance, often with evidence of defective mineralization.

Radiographic Features. The radiographs are uniquely characteristic, showing a marked reduction in radiodensity so that the teeth assume a **'ghost'** appearance (Fig. 1-60A, B). Both the enamel and dentin appear very thin and the pulp chamber is exceedingly large. The enamel layer often is not evident.

Histologic Features. The most characteristic features of the disease are the marked reduction in the amount of dentin, the



A B

Figure 1-60. Regional odontodysplasia.
The unusually large pulp, thin enamel, and dentin are evident ((A) *Courtesy of Dr E Jefferson Burkes, and* (B) *of Dr Joseph L Bigelow*).

widening of the predentin layer, the presence of large areas of interglobular dentin, and an irregular tubular pattern of dentin. Characteristically, the reduced enamel epithelium around non-erupted teeth shows many irregular calcified bodies. Ultrastructural studies by Sapp and Gardner have proved enlightening in detailing some of the fine components of both the soft and calcified tissues in regional odontodysplasia.

Treatment. Because of the poor cosmetic appearance of these teeth, extraction with restoration by a prosthetic appliance is usually indicated.

Dentin Hypocalcification

Normal dentin is calcified by deposition of calcium salts in the organic matrix in the form of globules, which increase in size by further peripheral deposition of salts until all the globules are finally united into a homogeneous structure. In dentinal hypocalcification there is failure of union of many of these globules, leaving interglobular areas of uncalcified matrix. This globular dentin is easily detected in both ground sections and decalcified histologic sections of teeth, but there is no alteration in the clinical appearance.

Many clinicians believe that they can detect areas of globular dentin by the softness of the dental structure. Although this remains to be proved, it is logical that hypocalcified dentin would be softer than well-calcified dentin.

The causes of dentin hypocalcification are similar to those of environmental enamel hypocalcification and enamel hypoplasia. Obviously, any factor which interferes with normal calcification, such as parathyroid deficiency or rickets, could produce hypocalcification.

DISTURBANCES OF GROWTH (ERUPTION) OF TEETH

It is recognized that a broad range of variation exists in the normal eruption times of the deciduous and permanent teeth in different persons. A valuable modification of the usually accepted chronology of the calcification and eruption times of the deciduous teeth has been published by Lunt and Law. Because of this inherent biologic variation, which is particularly notable in the human being, it is difficult to determine when the eruption dates of the teeth of a given person are outside the limits of the normal range. Nevertheless, certain cases do occur in which the eruption time is grossly beyond the extremes of normality and may be considered a pathologic state. The significance of this is frequently not apparent.

Premature Eruption

Deciduous teeth that have erupted into the oral cavity are occasionally seen in infants at birth. These are called **natal teeth** in contrast with **neonatal teeth**, which have been defined as those teeth erupting prematurely in the first 30 days of life. Usually only one or two teeth erupt early, most often the deciduous and mandibular central incisors. The etiology of this phenomenon is unknown, although in some instances it follows a familial pattern. It is well recognized in experimental animals that the secretion of several endocrine organs (e.g. thyroid, adrenals, and gonads) may alter the eruption rate of teeth, and it has been suggested that in some cases of early eruption in humans a poorly defined endocrine disturbance may be present. In cases of the adrenogenital syndrome (q.v.) developing early in life, premature eruption of teeth is sometimes seen. Most cases; however, defy explanation.

Spouge and Feasby have pointed out that prematurely erupted teeth are often well formed and normal in all respects except that they may be somewhat mobile. These teeth should be retained even though nursing difficulties may be experienced. A series of 18 cases of natal and neonatal teeth has been studied clinically and histologically by Berman and Silverstone, who reported that these were essentially normal teeth compatible with their chronologic age of development.

The premature eruption of permanent teeth is usually a sequela of the premature loss of deciduous teeth. This is best demonstrated in the situation in which only a single deciduous tooth has been lost, with subsequent eruption of the succedaneous tooth. Occasionally, cases occur involving the entire dentition, and here again the possibility of an endocrine dysfunction (e.g. hyperthyroidism) must be considered.

Eruption Sequestrum

The eruption sequestrum, an anomaly associated with the eruption of teeth in children, was first described by Starkey and Shafer.

Clinical Features. The eruption sequestrum is a tiny irregular spicule of bone overlying the crown of an erupting permanent molar, found just prior to or immediately following the emergence of the tips of the cusps through the oral mucosa. The spicule directly overlies the central occlusal fossa but is contained within the soft tissue. As the tooth continues to erupt and the cusps emerge, the fragment of bone completely sequestrates through the mucosa and is lost. For a few days, the fragment of bone may be seen lying on the crest of the ridge in a tiny depression from which it may easily be removed (Fig. 1-61A).

Radiographic Features. It is possible to recognize the eruption sequestrum radiographically even before the teeth begin to erupt into the oral cavity or before the bony spicule perforates the mucosa. It appears as a tiny irregular opacity overlying the central occlusal fossa but separated from the tooth itself (Fig. 1-61B).

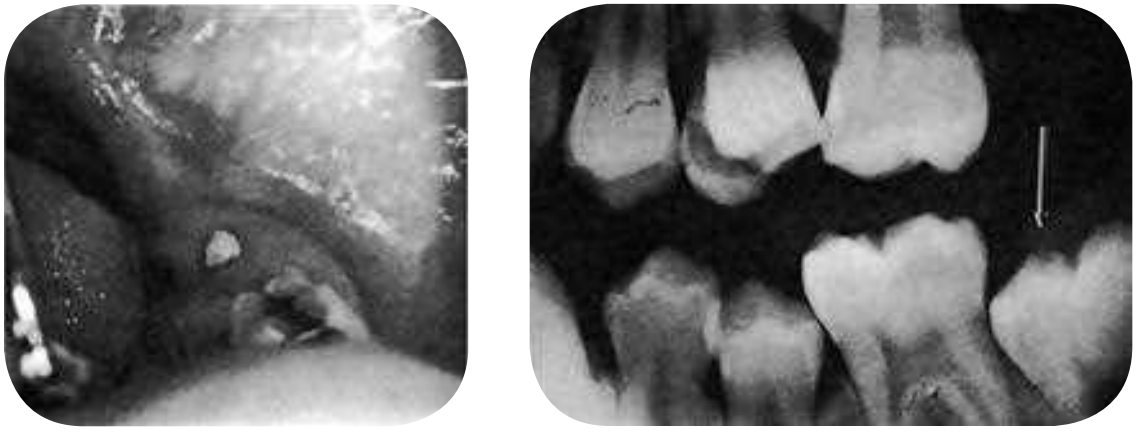
Etiology. The explanation of this phenomenon is relatively simple. As the molar teeth erupt through the bone, they will occasionally separate a small osseous fragment from the surrounding contiguous bone, much in the fashion of a corkscrew. In most cases, this fragment probably undergoes total resorption prior to eruption. If the bony spicule is larger or eruption is fast, complete resorption cannot occur and the eruption sequestrum is observed.

Clinical Significance and Treatment. The clinical significance associated with this condition is that, occasionally, a child may complain of a slight soreness in the area, probably produced by compression of the soft tissue over the spicule during eating and just prior to its breaking through the mucosa, or by the movement of the spicule in the soft tissue crypt during mastication and following eruption through the mucosa. No treatment is necessary, since the condition corrects by itself.

Delayed Eruption

Retarded or delayed eruption of the deciduous teeth is difficult to establish unless the eruption is grossly overdue. In many cases the etiology is unknown, although in some instances it may be associated with certain systemic conditions, including rickets, cretinism, and cleidocranial dysplasia (q.v.). Local factors or circumstances may also delay eruption, as in the case of fibromatosis gingivae, in which the dense connective tissue will not permit eruption.

When the local factors can be established as the cause, their treatment may alleviate the condition. In cases of generalized or systemic disturbances in which the dental problem is of secondary importance, treatment of the primary condition, if possible, will frequently bring about tooth eruption.



A B

Figure 1-61. Eruption sequestrum.
The bony sequestrum is lying on the crest of the ridge **(A)** and may be seen as a small radiopacity **(B).** *(From PE Starkey, WG Shafer. Eruption sequestra in children. J Dent Child, 30: 84, 1963).*

Delayed eruption of the permanent dentition as a whole may be associated with the same local or systemic conditions causing the retardation of deciduous tooth eruption. Since there is a wider range of variation in the time of eruption of the permanent teeth, it is frequently difficult to state exactly when a case of retardation exists.

Multiple Unerupted Teeth

There is an uncommon condition in which there is a more or less permanently delayed eruption of teeth. The person affected may have retained his/her deciduous teeth, or more commonly the deciduous teeth may have been shed but the permanent teeth have failed to erupt. The term 'pseudoanodontia' is sometimes applied to this latter circumstance. In many instances, the clinical and radiographic examinations reveal apparently normal jaws and teeth. What seems to be lacking is eruptive force.

If this condition is due to an endocrine dysfunction, proper treatment may result in the eruption of teeth; if it is associated with cleidocranial dysplasia (q.v.), there is no known therapy.

Embedded and Impacted Teeth

Embedded teeth are individual teeth which are unerupted usually because of a lack of eruptive force. Impacted teeth are those prevented from erupting by some physical barrier in the eruption path. Some writers do not differentiate between the two terms and call all unerupted teeth impacted.

Lack of space due to crowding of the dental arches or to the premature loss of deciduous teeth with subsequent partial closure of the area they occupied is a common factor in the etiology of partially or completely impacted teeth (Fig. 1-62). Even more common; however, is the rotation of tooth buds resulting in teeth which are 'aimed' in the wrong direction because their long axis is not parallel to a normal eruption path.

Any tooth may be impacted, but certain ones are more commonly affected than others. Thus the maxillary and mandibular third molars and the maxillary cuspids are most frequently impacted, followed by the premolars and supernumerary teeth. Of the third molars, the mandibular teeth are more apt to exhibit severe impaction than the maxillary teeth.

Figure 1-62. Partial tooth impaction due to premature loss of deciduous molar.

Dachi and Howell have published the results of a study of 3,874 routine full-mouth radiographs of patients over 20 years of age. They found that 17% of these persons had at least one impacted tooth. The incidence of impaction of maxillary and mandibular third molars was 22% and 18%, respectively, while the incidence of impacted maxillary cuspids was 0.9%.

Impacted mandibular third molars may exhibit a great variety of positions (Fig. 1-63). A simple classification of the types of impactions of mandibular third molars, based upon position, has been devised by Winter as follows:

Mesioangular impaction. The third molar lies obliquely in the bone, the crown pointing in a mesial direction, usually in contact with the distal surface of the root or crown of the second molar. This is the most common type of impaction.

Distoangular impaction. The third molar lies obliquely in the bone, the crown of the tooth pointing distally toward the ramus, the roots approximating the distal root of the second molar.

Vertical impaction. The third molar is in its normal vertical position, but is prevented from erupting by impingement on the distal surface of the second molar or the anterior border of the ramus. Thus, in most cases of this type, there is simply lack of space for eruption.

Horizontal impaction. The third molar is in a horizontal position with respect to the body of the mandible, and the crown may or may not be in contact with the distal surface of the second molar crown or roots. In this type of impaction, the third molar may lie at any level within the bone from the crest of the ridge to the inferior border of the mandible.

In addition to these types of impaction in which there is variation of angulation in the sagittal plane, the impacted third molars may also be deflected either buccally or lingually in any case of the foregoing circumstances. Cases also have been recorded of complicated impactions in which the third molar is inverted, the crown pointing toward the inferior border of the mandible, or in which the third molar has been situated completely within the ramus of the mandible.

In the case of impaction of any tooth, but particularly of the mandibular third molar, it is important to determine whether the tooth is completely or only partially impacted. By definition, a completely impacted tooth is one which lies completely within the bone and has no communication with the oral cavity. A partially impacted tooth is not completely encased in bone but lies partially in soft tissue. Although there may be no obvious communication of the tooth with the oral cavity, one may exist (e.g. through a periodontal pocket on the distal of the second molar) and create an ideal situation for infection and even dental caries of the impacted tooth crown. A completely embedded or impacted tooth cannot become infected or carious.

Impacted maxillary third molars may be impacted in a manner similar to the mandibular third molar (Fig. 1-64). Thus they may show a mesioangular, distoangular, vertical, or even a horizontal position and may be deflected buccally or lingually.

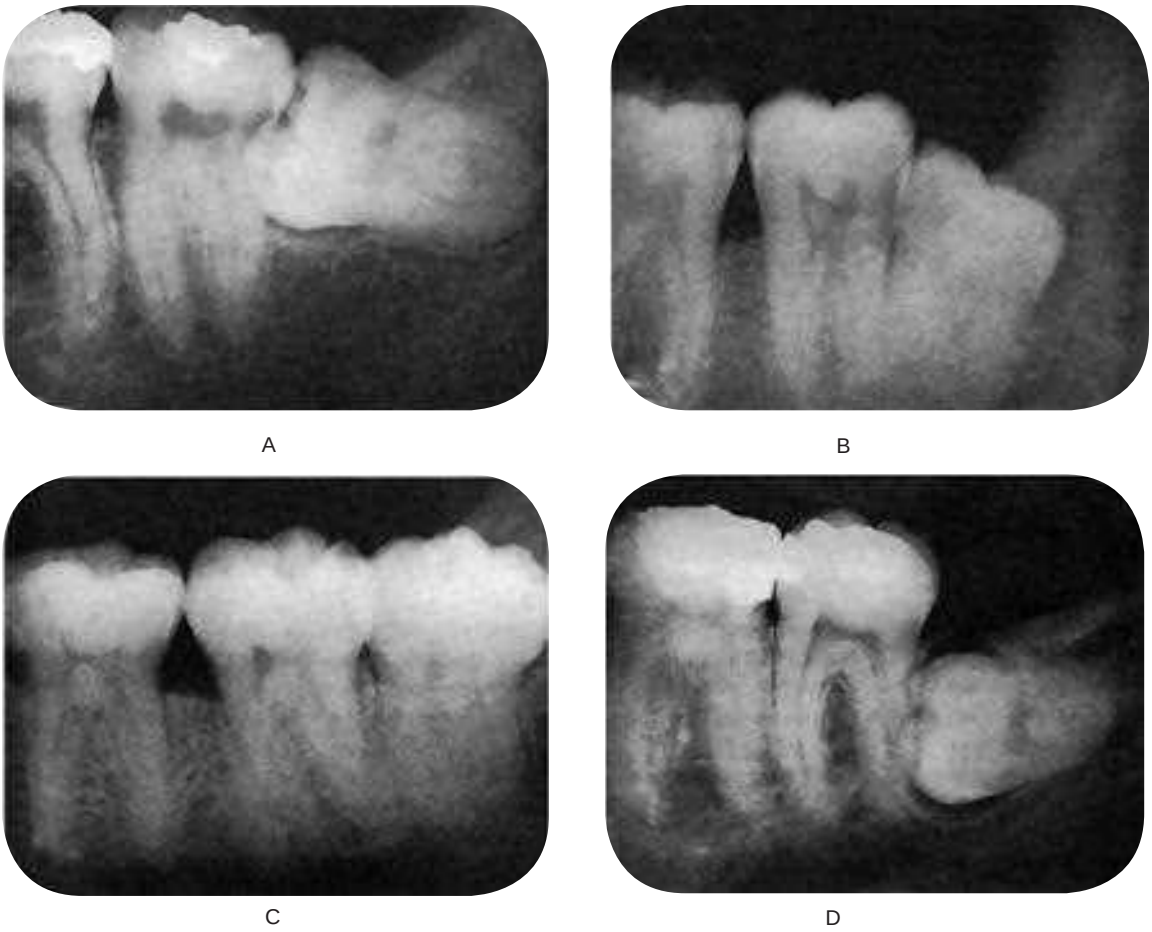


Figure 1-63. Impacted mandibular third molars.
(A) Mesioangular impaction. **(B)** Distoangular impaction. (C) Vertical impaction. (D) Horizontal impaction *(Courtesy of Dr Wilbur C Moorman).*

Figure 1-64. Partially impacted maxillary third molar (mesioangular type).

Impacted maxillary cuspids also assume a variety of positions ranging from horizontal to vertical (Fig. 1-65). In horizontally impacted cuspids the crown usually points in an anterior direction and may impinge on the roots of any of the incisors or premolars. The horizontal tooth may lie either labial or lingual to the associated teeth. The vertically impacted cuspid is usually situated between the roots of the

Figure 1-65. Bilateral impacted maxillary cuspids.
(Courtesy of Dr Wilbur C Moorman).

lateral incisor and first premolar and is prevented from eruption simply by lack of space.

The treatment of an impacted tooth depends to a great extent upon the type of tooth involved and the individual circumstances. In some cases, such as the impacted cuspid, it is possible by a suitable orthodontic appliance to bring the tooth into normal occlusion. The majority of impacted teeth; however, must be surgically removed. Because of their location, impacted teeth frequently cause resorption of the roots of adjacent teeth. They may also cause periodic pain and even trismus, particularly when infection occurs around partially impacted teeth. Referred pain from impacted teeth has also been described.

A dentigerous cyst may develop around the coronal portion of an impacted tooth and may cause displacement of the tooth and destruction of bone. In the study of Dachi and Howell, 37% of impacted mandibular third molars and 15% of impacted maxillary third molars exhibited an area of radiolucency about the crown. About 10% of these radiolucencies were of such a size that they could be considered dentigerous cysts. Furthermore, cases of ameloblastoma have been reported developing in the wall of such a cyst (dentigerous cysts are discussed in more detail in Chapter 4 on Cysts and Tumors of Odontogenic Origin).

Occasionally, impacted teeth allowed to remain *in situ* may undergo resorption. The reason that some teeth are resorbed whereas others are not is unknown. The process usually begins on the crown of the tooth and results in destruction of the enamel and dentin, a well as of the cementum, with subsequent replacement by bone. Radiographically, early resorption resembles a carious lesion of the crown and has often been mistakenly called caries of an impacted tooth. Obviously, caries is impossible in a tooth that is completely impacted.

Ankylosed Deciduous Teeth
(Submerged teeth)

'Submerged' teeth are deciduous teeth, most commonly mandibular second molars, that have undergone a variable degree of root resorption and then have become ankylosed to the bone. This process prevents their exfoliation and subsequent replacement by permanent teeth (Fig. 1-66). After the adjacent permanent teeth have erupted, the ankylosed tooth appears to have submerged below the level of occlusion. This illusion is explained by the fact that there has been continued growth of the alveolar process and also that the crown height of the deciduous tooth is less than that of the adjacent permanent teeth, so that the relative level of occlusion has been changed, not the position of the deciduous tooth. This relation between submersion and ankylosis of human deciduous molars has been studied in detail by Darling and Levers.

The diagnosis of ankylosis of a tooth is usually suspected clinically and confirmed by radiographic examination. The teeth affected lack mobility even though root resorption is far advanced. Upon percussion, an ankylosed tooth imparts a characteristic solid sound in contrast to the dull, cushioned sound of a normal tooth. Radiographically, at least partial absence of the periodontal ligament is seen, with areas of apparent blending between the tooth root and bone. The process is basically one of resorption of tooth substance and bony repair with the result that the tooth is locked in bone.

Figure 1-66. Ankylosed (submerged) deciduous second molar.
The ankylosed deciduous tooth appears submerged because of the difference in crown height between the deciduous and permanent teeth and continued growth of the alveolar process.

The cause of ankylosis is not known, although in some cases trauma, infection, disturbed local metabolism, or a genetic influence has been considered an important etiologic factor. These influences have been discussed by Henderson, who also emphasized that a patient who has had one or two ankylosed teeth is very likely to have other teeth ankylosed over a period of time. This condition is usually treated by the surgical removal of the ankylosed tooth to prevent the development of a malocclusion, a local periodontal disturbance, or dental caries.

FISSURAL (INCLUSION, DEVELOPMENTAL) CYSTS OF ORAL REGION

A number of different types of fissural (or inclusion) cysts of bone occur in the jaws and have generally been considered arising, as the name would indicate, along the lines of fusion of various bones or embryonic processes. These are true cysts (i.e. pathologic cavities lined by epithelium, usually containing fluid or semisolid material), the epithelium being derived from epithelial cells which are entrapped between embryonic processes of bones at union lines. These fissural cysts may be classified: (1) median anterior maxillary cyst, (2) median palatal cyst, (3) globulomaxillary cyst, and (4) median mandibular cyst.

There are several additional developmental cysts derived from embryologic structures or faults which involve the oral or adjacent soft tissue structures. These may be listed as: (1) nasoalveolar cyst, (2) palatal cysts of the neonate, (3) thyroglossal tract cyst, (4) benign cervical lymphoepithelial cyst, (5) epidermoid and dermoid cyst, and (6) heterotopic oral gastrointestinal cyst.

Nasopalatine Duct Cyst

(Nasopalatine canal cyst, incisive canal cyst)

The most common of the nonodontogenic cyst, the nasopalatine duct cyst (NPDC) is a developmental cyst, non-neoplastic in nature. Its location is peculiar and specific in that it affects the midline anterior maxilla.

The nasopalatine ducts ordinarily undergo progressive degeneration; however, the persistence of epithelial remnants may later become the source of epithelia that gives rise to NPDC, from either spontaneous proliferation or proliferation following trauma (e.g. removable dentures), bacterial infection, or mucous retention. Genetic factors have also been suggested. The mucous glands present among the proliferating epithelium can contribute to secondary cyst formation by secreting mucin within the enclosed structure. NPDC can form within the incisive canal, which is located in the palatine bone and behind the alveolar process of the maxillary central incisors, or in the soft tissue of the palate that overlies the foramen, called the cyst of the incisive papilla.

Etiology. The cause of NPDC is essentially unknown. Trauma, infection, and mucous retention within associated salivary gland ducts have all been suggested as possible pathogenic factors; however, most believe that spontaneous cystic degeneration of residual ductal epithelium is the most likely etiology.

Clinical Features. No data currently available on the international frequency of this type of cyst. No racial predilection is known. Males are affected 18–20 times more often than females. NPDCs occur over a wide age range (8–84 year), although they also occur in fetuses. Most patients who are affected are aged 40–60 years.

Small cysts in the early stages of their development are frequently asymptomatic. Large cysts can be responsible for a variety of symptoms, including swelling (52–88%), discharge (25%), and pain (20–23%). About 70% of patients experience a combination of these symptoms. Paradoxically, patients with small cysts may have disproportionately severe symptoms, whereas patients with large ones may experience few or no symptoms. A salty taste in the mouth and devitalization of the pulps of associated teeth have been reported. Large and more destructive cysts that have perforated the labial and palatal bony plates may present as expansile, fluctuant swellings of the anterior palate and the palate. Extrabony cysts that develop within the soft tissues of the incisive papilla area of the anterior hard palate (called the **cyst of the incisive papilla**) may present as a translucent or bluish colored, dome-shaped swelling. The clinically apparent discoloration is due to the accumulation of fluid contents within the cyst. NPDCs clinically demonstrate slow and progressive growth, sometimes exceeding 60 mm in diameter. Tooth displacement is common finding, having been reported to occur in 78% of patients, whereas bony expansion is noted in only 1.4% of patients.

Histologic Features. Histopathologic examination discloses a cavity lined by epithelium and surrounded by a connective tissue wall. A reported 71.8% of NPDCs have squamous, columnar, cuboidal, or some combination of these epithelial types; respiratory epithelium is seen in 9.8%. The type of epithelium depends on the localization of the cyst, and it may also be reflective of the pluripotential character of the embryonic epithelial remnants. Rarely, dendritic melanocytes have been reported within the epithelium. Malignant transformation of the lining epithelium has not been reported. Often (81% of cases), a chronic inflammatory reaction consisting of lymphocytes and plasma cells is observed in the cyst wall; hemorrhage has been noted in 71% of the cases. Also helpful in the microscopic diagnosis of NPDC are the presence of structural elements in the cyst wall that are native to the nasopalatine canal (e.g. moderately sized peripheral nerves, arteries and veins, mucous glands, adipose tissue). A clear or straw-colored fluid aspirate is suggestive of NPDC; however, other cystic processes (e.g. lateral radicular cyst, cystic ameloblastoma) cannot be excluded on the basis of this finding alone. The cyst fluid has been reported to contain erythrocytes, leukocytes, desquamated epithelial cells, tissue debris, and bacteria.

Treatment. NPDCs are treated by enucleation via a palatine or buccal approach.

Median Palatal Cyst

The median palatal cyst arises from epithelium entrapped along the line of fusion of the palatal processes of the maxilla.

Clinical Features. The median palatal cyst is located in the midline of the hard palate between the lateral palatal processes. It may become large over a prolonged period of time and produce a definite palatal swelling that is visible clinically (Fig. 1-67A). The cause the epithelial proliferation and subsequent cyst formation is unknown.

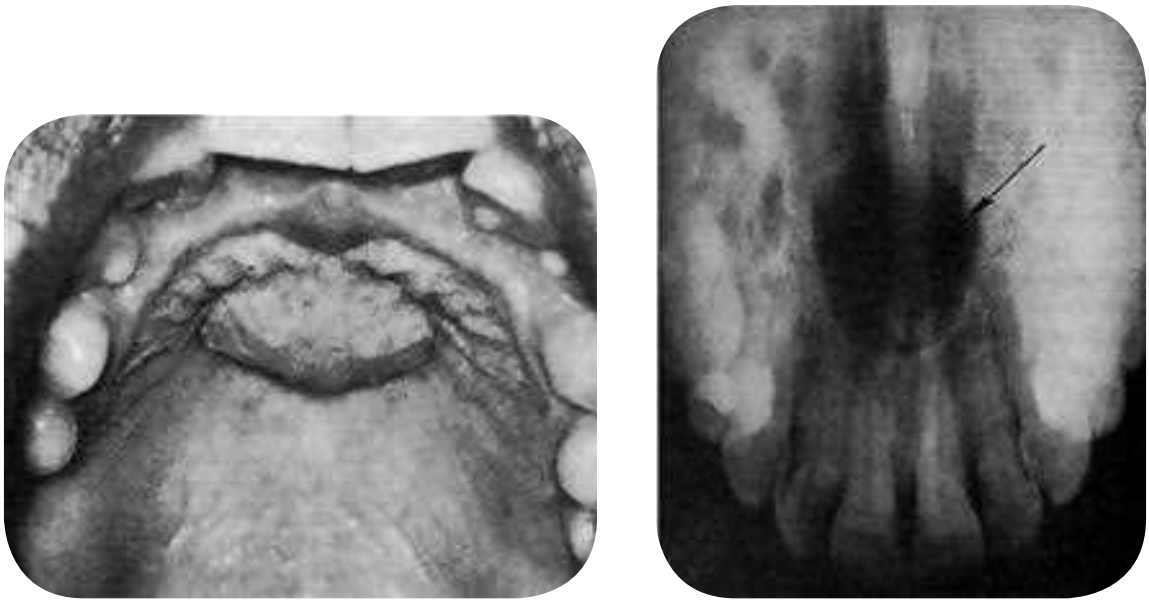
Radiographic Features. On the palatal radiograph a well-circumscribed radiolucent area is seen opposite the bicuspid and molar region, frequently bordered by a sclerotic layer of bone (Fig. 1-67B).

Histologic Features. The lining of such a cyst usually consists of stratified squamous epithelium overlying a relatively dense fibrous connective tissue band which may show chronic inflammatory cell infiltration. However, occasional cases have been reported to be lined by pseudostratified ciliated columnar epithelium or even a 'modified' squamous epithelium, as pointed out by Courage and his associates in a review of this lesion.

Treatment. The treatment, as for most of the fissural cysts, is surgical removal and thorough curettage.

Globulomaxillary Cyst

The globulomaxillary cyst has traditionally been described as a fissural cyst found within the bone between the maxillary lateral incisor and canine teeth. Radiographically, it is a well-defined radiolucency which frequently causes the roots of the adjacent teeth to diverge. While there can be no doubt that cyst do occur in this region and that the pulps of the adjacent teeth



A B

Figure 1-67. Median palatal cyst.
A large swelling **(A)** and underlying defect in the bone **(B)** are present in the midline of the palate. This cyst is not associated with the teeth and is posterior to the area of the incisive canal.

may give positive vitality responses, there is now a considerable body of opinion against the idea that they are fissural cysts. The evidence against their being fissural cysts is, in fact, more substantial than the evidence in favor (Shear, 1996).

The WHO classification of cyst of the jaws (1992) considered this entity under the rubric 'of debatable origin.' We have included here a description of this cyst due to the cited reason.

The globulomaxillary cyst is found within the bone at the junction of the globular portion of the medial nasal process and the maxillary process, the globulomaxillary fissure, usually between the maxillary lateral incisor and cuspid teeth. However, there are reports of evidence that the cyst actually forms in the bone suture between the premaxilla and maxilla, the incisive suture, so that its location may be different from the cleft ridge and palate. Because of this, Ferenczy has suggested the term **'premaxilla-maxillary cyst'** as more accurately describing its origin. The cause of the proliferation of epithelium entrapped along this line of fusion is unknown. Virtanen and Laine have carried out an extensive review and discussion of the globulomaxillary cyst.

Christ has also thoroughly evaluated the literature dealing with globulomaxillary cysts and has concluded that, embryologically, facial processes *per se* do not exist, and therefore, ectoderm does not become entrapped in the facial fissures of the nasomaxillary complex. Thus, he believes that this cyst should be removed from the category of orofacial fissural cysts, since modern embryologic concepts do not support such a view. Instead, he suggests that an odontogenic origin for this cyst is far more likely, the clinical and radiographic appearance being entirely compatible with a lateral periodontal, lateral dentigerous, or primordial cyst. In addition, numerous reported cases have had the histologic features of the odontogenic keratocyst (q.v.), while nests of odontogenic epithelium in the wall of globulomaxillary cysts are not rare. Furthermore, there is at least one case, reported by Aisenberg and Inman, of an ameloblastoma developing in a globulomaxillary cyst, which suggests an odontogenic origin.

Clinical Features. The globulomaxillary cyst seldom if ever presents clinical manifestations. Nearly every recorded case has been discovered accidentally during routine radiographic examination. Rarely, the cyst does become infected, and the patient may complain of local discomfort or pain in the area.

Radiographic Features. This cyst, on the intraoral radiograph, characteristically appears as an inverted, pear-shaped radiolucent area between the roots of the lateral incisor and cuspid, usually causing divergence of the roots of these teeth (Fig. 1-68A). Interestingly, there are several known cases of bilateral globulomaxillary cyst (Fig. 1-68B).

Care must be exercised not to confuse this lesion with an apical periodontal cyst arising as a result of pulp involvement or trauma to one of the adjacent teeth. The teeth associated with a globulomaxillary cyst are vital unless coincidentally infected.

It has been emphasized recently by Wysocki, reviewing 37 cases of 'globulomaxillary radiolucencies' that many different types of lesions may present radiographically with features characteristic of a globulomaxillary cyst and that these must be included in any differential diagnosis of such a radiolucency in this area. He cited as examples such lesions as the periapical granuloma, apical periodontal cyst, lateral periodontal cyst, odontogenic keratocyst, central giant cell granuloma, calcifying odontogenic cyst, and odontogenic myxoma. He also concluded, in agreement with Christ, that cysts in the globulomaxillary region are odontogenic rather than fissural in origin.

A B

Figure 1-68. Globulomaxillary cyst.
There is a large cyst between the maxillary lateral incisor and cuspid teeth with a characteristic inverted pear shape **(A)**. The same type of cyst may occur bilaterally **(B)**. Note the divergence of the roots of these teeth *(Courtesy of Dr Michael J Freeman and Richard Oliver)*

Histologic Features. The globulomaxillary cyst classically has been described as being lined by either stratified squamous or ciliated columnar epithelium. However, Christ has emphasized that, in the literature, there is no accepted case of globulomaxillary cyst that is lined by pseudostratified ciliated columnar epithelium. The remainder of the wall is made up of fibrous connective tissue, usually showing inflammatory cell infiltration.

Treatment. This type of cyst should be surgically removed, preserving the adjacent teeth if possible.

Median Mandibular Cyst

The median mandibular developmental cyst is an extremely rare lesion occurring in the midline of the mandible. It is of disputed origin. Some authorities consider it a true developmental condition originating from proliferation of epithelial remnants entrapped in the median mandibular fissure during fusion of the bilateral mandibular fissure during fusion of the bilateral mandibular arches. The possibility does exist; however, that the lesion may represent some type of odontogenic cyst such as a primordial cyst originating from a supernumerary enamel organ in the anterior mandibular segment, particularly since the bones uniting at the mandibular symphysis originate deep within the mesenchyme and thereby provide little opportunity for inclusion and subsequent proliferation of epithelial rests deep within the bone. It is also conceivable that this lesion represents a lateral periodontal cyst occurring in the midline, although the origin of this latter lesion is also obscure. The pertinent literature about this unusual type of cyst has been reviewed by White and his coworkers.

Clinical Features. Most of the median mandibular developmental cysts are clinically asymptomatic and are discovered only during routine radiographic examination. They seldom produce obvious expansion of the cortical plates of bone, and the associated teeth; unless otherwise involved, they react normally to pulp vitality tests.

Radiographic Features. The radiographic appearance of the cyst is generally that of a unilocular, well-circumscribed radiolucency, although it may also appear multilocular (Fig. 1-69).

Histologic Features. Histologic examination of the lesion shows a thin, stratified squamous epithelium, often with many folds and projections, lining a central lumen. But in some reported cases, the cyst has been lined by a pseudostratified ciliated columnar epithelium.

Treatment and Prognosis. Too few cases have been reported to be certain of the prognosis of the median mandibular developmental cyst, but conservative surgical excision with preservation of associated teeth, if possible, is deemed advisable.

Nasoalveolar Cyst
(Nasolabial cyst, Klestadt's cyst)

The nasoalveolar cyst is not found within bone, but is usually described as a rare fissural cyst that may involve bone secondarily. It has been thought to arise at the junction of the globular process, the lateral nasal process, and the maxillary

Figure 1-69. Median mandibular cyst.
All teeth in the anterior segment were vital *(Courtesy of Dr Howard H Morgan).*

process as a result of proliferation of entrapped epithelium along the fusion line.

Clinical Features. The nasoalveolar cyst may cause a swelling in the mucolabial fold as well as in the floor of the nose, being located near the attachment of the ala over the maxilla. Superficial erosion of the outer surface of the maxilla may be produced by pressure of the nasoalveolar cyst, but it should be noted that they are not primarily central lesions and therefore may not be visible on the radiograph. Bilateral cases, such as reported by Brandao and his associates, are very rare.

Roed-Petersen, in a discussion of this lesion, reviewed 160 reported cases and noted that slightly over 75% of cases occurred in women. The mean age of occurrence was between 41 and 46 years, although cases have been reported in persons from 12–75 years of age.

Excellent reviews of the nasoalveolar cyst, with recapitulations of its etiology and pathogenesis, have been published by Moeller and Philipsen and by Campbell and Burkes. It has been suggested by Roed-Petersen and emphasized by Christ that this cyst probably originates from the lower anterior part of the nasolacrimal duct rather than from epithelium entrapped in the naso-optic furrow.

Histologic Features. Histologically, the nasoalveolar cyst may be lined by pseudostratified columnar epithelium which is sometimes ciliated, often with goblet cells, or by stratified squamous epithelium.

Treatment. The cyst should be surgically excised, although care must be exercised to prevent perforation and collapse of the lesion.

Palatal and Alveolar Cysts of Newborns
(Epstein's pearls, Bohn's nodules, gingival cysts of the newborn)

A special form of odontogenic cyst is found in as many as 80% of newborn infants. Although this gingival cyst of the newborn has the microscopic appearance of an epidermoid cyst, it arises from epithelial remnants of the deeply budding dental lamina during tooth development, after the fourth month *in utero,* and is, therefore, discussed with the odontogenic lesions in the present text. A similar palatal cyst of the newborn is commonly found in the posterior midline of the hard palate, where it arises from epithelial remnants remaining in the stroma after fusion of the palatal processes which meet medially to form the palate. As originally described, the cysts along the median raphe of the palate were called Epstein's pearls and the term Bohn's nodules was used for cysts which originated from palatal gland structures and were scattered more widely over the hard and soft palates. Today these two terms are used interchangeably for both palatal and gingival cysts of newborns.

Clinical Features. Palatal cysts of the newborn typically present as multiple (usually less than six) 1–4 mm yellow-white, sessile mucosal papules of the posterior hard palate, and occasionally of the anterior soft palate. Occasional cysts are located at some distance from the midline. The cysts are usually somewhat larger and less numerous than the gingival cysts of the alveolar processes in newborns, but the two entities are, otherwise, clinically identical. Both types of cysts are so superficial that several may be ruptured at the time of examination (Fig. 1-70).

Histologic Features. Both gingival and palatal cysts of the newborn show a thin, stratified squamous epithelium cyst lining with a routine fibrovascular connective tissue stroma,

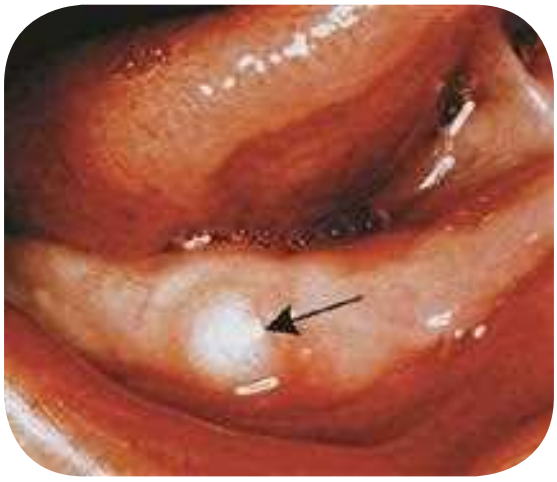


Figure 1-70. Alveolar cysts of newborn.

usually without an inflammatory cell infiltrate. The cystic lumen is filled with degenerated keratin, usually formed into concentric layers or **onion rings** and the epithelium lacks rete processes. Occasional cysts will demonstrate a communication with the surface.

Treatment and Prognosis. No treatment is required for gingival or palatal cysts of the newborn. The cysts are very superficial and within weeks will rupture to harmlessly spill their contents into the oral or pharyngeal environment. The cyst lining then fuses with the overlying mucosa and becomes part of it. Occasionally, a larger cyst or a cyst situated more deeply in the submucosal stroma will remain for six to eight months before rupturing.

Thyroglossal Duct Cyst

The thyroglossal duct cyst is a rare but occasional cause of a benign midline neck mass. The cyst is usually located at the midline of the neck. The duct extends upward from the cyst with varying numbers of branches and secretory glands. These ducts or branches merge into a single duct at the level of the hyoid bone.

Thyroglossal duct cysts result from the dilatation of a remnant at the site where the primitive thyroid descended from its origin at the base of the tongue to its permanent location, low in the neck. Failure of subsequent closure and obliteration of this tract predisposes to thyroglossal cyst formation.

It most often occurs before age 20, but may be found in the older population as well.

Clinical Features. Thyroglossal duct cysts most often present with a palpable (able to be felt) asymptomatic midline neck mass at or below the level of the hyoid bone. The neck mass moves with swallowing. Some patients will have neck or throat pain, or dysphagia (difficulty in swallowing). The spectrum of clinical symptoms may be as varied.

Since the persistent duct or sinus can promote oral secretions, such cysts can become infected. Up to one half of thyroglossal cysts are not diagnosed until adult life. The tract may lie dormant for years or decades until some stimulus leads to cystic dilatation. Infection sometimes causes transient appearance of a mass or enlargement of the cyst, at times with periodic recurrences. Spontaneous drainage occurs in some instances.

Diagnosis is usually made clinically.

Histologic Features. The thyroglossal tract cyst may be lined by stratified squamous epithelium, ciliated columnar epithelium, or intermediate transition type, since it is actually derived from cells originating from the embryonic pharyngeal floor (Fig. 1-71 A–D). With increased intracystic pressure, the cells may become flattened. The connective tissue wall of the cyst will frequently contain small patches of lymphoid tissue, thyroid tissue, and mucous glands. Interestingly, nodular collections of sebaceous glands in association with thyroglossal duct like structures of the tongue occasionally have been reported. Leider and his associates have described such a case as a sebaceous choristoma of the lingual thyroglossal duct.

Treatment and Prognosis. Antibiotics are indicated if there is infection. Definitive surgical management requires excision not only of the cyst but also of the path's tract and branches. The intimate association of the tract with hyoid bone mandates simultaneous removal of the central portion of the hyoid bone to ensure complete removal of the tract (Sistrunk procedure). Recurrence is unlikely after such an operation except with skin involvement and intraoperative cyst rupture.

Before thyroglossal duct cysts are excised, it is important to demonstrate that normally functioning thyroid tissue is in its usual location. Thyroid scans and thyroid function studies are ordered preoperatively.

Epidermal Inclusion Cyst

(Epidermal cyst, epidermoid cyst, epithelial cyst, keratin cyst, sebaceous cyst, milia)

The terminology and nomenclature of jaw cysts varies. Epidermal inclusion cysts are the result of implantation of epidermal elements and its subsequent cystic transformation. The term epidermoid cysts is used in a general context in that, irrespective of the source of the epithelium, the term persists. Milia merely represent miniature epidermoid cysts. Sebaceous cyst is a misnomer, and the term should not be used at all because these cysts are not of sebaceous origin.

Etiology. The origin of epidermoid cyst is varied. They may form by the sequestration and implantation of epidermal rest during embryonal period, occlusion of the pilosebaceous unit, or iatrogenic or surgical implantation of epithelium into the jaw mesenchyme. HPV infection and eccrine duct occlusion may be additional factors in the development of palmoplantar epidermoid cysts. Epidermoid cysts result from the proliferation of epidermal cells within a circumscribed space of the dermis. They have been shown not to be of sebaceous origin based on the analysis of their lipid pattern, which demonstrates similarities to the epidermis. In addition, epidermoid cysts express cytokeratins 1 and 10, which are constituents of the suprabasilar layers of the epidermis. The source of this epidermis is often the infundibulum of the hair follicle. Inflammation is in part mediated by the horny material contained in epidermoid cysts. Extracts of this material have been shown to be chemotactic for polymorphonucleocytes.

Clinical Features. The epidermoid cysts are indolent in nature, slow to progress and remains asymptomatic until or unless secondarily infected. The occurrence of secondary malignancies of the types basal cell carcinoma, Bowen disease, SCC and even mycosis fungoides have been reported albeit rarely. In one study, epidermoid cysts were approximately twice as common in men as in women. Epidermoid cysts may occur at any time in life, but they are most common in the third and fourth decades of life. Gardner syndrome is an exception; the average patient age at onset is 13 years. Discharge of a foul-smelling cheese-like material is a common complaint. Less frequently, the cysts can become inflamed or infected, resulting in pain and tenderness. In the uncommon event of

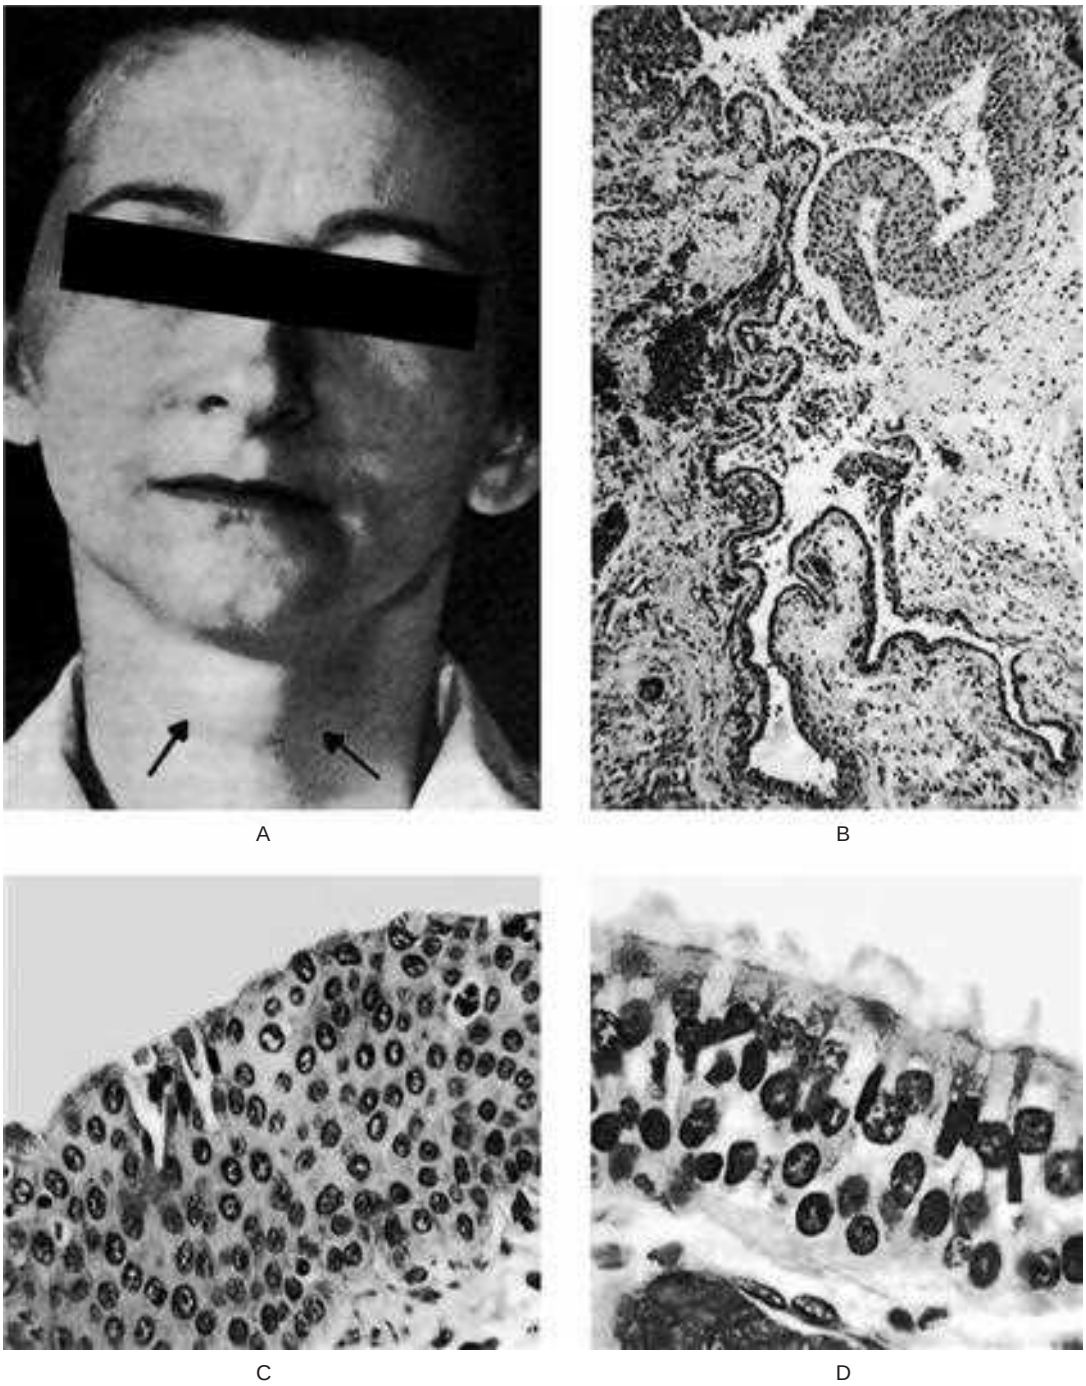

Figure 1-71. Thyroglossal tract cyst.
Patient demonstrates a midline palpable fluctuant lesion **(A)**, which was found to be an epithelium-lined cyst **(B)** composed of both stratified squamous epithelium **(C)** and pseudostratified, ciliated columnar epithelium **(D)**. *(Courtesy of Dr James O Beck Jr)*.

malignancy, rapid growth, friability, and bleeding have been reported. When located orally, the cysts can cause difficulty in feeding, swallowing, or even speaking (Fig. 1-72). Epidermoid cysts appear as firm, round, mobile, flesh-colored to yellow or white subcutaneous nodules of variable size. A central pore or punctum is an inconsistent finding that may adhere the cyst to the overlying epidermis and from which a thick cheesy material can sometimes be expressed. In individuals with dark pigmentation, epidermoid cysts may also be pigmented. In a study of Indian patients with epidermoid cysts, 63% of the cysts contained melanin pigment.

This cyst is mainly reported from sites of face, the trunk, the neck, the extremities, and the scalp. While facial involvement is also frequent in Gardner syndrome, the extremities tend to be affected more than the trunk. The ocular and oral mucosae can also be affected, and cysts have been reported on the palpebral

Figure 1-72. Epidermoid cyst.
Lesion appears as a symmetrical swelling in the floor of the mouth *(Courtesy of Dr N Gururaj, CSI Dental College, Madurai, Tamil Nadu)*.

conjunctivae, on the lips, on the buccal mucosa, under the tongue, and even on the uvula. The anterior fontanelle is an unusual location where epidermoid cysts have been found.

Certain hereditary syndromes have epidermoid cysts as part of their features. Examples include **Gardner syndrome, basal cell nevus syndrome,** and **pachyonychia congenita.** An epidermoid cyst may be a feature of pachyonychia congenita.

Histologic Features. The cystic lining is comprised of stratified squamous epithelium with glandular differentiation and is filled with desquamated keratin disposed in a laminar pattern. Dystrophic calcification and reactive foreign body reaction are seen associated with the cystic capsule. Malignant transformation of the cystic lining is noticed not infrequently.

Pigmented epidermoid cysts may demonstrate melanin pigment in the wall and a keratin mass. A surrounding infiltrate of melanocytes and melanophages may also be observed. Palmoplantar epidermoid cysts that are infected with HPV show characteristic histologic changes. The findings include intracytoplasmic eosinophilic inclusion bodies in the cyst wall, vacuolated cells and cells with condensed keratohyalin granules in the granular layer, elongated rete ridges, and vacuolated structures and parakeratotic nuclei in the keratinous mass. Structures resembling eccrine ducts are also observed in some lesions.

Treatment and Prognosis. Surgical removal seems to be the mainstay in the management protocol and recurrence is seldom noticed. Malignancies have been identified in epidermoid cysts. An unusual complication reported from an oral epidermoid cyst was sialadenitis due to pressure on the submandibular salivary duct.

Dermoid Cyst

(Dermoid cystic tumor, cystic teratoma, ovarian cystic teratoma, cystic tumor of ovary, cystic tumors of omentum, congenital cyst of spine, spinal dermoid cysts)

A hamartomatous tumor containing multiple sebaceous glands and almost all skin adnexa, this may contain substances such as nails and dental, cartilage like, and bone like structures. If limited to the skin or subcutaneous tissue, dermoid cysts are thin-walled tumors that contain different amounts of fatty masses; occasionally, they contain horny masses and hairs. The origin of this cyst is probably by sequestration of skin and subsequent implantation of it along the lines of embryonic closure.

Clinical Features. Dermoid cyst occurs mostly on the face, neck, or scalp. In addition to the skin, dermoid cysts can be intracranial, intraspinal, or perispinal. Intra-abdominal cysts, such as cystic tumors of the ovary or omentum, occur as well. No racial predilection appears to exist; however, most cases of dermoid cysts in the literature occurred in whites. Dermoid cysts of the ovary or omentum are gender restricted, that is, they occur only in the female population. In other dermoid cysts, no gender predilection has been found. Dermoid cysts are described in persons of all ages. Intracranial or perispinal dermoid cysts are most often found in infants, children, or young adolescents. Intra-abdominal dermoid cysts are described in females aged 15–40 years. For example, cystic teratoma is a relatively rare tumor that most often occurs in females aged 15–40 years. Most dermoid cysts on the floor of the mouth occur in individuals aged 10–30 years. Only a few cases describe oral dermoid cysts in newborns or children. Dermoid cysts that are congenital and localized on the neck, head, or trunk are usually visible at birth. Occasionally, they occur on the neck or in a midline region. When on the head, dermoid cysts are often adherent to the periosteum. The usual diameter of the lesions is 1–4 cm. In many patients, dermoid cysts occur on the floor of the mouth or elsewhere in the mouth. Three subclasses of congenital mouth cysts are described in the literature: **epidermoid (simple) cysts, dermoid (complex) cysts, and teratoid (complex) cysts.** Most of these lesions occur in individuals aged 10–30 years. Other rare dermoid cysts in the oral cavity are those on the tongue. As of early 2000, 17 patients with intralingual dermoid cysts are described in the English-language literature. All cases occurred in young patients.

Histologic Features. In contrast to epidermal cysts, dermoid cysts in the skin are lined by an epidermis that possesses various epidermal appendages. As a rule, these appendages are fully mature. Hair follicles containing hairs that project into the lumen of the cyst are often present. The dermis of dermoid cysts usually contains sebaceous glands; eccrine glands; and, in many patients, apocrine glands. Occasionally, the lining epithelium may proliferate as papillary boundaries extend externally or inward toward the lumen of the cyst. This proliferation may have some superficial resemblance to epidermal carcinomatous proliferation, and the growth may be misdiagnosed as a cancer.

Treatment and Prognosis. Surgical excision is the treatment of choice in any localization.

Heterotopic Oral Gastrointestinal Cyst

Heterotopic islands of gastric mucosa have been found in the esophagus, small intestine, thoracic cysts, omphalomesenteric cysts, pancreas, gallbladder, and Meckel's diverticulum,

according to the review by Gorlin and Jirasek. In addition, Harris and Courtemanche cited at least 17 cases of cysts lined by gastric or intestinal mucosa occurring in the oral cavity, in the tongue, or in the floor of the mouth, probably from misplaced embryonal rests.

Clinical Features. This choristomatic cyst can be found in patients at any age, although the majority have been infants or young children. It may be significant that the lesion occurs overwhelmingly in males.

The cyst presents as a small nodule entirely within the body of the tongue, either anterior or posterior, or in the floor of the mouth, in the neck, or adjacent to the submaxillary gland. It may be asymptomatic or may cause difficulty in eating or speaking. Some cysts communicate with the surface mucosa by a tube or duct like structure.

Histologic Features. This cyst is usually lined partly by stratified squamous epithelium and partly by gastric mucosa similar to that found in the body and fundus of the stomach, with both parietal and chief cells. Sometimes intestinal epithelium is found, including Paneth, goblet and argentaffin cells. A muscularis mucosa may or may not be present.

Treatment. Surgical excision is the treatment of choice, although this lesion cannot be diagnosed clinically and is seldom suspected.

CHAPTER 2

Benign and Malignant Tumors of the Oral Cavity

■ T"TCLGPFTCP

CHAPTER OUTLINE

The study of tumors of the oral cavity and adjacent structures constitutes an important phase of dentistry because of the role which the dentist plays in the diagnosis and treatment of these lesions. Although tumors constitute only a small number of the pathologic conditions seen by the dentist, they are of great significance since they have the potential ability to jeopardize the health and longevity of the patient. Many of the great variety of oral tumors will seldom be seen by the general practitioner of dentistry. Yet, it is of utmost importance that he/she be familiar with them so that when one does present itself, he/she may either institute appropriate treatment or refer the patient to the proper therapist.

A tumor, by definition, is simply a swelling of the tissue in the strict sense, the word does not imply a neoplastic process. Many of the lesions to be discussed in this chapter are called tumors only because they are manifested as swellings; they are in no way actually related to true neoplasms.

Neoplasia is a poorly understood biological phenomenon which, in some instances, cannot be clearly differentiated from other processes or tissue reactions. A neoplasm can be defined as an abnormal mass of tissue, the growth of which exceeds and is uncoordinated with that of the normal tissues and persists in the same excessive manner after cessation of the stimuli which evoked the change (Willis 1952).

BENIGN TUMORS OF EPITHELIAL TISSUE ORIGIN

Squamous Papilloma

The oral squamous papillomas are seemed to be associated with papilloma virus, the one commonly incriminated as causative in skin warts. It is the fourth most common oral mucosal mass and is found in 4 of every 1,000 and accounts for 3–4% of all biopsied oral soft tissue lesions.

The HPV types 6 and 11, commonly associated with squamous papillomas, failed to be demonstrated in oral malignancies as well as potentially malignant oral lesions. Even though all HPV lesions are infective, the squamous papilloma appears to have an extremely low virulence and infectivity rate; it does not seem to be contagious.

Since the squamous papilloma may be clinically and microscopically indistinguishable from verruca vulgaris, the virus-induced focal papillary hyperplasia of the epidermis, it is briefly discussed in this section.

Clinical Features. The papilloma is an exophytic growth made up of numerous, small finger like projections which result in a lesion with a roughened, verrucous or 'cauliflower like' surface. It is nearly always a well circumscribed pedunculated tumor, occasionally sessile. It is painless, usually white but sometimes pink in color. Intraorally it is found most commonly on the tongue, lips, buccal mucosa, gingiva and palate, particularly that area adjacent to the uvula (Fig. 2-1). The majority of papillomas are only a few millimeters in diameter, but lesions may be encountered which measure several centimeters. These growths occur at any age and are seen even in young children. A series of 110 cases has been reported by Greer and Goldman, while a series of 464 cases has been studied by Abbey and his coworkers; this is somewhat indicative of the prevalent nature of the lesion.

The common wart or verruca vulgaris, is a frequent tumor of the skin analogous to the oral papilloma. It is uncommon

Figure 2-1. Papilloma.
Large **(A)** and small **(B)** papillomas of the tongue illustrate the variation in clinical appearance of the lesion. The photomicrograph **(C)** illustrates the many finger like projections (1), each containing a thin, central connective tissue core (2), of which the lesion is composed.

on oral mucous membranes but extremely common on the skin. The associated viruses in verruca are the subtypes HPV-2, HPV-4 and HPV-40. Clinically it shows pointed or verruciform surface projections, a very narrow stalk, appears white due to considerable surface keratin, and presents as multiple or clustered individual lesions. It enlarges rapidly to its maximum size, seldom achieving more than 5 mm in greatest diameter. Verruca vulgaris is contagious and capable of spreading to other parts of an affected person's skin or membranes by way of autoinoculation. Lesions that are histologically identical to the verruca vulgaris of the skin are frequently found on the lips and occasionally intraorally (Fig. 2-2). These are often seen in patients with verrucae on the hands or fingers, and the oral lesions appear to arise through autoinoculation by finger sucking or fingernail biting.

Papilloma like or papillomatous lesions as well as 'pebbly' lesions and fibromas of various sites in the oral cavity are recognized as one of the many manifestations of the multiple hamartoma and neoplasia syndrome (Cowden's syndrome). This is an autosomal dominant disease characterized by facial trichilemmomas associated with the gastrointestinal tract, the thyroid, CNS and musculoskeletal abnormalities as well as oral lesions. It is also considered a cutaneous marker of breast cancer.

Figure 2-2. Verruca vulgaris.
These verrucae of the lips occurred in a girl, with similar lesions on the fingers, who habitually bit her fingernails *(Courtesy of Dr Paul E Starkey)*.

Histologic Features. The microscopic appearance of the papilloma is characteristic and consists of many long, thin, finger-like projections extending above the surface of the mucosa, each made up of a continuous layer of stratified squamous epithelium and containing a thin, central connective tissue core which supports the nutrient blood vessels (Fig. 2-1C). Some papillomas exhibit hyperkeratosis, although this finding is probably secondary to the location of the lesion and the amount of trauma or frictional irritation to which it has been subjected. The essential feature is a proliferation of the spinous cells in a papillary pattern; the connective tissue present is supportive stroma only and is not considered a part of the neoplastic element. Occasional papillomas demonstrate pronounced basilar hyperplasia and mild mitotic activity which should not be mistaken for mild epithelial dysplasia. **Koilocytes** (HPV altered epithelial cells with perinuclear clear spaces and nuclear pyknosis) may or may not be found in the superficial layers of the epithelium. The presence of chronic inflammatory cells may be variably noted in the connective tissue.

Treatment and Prognosis. Treatment of the papilloma consists of excision, including the base of the mucosa into which the pedicle or stalk inserts. Removal should never be accomplished by an incision through the pedicle. If the tumor is properly excised, recurrence is rare. The possibility of malignant degeneration in the oral papilloma is quite unlikely, although fixation of the base or induration of the deeper tissues should always be viewed with some suspicion.

Intraoral verruca vulgaris is also treated effectively by conservative surgical excision or curettage, but liquid nitrogen cryotherapy and topical application of keratinolytic agents (usually containing salicylic acid and lactic acid) are also effective. Recurrence is seen in a small proportion of treated cases.

Squamous Acanthoma

The squamous acanthoma is an uncommon lesion which probably represents a reactive phenomenon of the epithelium rather than a true neoplasm. It bears no known relationship to the clear cell acanthoma, which occurs with considerable frequency on the skin and may also be found on the lips, as in the two cases reported by Weitzner.

The squamous acanthoma has no distinctive clinical appearance by which it may be identified or even suspected, and may occur at virtually any site on the oral mucosa, usually in older adults. It is generally described as a small flat or elevated, white, sessile or pedunculated lesion on the mucosa. The lesion is histologically distinctive and consists of a well-demarcated elevated and/or umbilicated epithelial proliferation with a markedly thickened layer of orthokeratin and underlying spinous layer of cells. Tomich and Shafer, who originally described this lesion, postulated that it was caused by trauma and developed its characteristic morphology through a series of epithelial alterations beginning with a localized pseudoepitheliomatous hyperplasia. It is not known to recur after excision.

Keratoacanthoma

(Self-healing carcinoma, molluscum pseudocarcinomatosum, molluscum sebaceum, verrucoma)

A lesion which clinically and pathologically resembles squamous cell carcinoma, keratoacanthoma is a relatively common low-grade malignancy that originates in the pilosebaceous glands. It is considered to be a variant of invasive squamous cell carcinoma.

The definite cause of this lesion remains unclear but similarity in epidemiologic data with squamous cell carcinoma and Bowen disease supports sunlight as an important etiologic factor. Industrial workers exposed to pitch and tar have been well established as having a higher incidence of keratoacanthoma, thus chemical carcinogens may be one of the etiologic factors. Trauma, human papilloma virus (specifically types 9, 11, 13, 16, 18, 24, 25, 33, 37, and 57), genetic factors and immunocompromised status also have been implicated as etiologic factors. Recent studies identified that up to one-third of keratoacanthomas harbor chromosomal aberrations such as gains on 8q, 1p, and 9q with deletions on 3p, 9p, 19p, and 19q. One other report identified a 46, XY, t (2;8) (p13; p23) chromosomal aberration.

Clinical Features. Keratoacanthoma has been reported in all age groups, but incidence increases with age. It occurs twice as frequently in men as in women and is less common in darker skinned individuals. Most keratoacanthomas occur on sun-exposed areas. The face, neck, and dorsum of the upper extremities are common sites; 8.1% of the cases occurred on the lips and the vermilion border of both the upper and lower lip are affected with equal frequency. Intraoral lesions are quite uncommon, a total of four cases were reviewed by Freedman and his associates.

Lesions typically are solitary and begin as firm, round, skin-colored or reddish papules that rapidly progress to dome-shaped nodules with a smooth shiny surface and a central crateriform ulceration or keratin plug that may project like a horn. The lesion appears as an elevated umbilicated or crateriform one with a depressed central core or plug (Fig. 2-3). It is seldom over 1.0 to 1.5 cm in diameter. The lesion is often painful and regional lymphadenopathy may be present.

The clinical course of the lesion is one of its unusual aspects. It begins as a small, firm nodule that develops to full size over a period of four to eight weeks, persists as a static lesion for another four to eight weeks, then undergoes spontaneous regression over the next six- to eight-week period by expulsion of the keratin core with resorption of the mass. However, lesions with an overall duration of as long as two years have been reported. Recurrence is rare.

The differential diagnoses include actinic keratosis, molluscum contagiosum, Muir-Torre syndrome, squamous cell carcinoma, and verrucous carcinoma.

Histologic Findings. The lesion consists of hyperplastic squamous epithelium growing into the underlying connective tissue. The surface is covered by a thickened layer of parakeratin

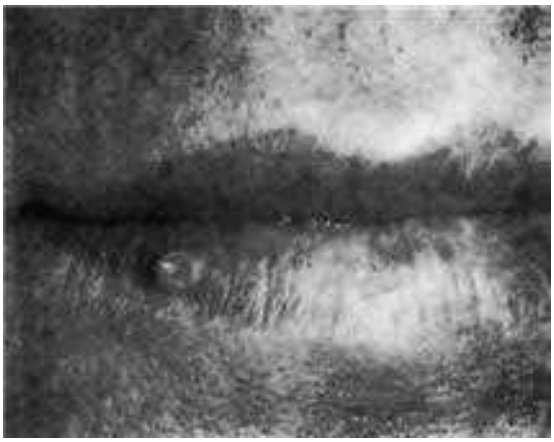

Figure 2-3. Keratoacanthoma.
This small keratoacanthoma of the lip illustrates the typical elevated, umbilicated appearance of the lesion *(Courtesy of Dr Charles E Huttom)*.

or orthokeratin with central plugging. The epithelial cells do not usually show atypia but occasionally dysplastic features are found. At the deep leading margin of the tumor, islands of epithelium often appear to be invading and frequently this area cannot be differentiated from epidermoid carcinoma. Lapins and Helwig, among others, have also reported that the keratoacanthoma on occasion may invade perineural spaces, but this does not adversely affect the biologic behavior of the lesion; neither can it be used as a distinguishing characteristic between keratoacanthoma and epidermoid carcinoma. Pseudocarcinomatous infiltration typically presents a smooth, regular, well-demarcated front that does not extend beyond the level of the sweat glands. The connective tissue in the area shows chronic inflammatory cell infiltration. The most characteristic feature of the lesion is found at the margins where the normal adjacent epithelium is elevated towards the central portion of the crater; then an abrupt change in the normal epithelium occurs as the hyperplastic acanthotic epithelium is reached. For this reason, the diagnosis may be impossible if the adjacent border of the specimen is not included in the biopsy.

The term squamous cell carcinoma, keratoacanthoma type has been introduced for otherwise classic keratoacanthomas that reveal a peripheral zone formed by squamous cells with atypical mitotic figures, hyperchromatic nuclei, and loss of polarity to some degree. These marginal cells also may penetrate into surrounding tissue in a more aggressive pattern.

Treatment. The lesion is usually treated by surgical excision. Spontaneous regression does not occur in every case; where it has occurred, residual scar may be present. Prognosis is excellent following excisional surgery. Recurrent tumors may require more aggressive therapy. Patients with a history of keratoacanthoma should be followed for the development of new primary skin cancers (squamous cell carcinoma, in particular).

Oral Nevi

(Oral melanocytic nevus, nevocellular nevus, mole, mucosal melanocytic nevi)

Categorized as hamartomas, developmental malformations, the nevi are benign proliferations of nevus cells in either epithelium or connective tissue. In 1943, Ackermann and Field have reported the first case of an oral nevus. King et al, adopted the less anatomically specific term, intramucosal nevus. Adult whites harbor this lesion rather commonly but intraoral lesions are much less common.

Nevi may also be classified as **congenital** or **acquired** (Buchner and Hansen). On the basis of the histologic location of the nevus cells, cutaneous acquired nevi can be classified into three categories:

- **Junctional nevus**—when nevus cells are limited to the basal cell layer of the epithelium
- **Compound nevus—**nevus cells are in the epidermis and dermis
- **Intradermal nevus** (common mole)—nests of nevus cells are entirely in the dermis.

Oral nevi follow the same classification where the term intradermal is replaced by intramucosal.

Oral acquired melanocytic nevi evolve through stages similar to those of nevi on the skin. Junctional nevi that are first noted in infants, children and young adults typically mature into compound nevi. Then, during later adulthood, the lesions mature into intramucosal nevi. As the nevus cells penetrate into the dermis, their pigmentation diminishes; approximately 15% of intramucosal nevi are nonpigmented.

The most common mucosal type is the intramucosal nevus, which accounts for more than one half of all reported oral nevi. The common **blue nevus** is the second most common type found in the oral cavity. The blue nevi is commoner in the mouth than in the skin; which account for 25–36% of all oral nevi, according to different studies. Junctional and compound nevi account for only 3–6% of all oral nevi.

Clinical Features. Ainsworth and her colleagues separate the congenital nevi of the skin into 'small' and 'garment' nevi. The 'small' nevi are greater than 1 cm in diameter and usually 3–5 cm. The 'garment' nevi are greater than 10 cm in diameter and can cover large areas of the skin. The congenital nevi occur in 1–2.5% of neonates and, with the passage of time, may change from flat, pale tan macules to elevated, verrucous, hairy lesions. Approximately 15% occur on the skin of the head and neck. Intraoral occurrence is extremely rare.

Acquired nevi are extremely common. They appear in about the eighth month of life and increase in number with age, apparently reaching their peak numerically in the late third decade of life. Clark has stated that the number of nevi which a person has is genetically determined. Interestingly, the number of nevi begin to decrease as one ages, so that elderly persons average far fewer nevi than younger adults.

The **intradermal nevus** (common mole) is one of the most common lesions of the skin, most persons exhibiting several, often dozens, scattered over the body. The common

A B

Figure 2-4. Pigmented cellular nevus.
Typical examples of nevi of the skin **(A)** and palate **(B)** are illustrated.

mole may be a smooth flat lesion or may be elevated above the surface; it may or may not exhibit brown pigmentation, and it often shows strands of hair growing from its surface (Fig. 2-4). This form of mole seldom occurs on the soles of the feet, the palms of the hands or the genitalia.

The **junctional nevus** may appear clinically similar to the intradermal nevus, the distinction being chiefly histologic. It is extremely important; however, that a distinction be drawn, since the prognosis of the two lesions is different, as will be pointed out later.

The **compound nevus** is a lesion composed of two elements: an intradermal nevus and an overlying junctional nevus.

The **spindle cell and/or epithelioid cell nevus (Spitz nevus)** occurs chiefly in children, only about 15% appearing in adults, and may appear histologically similar to malignant melanoma in the adult. Seldom; however, does this lesion exhibit clinically malignant features. Essentially, this lesion is clinically benign, but histologically malignant. Weedon and Little have reviewed 211 cases of spindle cell and epithelioid cell nevi while Allen has reviewed 262 cases, and none of these authors have found any nevus of this type on a mucous membrane surface, including the oral cavity.

The **blue nevus** is a true mesodermal structure composed of dermal melanocytes which only rarely undergo malignant transformation. It occurs chiefly on the buttocks, on the dorsum of the feet and hands, on the face and occasionally on other areas. The majority of blue nevi are present at birth or appear in early childhood and persist unchanged throughout life. The lesion is smooth, exhibits hairs growing from its surface and varies in color from brown to blue or bluish black. Scofield reviewed this lesion in 1959 and reported two intraoral cases, the first recorded occurrence of the lesions in the mouth. Since then, numerous intraoral lesions have been reported.

Histologic variants of acquired nevi such as neural, balloon cell and halo nevi occur. Only the halo nevus is clinicopathologically distinctive. The neural and balloon cell nevi are histologic variants of intradermal or compound nevi.

Oral Manifestations. Eight-five percent of oral nevi are found in patients younger than 40 years. Oral nevi are found in all races and more frequently in whites, in whom 55% of reported oral nevi occurred. Approximately 23% of oral nevi occurred in black patients. Patients with junctional or compound nevi were relatively young; they were aged 22 and 24 years, respectively, whereas the mean age of patients with intramucosal nevi and blue nevi was 35 years and 38 years, respectively. Studies have revealed that oral mucosal nevi are slightly predominant in women rather than men. Oral nevi most commonly occur on the hard palate, with almost 40% presenting in that location. The second most common location is the buccal mucosa (20% of cases). Other common locations include the vermilion border of the lip and the labial mucosa. Roughly 10% of all types of oral nevi are found on the gingiva. Only one mucosal nevus has been reported on the tongue or floor of the mouth.

Most oral nevi are asymptomatic, and the lesions are usually detected as an incidental finding on routine dental examination. Nevi are often mistaken for melanotic macules, amalgam tattoos, physiologic ethnic pigmentation, smoker's melanosis, or other vascular or pigmented lesions.

An aid in differential diagnosis is that melanotic macules and amalgam tattoos are usually flat while the majority of nevi elevate from the mucosal surface. Ethnic pigmentation is nearly always symmetric and rarely affects the surface topography or disturbs the normal stippling in the gingiva. Smoker's melanosis involves only the anterior gingiva and most often occurs in women who smoke and take oral contraceptives. Vascular lesions can be mistaken for melanocytic proliferations; the former usually blanch with compression, and aspiration may be helpful in differentiating a nevus from a vascular process. Malignant melanoma is frequently associated with diffuse areas of pigmentation, possible ulceration, nodularity, variegation in color, and an irregular outline.

Approximately 85% of oral nevi are pigmented. Pigmentation usually varies from brown to black or blue. Nevi are well circumscribed, round, or oval, and are raised or slightly raised

in 65–80% of cases. Approximately 15% of nevi are amelanotic. Many amelanocytic lesions appear as sessile growths that resemble fibromas or papillomas or excrescences of normal color.

The anatomic distribution of nevi closely follows its histologic type. Almost two-thirds of blue nevi occur in hard palate. Intramucosal nevi are distributed almost equally between the hard palate and buccal mucosa, with almost 25% in each location. Approximately 17% of intramucosal nevi are on the gingiva, 12% on the vermilion border of the lip, and almost 9% on the labial mucosa.

Histologic Features. The nevus cells are assumed to be derived from neural crest and their envisaged relationship with true melanocytes remains uncertain. Nevus cells are large ovoid, rounded, or spindle-shaped cells with pale cytoplasm; and may contain granules of melanin pigment in their cytoplasm. The nucleus is vesicular and lacks the dendritic processes typical of melanocytes. In addition, they either lack contact inhibition or lose it shortly after the proliferation process begins. Melanosomes are retained by nevus cells and are not transferred to adjacent keratinocytes. They tend to be grouped in sheets or cords which are called nest or thèque. Nevus cells also have the ability to migrate from the basal cell layer into the underlying connective tissue.

Multinucleated giant nevus cells are sometimes seen, but are of little prognostic significance. Mitotic figures are not common.

In the **intradermal nevus,** the nevus cells are situated within the connective tissue and are separated from the overlying epithelium by a well defined band of connective tissue. Thus, in the intradermal nevus, the nevus cells are not in contact with the surface epithelium (Fig. 2-5A).

In the **junctional nevus,** this zone of demarcation is absent, and the nevus cells contact and seem to blend into the surface epithelium. This overlying epithelium is usually thin and irregular and shows cells apparently crossing the junction and growing down into the connective tissue—the so-called *abtropfung* or 'dropping off' effect. This 'junctional activity' has serious implications because junctional nevi have been known to undergo transformation into malignant melanomas (Fig. 2-5D).

The **compound nevus** shows features of both the junctional and intradermal nevus. Nests of nevus cells are dropping off from the epidermis, while large nests of nevus cells are also present in the dermis (Fig. 2-5B, C).

The **spindle cell** and/or **epithelioid cell nevus** is commonly composed of pleomorphic cells of three basic types: spindle cells, oval or 'epithelioid' cells, and both mononuclear and multinucleated giant cells. These are arranged in well-circumscribed sheets and there is generally considerable junctional activity.

The **blue nevus** is of two types: the common blue nevus and the cellular blue nevus. In the common blue nevus, elongated melanocytes with long branching dendritic processes lie in bundles, usually oriented parallel to the epidermis, in the middle and lower third of the dermis. There is no junctional activity. The melanocytes are typically packed with melanin granules, sometimes obscuring the nucleus, and these granules may extend into the dendritic processes. In the cellular blue

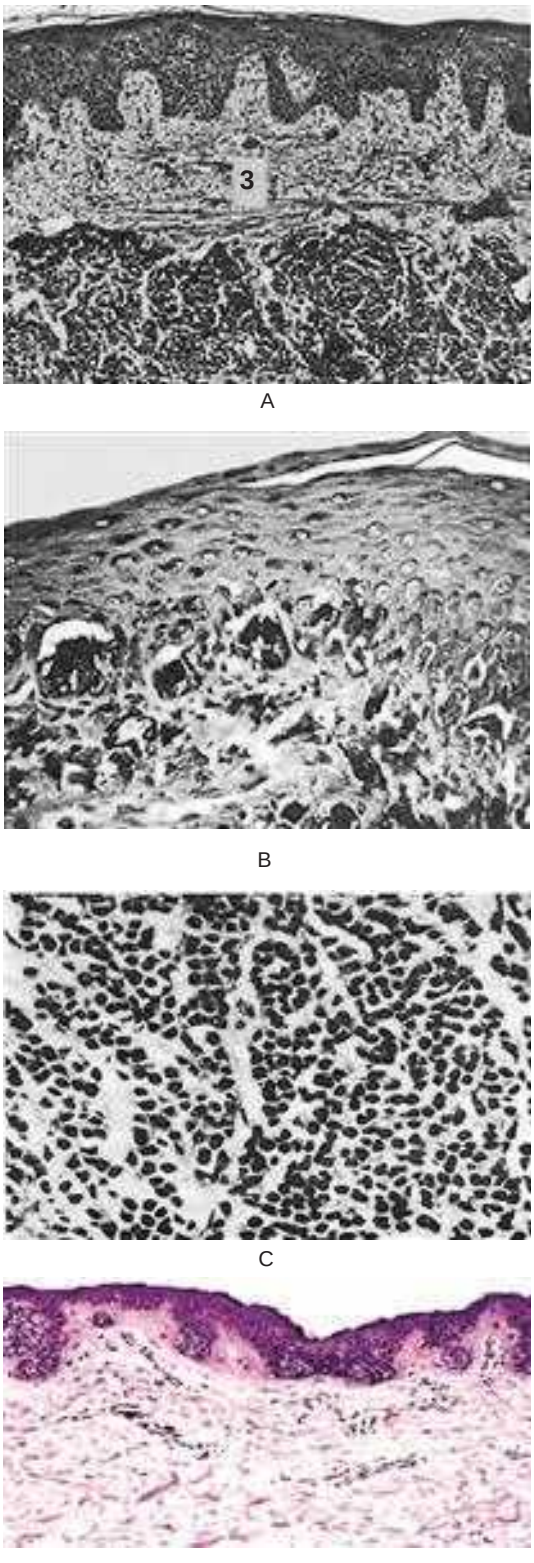

Figure 2-5. Pigmented cellular nevus.
The intradermal nevus **(A)** demonstrates a thick band of connective tissue (1) separating the nevus cells from the overlying epithelium. In the compound nevus **(B)**, the nevus cells are in contact with the overlying epithelium and are in the underlying connective tissue. The nevus cells are shown under high magnification **(C)**, Pigmented cellular nevus—nevus cells are in contact with the overlying epithelium and appear to blend into the epithelium **(D)**. *(Courtesy of Dr Hari S,Noorul Islam College of Dental Science,Trivandrum)*

nevus, an additional cell type is present: a large, round or spindle cell with a pale vacuolated cytoplasm. These cells commonly are arranged in an alveolar pattern.

Treatment and Prognosis. Since the acquired pigmented nevus is of such common occurrence, it would obviously be impossible to attempt to eradicate all such lesions. It has become customary to recommend removal of pigmented moles if they occur in areas which are irritated by clothing, such as at the belt or collar line, or if they suddenly begin to increase in size, deepen in color, or become ulcerated. Allen and Spitz have stated that it is fairly certain that trauma to an intradermal nevus will not induce malignancy. Whether simple trauma to a junctional nevus will produce malignancy is not known.

On the other hand, it is now well recognized that the congenital nevi have a great risk for transformation to malignant melanoma. Kaplan reported seven cases which were seen at the Stanford University Hospital and discussed 49 other cases. It is estimated that 14% of the large congenital nevi may undergo malignant transformation. Of particular interest is the occurrence of the B-K mole syndrome described by Clark and coworkers. This autosomal dominant condition is characterized by large pigmented nevi and a high risk for the development of melanoma. Its occurrence; however, has not been documented intraorally.

Surgical excision of all intraoral pigmented nevi is recommended as a prophylactic measure because of the constant chronic irritation of the mucosa in nearly all intraoral sites occasioned by eating, toothbrushing, etc.

'PREMALIGNANT' LESIONS/CONDITIONS OF EPITHELIAL TISSUE ORIGIN

Several lines of evidence, including clinical, experimental, and morphological data, support the concept that squamous cell carcinoma of the upper aerodigestive tract arises from noninvasive lesions of the squamous mucosa. These lesions encompass a histological continuum between the normal mucosa at one end and high grade dysplasia/carcinoma *in situ,* at the other, establishing a model of neoplastic progression. This continuum of preinvasive neoplasia is encountered in many other epithelia, including the lower respiratory tract and the cervix uteri.

The identification of preneoplastic lesions of the upper aerodigestive tract, through clinical, morphological and more recently, molecular means, helps in the early detection and treatment of head and neck squamous cell carcinoma. Moreover, understanding and documenting the morphological and molecular abnormalities associated with this progression may shed light on the biology of these tumors.

Historically, the definition of an oral premalignant lesion dates back to 1978, when it was defined by the World Health Organization (WHO) as "a morphologically altered tissue in which cancer is more likely to occur than in its apparently normal counterpart." The precancerous condition in its turn is "a generalized state associated with a significantly increased risk of cancer". Examples of precancerous conditions are sideropenic dysphagia, submucous fibrosis and possibly, lichen planus.

Cancer being a genetic disorder involves multiple alterations of the genome progressively accumulated during a protracted period, the overall effects of which surpass the inherent reparative ability of the cell. In the course of its progression, visible physical changes are taking place at the cellular level (atypia) and at the resultant tissue level (dysplasia). These alterations include genetic changes, epigenetic changes, surface alterations and alterations in intercellular interactions. The sum total of these physical and morphological alterations are of diagnostic and prognostic relevance and are designated as 'precancerous' changes. In many situations, the relationship between these changes and the progression towards neoplasia is not understood. Nevertheless, it seems probable that these changes are ultimately involved in driving cells further along the path to neoplastic transformation.

The diagnosis of precancers is primarily based on morphology and its grading on histology (dysplasia). Despite the fact that this estimation is subjective and therefore carries a low prognostic value of an impending malignancy, it is still widely practiced to assess the risk of malignant potential of such lesions. Because of this inherent discrepancy such lesions may well be designated as potentially malignant.

A premalignant phase in the development of oral cancer is predicted by the classic model of experimental epithelial carcinogenesis. Virtually all oral squamous cell carcinomas arise from a premalignant precursor, but it is difficult to specifically define the term 'premalignant'. Oral pathologists use the term epithelial dysplasia to indicate microscopic features in a biopsy specimen that are associated with a risk of malignant change and then assign a grade of severity. There is good correlation between higher grades of dysplasia and increasing risk of cancer but less so with the lower grades.

DYSPLASIA

The histologic connotation to premalignancy is marked by aberrant and uncoordinated cellular proliferation depicted basically at cellular level (atypia), reflections of which could be discerned at tissue levels too (dysplasia). Frequently it is the forerunner of cancer, the causation of this twilight zone in cellular transformation is by no means clear. Dysplasia is encountered principally in the epithelia. "It comprises a loss in the uniformity of the individual cells, as well as a loss in their architectural orientation." Dysplastic cells exhibit considerable pleomorphism (variation in size and shape) and often possess deeply stained (hyperchromatic) nuclei, which are abnormally large for the size of the cell. The nuclear: cytoplasmic ratio increases from 1:4 to 1:1, at the expense of the cytoplasmic volume. Mitotic figures are more abundant than usual, although almost invariably they conform to normal pattern. Frequently, the mitoses appear in abnormal locations within the epithelium and may appear at all levels rather than in its usual basal location. The usual proliferative organization of the epithelium (see below) is lost and is replaced by a disorderly arranged scramble of cells with varying degrees of differentiation arrest.

"Dysplasia is characteristically associated with protracted chronic irritation or inflammation", of which oral cavity is a common site. Due to its peculiar anatomic location and its constant presence of endogenous and exogenous micro-organisms, a sustained state of chronic subclinical infection is maintained at the oral cavity. Overlying physical trauma consistently inflicted on the oral mucosa, compounds the existing situation.

"Dysplasia is a reversible, and therefore presumably a controlled, cellular alteration. When the underlying inciting stimulus is removed, the dysplastic alterations revert to normal." However, there is an important and significant cellular change discerned at the morphological level which cautions its likelihood of subsequent neoplastic transformation. The line of demarcation when the cell surpasses the point of no return is rather faint and the underlying mechanism poorly defined. In short, dysplasia giving rise to neoplasia is akin to cellular changes in response to a noxious stimulus. As it is evident it traverses the stage of cellular adaptation, reversible damage, and finally, irreversible cell death. When a susceptive cell is exposed to a carcinogen it probably tries to adapt to it, depending on the extent and duration of stimuli. An increase in cell proliferation, diminishing the cytosolic volume and the associated organellar load, could be an attempt in this direction. In the context of oral epithelium, an accelerated growth phase depicted by broadening the progenitor compartment (hyperplasia) is the earlier sequela of exposure to an irritant. When the irritant persists, the epithelium shows features of cellular atrophy, again a well characterized feature of adaptation (atrophy). At a later stage when the stages of adaptation and reversible cell damage surpass, the cells progressively slip into a stage of irreversible cell damage; manifests either as cell death or neoplastic transformation. It appears that some mysterious line is crossed, whereby dysplastic cells escape the normal homeostatic controls and assume the autonomy of a tumor cell. The accelerated pace of cell division noted at the earlier stages of transformation as part of an adaptive response (to replace the damaged cell pool) is, in a way, facilitative of the accumulation of further genetic damage, thereby driving the cells further along the path of transformation. As it is apparent from the foregoing discussion, there is considerable overlap between the stages of cellular adaptation, reversible damage and atypia. Precise morphologic and genetic criteria delineating this line of demarcation between atypia (reversible damage) and neoplasia is unfortunately unknown and is the scope of the study of tumor biology.

Proliferative Organization of Oral Epithelium

Advances in our understanding of the proliferative organization of the oral epithelium has been a slow process for several reasons. These include a lack of suitable experimental models to test hypotheses, difficulty in extrapolating from other renewing cell systems and the need for new investigative techniques (Hume, 1991). The earlier rather mechanistic concept envisages a uniform progenitor compartment occupying the basal layer, retained in a state of sustained replication readiness with roughly equal cell cycle times and their migration towards the surface layers is simply by physical process of forward push induced during waves of cell division. Experimental work to elucidate these underpinned concepts and radical revisions are made (Leblond et al, 1964).

Between 1969 and 1975, a number of workers showed that these concepts were too simple, which suggested that a complex pattern of migration from the basal layer to the surface had to occur to maintain this highly ordered and non-random cell stacking. This, in turn, focused attention on the pattern of cell proliferation in the basal layer and led to the concept of the existence of a number of proliferative subpopulations, of which the stem cell population seemed to be of particular importance for tissue homeostasis and disease. This concept envisages that not all cells in the basal layer can divide, that a number are instead already differentiating, that cells capable of division comprise a number of subpopulations and finally, that cell migration is not caused by cell proliferation pressure but is an independent biological process.

The use of oral epithelium as a model for the investigation of the behavior of proliferative subpopulations followed on from the work that had already begun in rodent skin, it is also true that because of its particular morphological structure and marked circadian (diurnal) variation in cell proliferation, it has contributed significantly to the development of an integrated cell proliferation model applicable also to bone marrow, intestine, testis, nematodes and also to developmental situations (Hume, 1991).

Staging of Oral Precancerous Lesions

The value of histology as an indicator of cancer risk is time-tested not only in the oral cavity or other head and neck regions, but also in other sites, including the uterine cervix, lung, breast, skin, and esophagus. More likely, the future will see gradual extension of the classical histological and clinical approaches to include an evaluation of molecular markers.

An increase in abnormality in either histology or genetic markers was associated with an increase in cancer risk (Fig. 2-6). More recently, studies reported an association of ploidy status (DNA content) in dysplastic lesions with progression risk of oral precancers. The lowest risk was associated with diploid dysplastic lesions (3% progressed into oral squamous cell carcinoma), tetraploid lesions had an intermediate risk (60% showed progression), and aneuploid dysplasia showed the greatest risk (84% progressed). (Lippmann SM, Hong WK, 2001). With time, more such studies will accrue. A future goal will be to determine which combinations of histological and molecular markers best predict risk.

How can such information best be handled? One possibility is to develop staging systems that incorporate different risk factors into risk models. One such model is presented in Table 2-1. For the sake of simplicity, this hypothetical model only includes pathological and molecular markers (clinical features such as appearance, site, and size of the lesion, are not included but should be part of an eventual screening system). In this model, the majority of lesions would be placed into

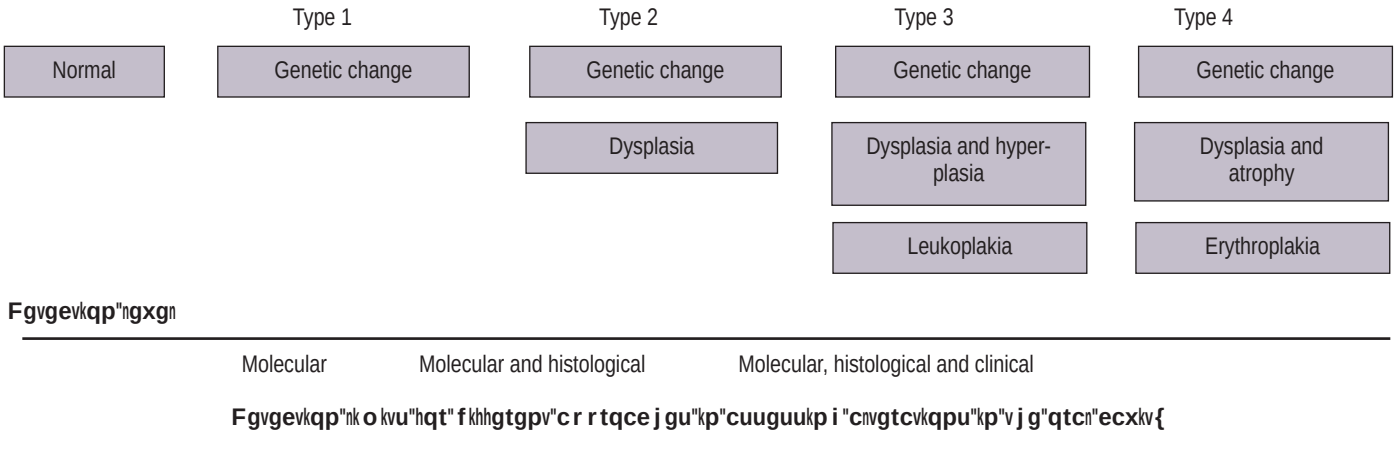

Figure 2-6. Types of alterations to oral cavity.

Table 2-1: Staging of oral premalignant lesions with both pathologic and genetic indices[a]

Stage (cancer risk)	Pathology (P)[b] and genetic (G)[c] patterns
1	$P_1 + G_1$
2	$P_1 + G_2$
	$P_2 + G_1$
	$P_2 + G_2$
3	$P_3 + G_1$
	$P_3 + G_2$
	$P_1 + G_3$
	$P_2 + G_3$
	$P_3 + G_3$

a Adapted from Zhang and Rosin (2001).

b Pathological indices: P_1, no dysplasia or mild dysplasia; P_2, moderate dysplasia and P_3, severe dysplasia/CIS.

c Genetic patterns, categorized by increasing risk: G_1, low risk; G_2, intermediate risk, and G_3, high risk.

stage 1, with the lowest probability of progressing to cancer. Such lesions would contain both low-risk pathology (P_1) and genetic patterns (G_1). The emergence of intermediate-risk patterns in either histology (P_2) or genetic profile (G_2) would place a lesion into stage 2. Stage 3 would contain lesions with a high-risk genetic or histology pattern. It should be noted that the greatest impact of such a staging system would be on lesions in stage 3. Such lesions would now include cases with a relatively benign phenotype (without or with minimal dysplasia) but a high-risk genotype (e.g. $P_1 + G_3$).

LEUKOPLAKIA (LEUKOKERATOSIS)

Leukoplakia (white patch) is the most common potentially malignant lesion of the oral mucosa. However, its usage should be limited exclusively to the clinical context by the exclusion of other lesions, which present as oral white plaques. Such lesions are lichen planus (hypertrophic), chronic cheek-bite (morsicatio), frictional keratosis, tobacco-induced keratosis (nicotine stomatitis), leukoedema and white sponge nevus. When a biopsy is taken, the term leukoplakia should be replaced by the diagnosis obtained histologically. In other words, leukoplakia denotes a negative diagnosis based on exclusion criteria. It represents an area localized in distribution, hyperkeratotic in nature and white in appearance due to wetting of the keratotic patch while in contact with saliva. It should be stressed that the diagnosis of leukoplakia denotes mainly, that

- The mucosa is irritated by either mechanical, chemical or galvanic means, and
- The mucosa is trying to adapt to the noxious stimuli by undergoing hyperkeratinization of its surface (good example of tissue adaptation—see earlier paragraphs).

Since leukoplakia is an adaptive response, offered by a viable and healthy oral mucosa against some forms of sustained, low-grade irritant, it is irrational to consider it as a disease entity (hence its assumption of a negative diagnostic state).

Definition and Terminology

Oral leukoplakia has recently been redefined as "a predominantly white lesion of the oral mucosa that cannot be characterized as any other definable lesion; some oral leukoplakia will transform into cancer" (Axell T, 1996). A provisional diagnosis is made when a lesion at clinical examination cannot be clearly diagnosed as any other disease of the oral mucosa with a white appearance. A definitive diagnosis is made when it is histopathologically examined. The term preleukoplakia is sometimes used when the whiteness is not very distinct and should not be confused with leukoedema (a hereditary malformation of the oral mucosa).

Definable White Lesions. Examples include:

- ***Hyperplastic candidiasis (candidal leukoplakia).*** When dealing with a hyperplastic epithelial lesion in which the presence of *Candida albicans* is demonstrated, it is referred to as candida-associated leukoplakia or others prefer the term hyperplastic candidiasis. In the absence of clinical response to antifungal treatment, it seems preferable to consider such lesion as leukoplakia (van der Waal, 1997).

- ***Hairy leukoplakia (Greenspan lesion).*** The term 'hairy leukoplakia' is a misnomer due to several reasons. First of all, hairy leukoplakia is a definable lesion. Furthermore, the lesion is not premalignant in nature. Therefore, the use of the term should be abandoned. As an alternative, the term 'Greenspan lesion' has been suggested.
- ***Tobacco-induced white lesions.*** Smoker's palate (leukokeratosis nicotina palati), palatal keratosis in reverse smokers and snuff dippers lesions are clearly related to tobacco use and, therefore, are usually listed as 'tobacco-induced lesions'. These lesions are being regarded as 'definable lesions' and are traditionally not described as leukoplakia. Nevertheless, some of these lesions may transform into cancer.
- ***Tobacco-associated leukoplakia.*** The etiological role of tobacco in patients who smoke cigarettes, cigars or pipes is less obvious. Therefore, preference has been given to the term 'tobacco-associated leukoplakia' (leukoplakia in smokers) over the term 'tobacco-induced white lesions'.
- ***Idiopathic leukoplakia.*** One also recognizes nontobacco-associated leukoplakia (leukoplakia in nonsmokers), often referred to as idiopathic leukoplakia.

Premalignant/Potentially Malignant Lesion. In two studies from India (Gupta PC et al, 1980, Silverman S et al, 1976), rather low annual malignant transformation rates of oral leukoplakia have been reported, 0.3% and 0.06%, respectively. In reports from western countries, usually based on hospital material, somewhat higher figures have been mentioned (Axell T, 1987). One must take the following into account, when studying percentages of malignant transformation rates of oral leukoplakia:

- The length of observation period
- The type of study population
- The therapeutic approach.

On the basis of the lowest reported annual malignant transformation rate of oral leukoplakia, it can be calculated that patients with oral leukoplakia carry a five fold higher risk of developing oral cancer than controls. Recently the role(s) of dietary factors in determining the precancerous nature of oral leukoplakia among tobacco habitues revealed interesting results (Gupta PC et al, 1998). A population-based case control study in the Bhavnagar district, Gujarat, India estimated nutrient intake in blinded, house-to-house interviews. Among 5,018 male tobacco users, 318 were diagnosed as cases. An equal number of controls matched on age (± 5 years), gender, village, and use of tobacco were selected. Odd ratio (OR), a measure of the relative risk of malignant transformation of individual lesions were calculated from multiple logistic regression analysis controlling for relevant variables (type of tobacco use and economic status), a protective effect of fiber was observed for both oral submucous fibrosis (OSF) and leukoplakia; with 10% reduction in risk per gm day ($p<0.05$). Ascorbic acid (vitamin C) appeared to be protective against leukoplakia with the halving of associated risk of malignant transformation (OR=0.46; $p<0.10$). It is apparent that in addition to tobacco use, intake of specific nutrients and their deficiency may have a role in the development and progression of oral precancerous lesions.

Epidemiology. The *prevalence* of this lesion in Ernakulam district (Kerala, India) was 17 per 1,000; it was highest (61 per 1,000) among people with mixed habits. The annual age adjusted incidence rate was 2.1 per 1,000 among men and 1.3 per 1,000 among women; the highest incidence (6.0 per 1,000) was among men who both chewed and smoked. In an adult Swedish population a 3.6% prevalence rate was recorded (Axell T, 1976). Almost all leukoplakia in India occur in tobacco users. A definite dose-response relationship between leukoplakia and various forms of tobacco use in this area has been demonstrated. The dose-response relationship was stronger for the smoking habit than for the chewing habit and remained significant after taking account of age, gender and type of tobacco habit.

Age and Gender. The onset of leukoplakia usually takes place after the age of 30 years; resulting in a peak incidence above the age of 50 years. The gender distribution in most studies varies, ranging from a strong male predominance in different parts in India, to almost 1 : 1 in the western world.

Etiology. Leukoplakia occurs more frequently in smokers of tobacco than in nonsmokers. There is a dose-response relationship between tobacco usage and the prevalence of oral leukoplakia. Reducing or cessation of tobacco use may result in the regression or disappearance of oral leukoplakia (Gupta et al, 1995). On the other hand, disappearance of oral leukoplakia has occasionally been reported in patients who continued to smoke (Silverman and Rozen, 1968). Tobacco was most often chewed as an ingredient in betel quid (smokeless tobacco or *paan*) in India. The *paan*-chewers' lesion consists of a thick, brownish-black encrustation on the buccal mucosa at the site of the placement of betel quid. It is often seen in heavily addicted betel quid chewers. It could be scraped off with a piece of gauze (leukoplakia); it regresses spontaneously when the habit is discontinued. Due to these reasons the *paan*-chewer's lesion does not deserve the designation of leukoplakia. This is a specific entity and rarely progresses to leukoplakia. Whether the use of alcohol by itself is an independent etiological factor in the development of oral leukoplakia, is still questionable. Its effect, at best, may be synergistic to other well-known etiological factors (physical irritants). The role of *Candida albicans* as a possible etiological factor in leukoplakia and its possible role in malignant transformation is still unclear. About 10% of oral leukoplakias satisfy the clinical and histological criteria for chronic hyperplastic candidiasis (candidal leukoplakia). Epithelial dysplasia is reported to occur four to five times more frequently in *Candida leukoplakia* than in leukoplakia in general. However, this change is more common in the speckled variant than in homogeneous leukoplakia and carcinomatous change is more a characteristic of the speckled lesion than that of candidal superinfection. Various kinds of evidence has been presented to justify an etiologic role for candida in neoplastic transformation, which includes, among others, the catalytic transformation *in vitro* of the carcinogenic

Table 2-2: Forms of leukoplakia

1. Homogeneous	Lesions that are uniformly white
2. Nonhomogeneous	Lesions in which part of the lesion is white and rest appears reddened
Alternatively, a more elaborate subdivision may be used such as:	
1. Homogeneous	(a) Smooth (b) Furrowed (fissured) (c) Ulcerated
2. Nonhomogeneous nodulospeckled: Well demarcated raised white areas, interspersed with reddened areas	
When recording leukoplakia, space has been allowed in the recording form for three different subdivisions	
1. Homogeneous	Smooth and fissured
2. Homogeneous	Ulcerated
3. Nonhomogeneous	Nodulospeckled

Adapted from Comm Denti and Oral Epidemiol 1980; 8: 1–26.

nitrosamine, N-nitrosobenzyl-methylamine, by strains of *C. albicans* demonstrated to be selectively associated with leukoplakia. The possible contributory role of viral agents (human papilloma virus strains 16, 18) in the pathogenesis of oral leukoplakia has also been discussed, particularly with regard to exophytic verrucous leukoplakia (Palefsky JM et al, 1995). In a study from India, serum levels of vitamin A, B_{12}, C, beta-carotene and folic acid were significantly decreased in patients with oral leukoplakia compared to controls, whereas, serum vitamin E was not (Ramaswamy G et al, 1996). Relatively little is yet known with regard to possible genetic factors in the development of oral leukoplakia.

Clinical Aspects. Preleukoplakia is defined as a low-grade or very mild reaction of the oral mucosa, appearing as a gray or grayish-white, but never completely white area with a slightly lobular pattern and with indistinct borders blending into the adjacent normal mucosa (Pindborg et al, 1968).

Clinical Classification. It is desirable to record, separately the various forms of leukoplakia and for this purpose subdivisions are recommended (WHO, 1980) (Table 2-2).

The adjective 'nonhomogeneous' is applicable both to the aspect of color, i.e. mixture of white and red changes (erythroleukoplakia) and to the aspect of texture, i.e. exophytic, papillary or verrucous. With regard to the latter lesions, no reproducible clinical criteria can be provided to distinguish (proliferative) verrucous leukoplakia from the clinical aspect of verrucous hyperplasia or verrucous carcinoma. The homogeneous type is usually otherwise asymptomatic, whereas the nonhomogeneous (mixed white and red) leukoplakia are often associated with mild complaints of localized pain or discomfort. In the presence of redness or palpable induration, malignancy may already be present (Fig. 2-7).

Figure 2-7. Speckled leukoplakia.
This mixed white and red lesion of the buccal mucosa showed moderate epithelial dysplasia *(Courtesy of Dr Crispian Scully)*.

Proliferative Verrucous Leukoplakia and its Related Lesions

Proliferative verrucous leukoplakia (PVL) and verrucous hyperplasia (VH) are two related oral mucosal lesions. The terms; however, are not clinically or pathologically interchangeable. The term PVL is preferably a clinical one, but the diagnosis of VH, on the other hand, must be made histologically.

PVL. First described by Hansen et al, in 1985, PVL continues to be recognized as a particularly aggressive form of oral idiopathic leukoplakia that has a considerable morbidity and a strong potential for malignant transformation. Diagnosis is often made late in the protracted course of PVL with the disease in an advanced stage when it is especially refractory to treatment. The histologic spectrum that is seen in PVL are:

- Verrucous hyperplasia (VH), a histologically defined lesion
- Varying degrees of dysplasia
- Three forms of squamous cell carcinoma: verrucous, conventional and according to some, papillary squamous cell carcinoma.

VH. This is a forerunner of verrucous carcinoma and the transition is so consistent that the hyperplasia, once diagnosed, should be treated like verrucous carcinoma.

Histopathological Aspects. It should be emphasized that leukoplakia is a clinical term, and its use carries no implications with regard to the histological findings. However, it is recommended that a histological report should always include a statement on the presence or

Table 2-3: Histopathological features of epithelial dysplasia

1.	Loss of polarity of the basal cells
2.	Presence of more than one layer of cells having a basaloid appearance
3.	Increased nuclear cytoplasmic ratio
4.	Drop-shaped rete processes
5.	Irregular epithelial stratification
6.	Increased number of mitotic figures (a few abnormal mitoses may be present)
7.	Presence of mitotic figures in the superficial half of the epithelium
8.	Cellular pleomorphism
9.	Nuclear hyperchromatism
10.	Enlarged nucleoli
11.	Reduction of cellular cohesion
12.	Keratinization of single cells or cell groups in the prickle layer

Adapted from Krammer et al., 1978.

absence of epithelial dysplasia, and if present, the assessment of its severity. The hallmarks of the histopathological aspects of leukoplakia are epithelial hyperplasia and surface hyperkeratosis. Epithelial dysplasia, if present, may range from mild to severe. In some instances, carcinoma *in situ* and even squamous cell carcinoma are encountered histologically. The various cellular changes that may occur in epithelial dysplasia are listed in Table 2-3. The clinical significance of human papilloma virus-associated epithelial dysplasia, so-called 'koilocytic dysplasia' remains to be investigated. The term 'lichenoid dysplasia' is sometimes used when the dysplastic epithelium may show features that, to some extent, resemble those of lichen planus. The term 'chevron' type of keratinization is used when it is associated with use of tobacco. Microabscesses may be observed in the superficial layers of the epithelium in the presence of *C. albicans* and inflammatory cell infiltration is commonly seen. Some of the exophytic, verrucous or papillomatous lesions, in spite of the absence of epithelial dysplasia, may in time progress to squamous cell carcinoma and that long-term follow-up should be considered. The final diagnosis of a white lesion of the oral mucosa can often only be made through a close dialogue between the clinician and the pathologist. Even then, cases may remain unsettled.

Grading of Epithelial Dysplasia. Epithelial dysplasia is usually assessed subjectively and considerable interobserver variability exists in its interpretation. Principally, what is lacking in this exercise is objectivity and lack of reproducibility. A consensus decision is, by and large, adopted in the management of individual lesions and based on the presence of dysplastic features, epithelial dyplasia is usually divided into three categories: mild, moderate and severe. It is recommended that the histological report of a leukoplakia should include a statement on the absence or presence of epithelial dysplasia and an assessment of its severity. The practical value of the grading of epithelial dysplasia is questionable. Although leukoplakia with moderate or severe epithelial dysplasia shows a greater disposition for malignant transformation than in the absence of dysplastic features, carcinomatous transformation may also take place in non-dysplastic leukoplakias.

Modified Classification and Staging System for Oral Leukoplakia

A proposal for a modified classification and staging system for oral leukoplakia (OLEP) has been presented by Van der Waal et al, 2000 in which the size of the leukoplakia and the presence or absence of epithelial dysplasia are taken into account. Altogether four stages are recognized:

L1 — Size of leukoplakia <2 cm
L2 — Size of leukoplakia 2–4 cm
L3 — Size of leukoplakia >4 cm
Lx — Size not specified
P — Pathology
P0 — No epithelial dysplasia
P1 — Distinct epithelial dysplasia
Px — Dysplasia not specified in the pathology report.

OLEP Staging System

Stage I — L1 P0
State II — L2 P0
Stage III — L3 P0 or L1 L2 P1
Stage IV — L3 P1

The proposed system should facilitate uniform reporting of treatment or management results of OLEPs in which a biopsy has become available. The system can easily be adjusted by replacing the histopathological criteria of epithelial dysplasia by a clinical subdivision in homogeneous and nonhomogeneous leukoplakia for cases in which no biopsy is available. It also could serve as a means for epidemiological studies. It has yet to be shown whether such a staging system may also be helpful in providing guidelines for the management of oral leukoplakias.

Diagnostic Procedures

Elimination of Possible Cause(s). The clinician should first try to rule out any of the definable white lesions before accepting a definitive clinical diagnosis of leukoplakia.

Biopsy. In homogeneous leukoplakia, the value of histological examination might, to some extent, be questioned. The occurrence of epithelial dysplasia is rather low in this clinical subtype, as is the risk of future malignant transformation. However, this cannot be taken as the dictum in all cases since at least in few cases it proves to be otherwise. Therefore, the taking of a biopsy in homogeneous leukoplakia should be the standard rule. If treatment consists of CO_2-laser evaporation, it is mandatory to have a biopsy taken prior to such treatment. In nonhomogeneous leukoplakia, biopsy should be taken at the site of symptoms, if present, and/or at a site of redness or induration. Diagnostic methods other than histological examination, such as the use of toluidine blue staining or Lugol's iodine and exfoliative cytology are of limited value when dealing with leukoplakia.

Treatment Modalities. Apart from the surgical excision, various treatment modalities are available, such as cryosurgery, CO_2- laser surgery, retinoids and other drugs, and recently, photodynamic therapy. The last is a rather recent application with regard to oral leukoplakia, therefore does not deserve comment on long-term results.

Possible Solutions. This overview demonstrates that tobacco smoking and betel quid chewing are detrimental to oral health, as they are strongly associated with oral leukoplakia, oral cancer and other mucosal pathologies. In view of these findings, specific studies for primary and secondary prevention of these lesions are warranted. Prevention was found to be feasible and effective (Gupta et al, 1980) by timely diagnosis and management of oral precancerous lesions like leukoplakia and by measures like habit alleviation. Effort in this direction will take us a long way into the overall control and management of potentially malignant oral mucosal lesions.

Leukoedema

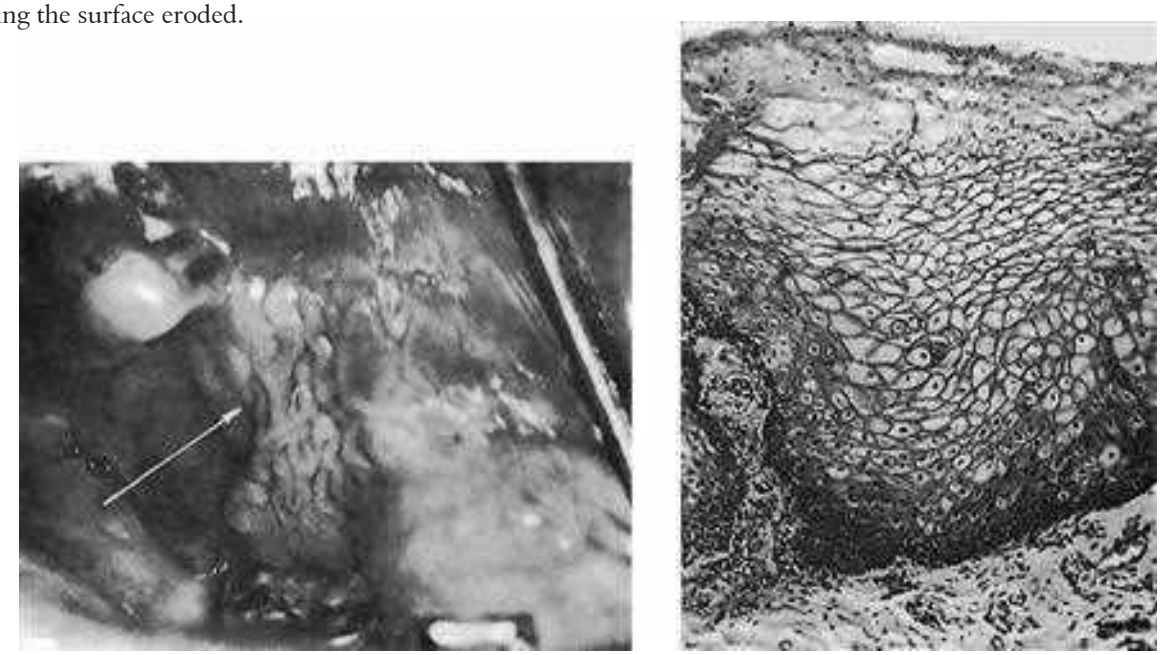
Leukoedema is an abnormality of the buccal mucosa which clinically resembles early leukoplakia, but appears to differ from it in certain respects.

Clinical Features. The gross appearance of leukoedema varies from a filmy opalescence of the mucosa in the early stages to a more definite grayish-white cast with a coarsely wrinkled surface in the later stages (Fig. 2-8A). Lesions occur bilaterally in the majority of cases and frequently involve most of the buccal mucosa, extending onto the oral surface of the lips. Leukoedema is most noticeable along the occlusal line in the bicuspid and molar region. In some cases, desquamation occurs, leaving the surface eroded.

Etiology. The etiology of leukoedema is unknown. An extensive study of this condition was carried out in the United States by Sandstead and Lowe, who found no apparent correlation between the incidence of the condition and the use of tobacco, the pH of the saliva, oral bacterial infection, syphilis or galvanic irritation. In their study, the incidence of leukoedema was approximately 45% in Caucasian men and 40% in Caucasian women, while it was 94% in Negro men and 86% in Negro women, all adults with an average age of 45 years.

It has now been identified in many countries around the world with a remarkable variation in prevalence that suggests some ethnic association. The different reported epidemiological studies have been reviewed by Axell and Henricsson, who also noted an incidence of occurrence of nearly 50% in a survey of over 20,000 persons aged 15 years and above in Sweden. Their data suggested that tobacco smoking was closely correlated with the occurrence of the leukoedema, although studies from India, where tobacco use is extremely prevalent, have shown a very low incidence of leukoedema.

Histologic Features. The microscopic features of leukoedema consist of an increase in thickness of the epithelium, intracellular edema of the spinous or malphigian layer, a superficial parakeratotic layer of several cells in thickness, and broad rete pegs which appear irregularly elongated (Fig. 2-8B). The characteristic edematous cells appear extremely large and pale, and they present a reticular pattern. The cytoplasm appears lost, and the nuclei appear absent, clear or pyknotic. Inflammatory cell infiltration of the subjacent connective tissue is not a common finding.



A B

Figure 2-8. Leukoedema.
The opaque appearance of the buccal mucosa **(A)** is somewhat different from that in leukoplakia. The photomicrograph **(B)** shows only acanthosis with intracellular edema of the spinous cells.

In a review and discussion of leukoedema, Archard and his coworkers have concluded that the clinical appearance of the lesion is due to a retained superficial layer of parakeratotic cells.

Clinical Significance. It has been suggested that leukoedema may represent a lesion of the oral mucosa in which leukoplakia is more apt to develop than in normal epithelium. This conclusion is based upon the fact that nearly all patients examined who manifested leukoplakia also exhibited leukoedema in the adjacent mucosa. However, Archard and his coworkers have concluded, on the basis of their studies, that there is no evidence to support this contention. Furthermore, they concluded that there is no evidence that this lesion is premalignant or in any way associated with potential malignant alteration.

Since leukoedema appears to be simply a variant of normal mucosa, no treatment is necessary.

Intraepithelial Carcinoma
(Carcinoma in situ)

Intraepithelial carcinoma is a condition which arises frequently on the skin, but occurs also on mucous membranes including those of the oral cavity. Some authorities believe that this disease represents a precancerous dyskeratotic process, but others say that it is a laterally spreading, intraepithelial type of superficial epithelioma or carcinoma. As Chandler Smith has expressed in a discussion on the concept of the term carcinoma *in situ*, it "does not reveal whether the lesion is a cancer now but has not yet become invasive, or whether it is not a cancer now but will become a cancer at some later time". Nevertheless, in this stage, it does not exhibit invasive malignant properties. Since metastasis cannot occur without infiltration of tumor cells into connective tissue and consequent accessibility to lymphatic or blood vessels, metastasis is impossible in intraepithelial carcinoma.

Bowen's disease is a special form of intraepithelial carcinoma occurring with some frequency on the skin, particularly in patients who have had arsenic therapy, and is often associated with the development of internal or extracutaneous cancer. On rare occasions, as reported by Gorlin, Bowen's disease may occur in the oral cavity.

Clinical Features. In a study of 82 lesions of carcinoma *in situ* in 77 patients reported by Shafer, he found that the clinical appearance was that of a leukoplakia in 45% of the lesions, an erythroplakia in 16% of the lesions, a combination of leukoplakia and erythroplakia in 9%, an ulcerated lesion in 13%, a white and ulcerated lesion in 5%, a red and ulcerated lesion in 1% and not stated in 11%.

These lesions have been reported to occur at all intraoral sites but the most common in the study of Shafer were floor of mouth (23%), tongue (22%) and lips in males (20%). This distribution is roughly comparable to that found in a series of 158 lesions of asymptomatic early oral epidermoid carcinoma reported by Mashberg and his associates. They appear to be somewhat more common in men than in women (1.8 : 1) and tend to occur principally in elderly persons.

Histologic Features. Intraepithelial carcinoma is characterized by a remarkable range of variation in histologic appearance. Keratin may or may not be found on the surface of the lesion but, if present, is more apt to be parakeratin rather than orthokeratin. Individual cell keratinization and epithelial or keratin pearl formation are exceedingly rare. In fact, these appear to be a hallmark of transformation of carcinoma *in situ* into invasive carcinoma, so that if these are found, a further search should be made for carcinomatous invasion. In some instances, there appears to be hyperplasia of the altered epithelium, while in others there is atrophy.

Certain cytologic alterations may also occur. An increased nuclear/cytoplasmic ratio and nuclear hyperchromatism are sometimes seen, but many cases do not show these. Cellular pleomorphism is quite uncommon. One of the most conspicuous and consistent alterations is loss of orientation of cells and loss of their normal polarity. Mitotic activity is extremely variable and of little significance unless overwhelming (Fig. 2-9).

It has also been found that sometimes a sharp line of division between normal and altered epithelium extends from the surface down to the connective tissue rather than a blending of epithelial changes. It is also not unusual to find multiple areas of carcinoma *in situ* interspersed by essentially normal appearing epithelium, producing multifocal carcinoma *in situ*.

All of the above changes occur within the surface epithelium, which remains confined by the basement membrane.

Treatment and Prognosis. There is no uniformly accepted treatment for intraepithelial carcinoma. The lesions have been surgically excised, irradiated, cauterized and even exposed to solid carbon dioxide. If the condition is left untreated, carcinomatous invasion is thought to occur eventually. Spontaneous regression of carcinoma *in situ* without treatment is known to occur in certain sites, chiefly the uterine cervix, in a significant percentage of cases. However, it is doubtful that this happens in the oral cavity; although progression into invasive carcinoma may take years in some instances, in others it apparently develops within months.

Erythroplakia
(Erythroplasia of Queyrat)

Whilst leukoplakia is a relatively common condition, erythroplakia is rare. In contrast to leukoplakia, erythroplakia is almost always associated with premalignant changes histologically and is, therefore, the most important precancerous lesion. The term 'erythroplakia' is used analogously to leukoplakia to designate lesions of the oral mucosa that present as bright red velvety plaques which cannot be characterized clinically or pathologically as due to any other condition. Just as there are many oral lesions that present clinically as white patches on the mucosa, so there are a number of conditions that appear as red areas. These include some dermatoses, inflammatory conditions due to local infection, or a more general subacute

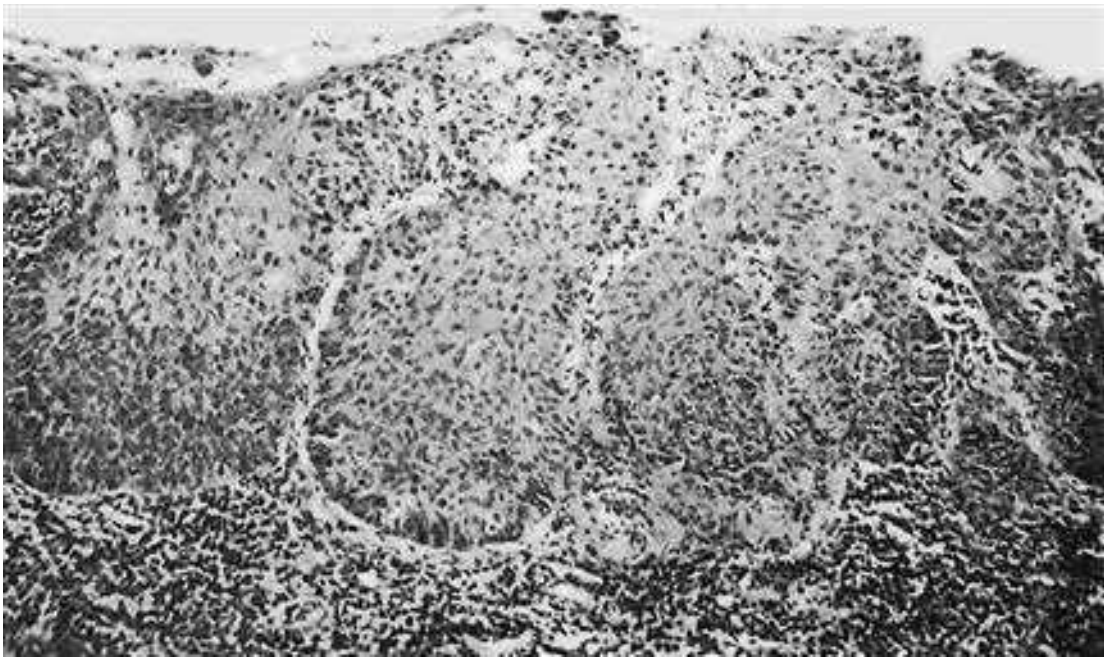


Figure 2-9. Intraepithelial carcinoma or carcinoma in situ.
The epithelial cells exhibit all the features of malignant cells, but invasion of the connective tissue has not begun.

or chronic stomatitis associated with the presence of dentures, tuberculosis, fungus infection and other conditions. Some red plaques prove to be early squamous cell carcinomas. The red patches that cannot be classified in any of these classes fall into the group of erythroplakia (a negative diagnosis— refer leukoplakia). The term 'erythroplasia' was originally used by Queyrat to describe a precancerous red lesion that develops on the penis. Oral erythroplakia is clinically and histopathologically similar to the genital process. Whereas red lesions of the oral mucosa have been noted for many years, the use of the term **erythroplakia** in this context was rare. Erythroplakia lesions are easily overlooked and the true prevalence of the condition is not known. This blatant underreporting probably reflects the fact that leukoplakias are more likely to be biopsied and emphasizes the lack of appreciation of the significance of erythroplakia clinically. Several clinical variants of erythroplakia have been described by different investigators, but there is no general agreement on classification. Shear, in 1972, described "homogeneous erythroplakia, erythroplakia interspersed with patches of leukoplakia, and granular or speckled erythroplakia" (the last category identical to speckled leukoplakia). The suggestion has also been made to change the term **speckled leukoplakia** to **speckled erythroplakia**, to emphasize the frequency with which this particular lesion is associated with cellular atypia. Many of these lesions are irregular in outline, and some contain islands of normal mucosa within areas of erythroplakia, a phenomenon that has been attributed to coalescence of a number of precancerous foci. The high rate of premalignant and malignant changes noticed in erythroplakia is true for all clinical varieties of this lesion and not solely a feature of speckled erythroplakia. Different studies have demonstrated that 80–90% of erythroplakias are histopathologically either severe epithelial dysplasia, carcinoma *in situ*, or invasive carcinoma. Erythroplakia has no apparent sex predilection; most cases reported have occurred in the sixth and seventh decades. The etiology of erythoplakia is unknown, although it seems likely that smoking and alcohol abuse are important etiological factors.

Histopathologic Features. The epithelium shows lack of keratin production and is often atrophic, but it may be hyperplastic. This lack of keratinization, especially when combined with epithelial thinness, allows the underlying microvasculature to show through, thereby causing the red color. The underlying connective tissue often demonstrates chronic inflammation. Differentiation of erythroplakia with malignant change and other early squamous cell carcinomas from benign inflammatory lesions of the oral mucosa can be enhanced by use of 1% toluidine blue (tolonium chloride) solution applied topically with a swab or as an oral rinse. This technique gives excellent results in detecting epithelial dysplasia with false-negative (underdiagnosis) and false positive (overdiagnosis) rates of well below 10%.

Treatment. It should follow the same principles outlined for leukoplakia. Observation for one to two weeks following elimination of suspected irritants is acceptable. Prompt biopsy is thereafter mandatory for lesions that persist. Surgical excision gives excellent results and a recurrence rate of less than 5% is reported.

Leukokeratosis Nicotina Palati

This lesion commonly seen among conventional smokers, consists of a grayish-white palate with small nodular excrescences having small central red spots corresponding to the inflamed orifices of the minor salivary glands (Murti et al, 1992).

Epidemiology. The prevalence of this lesion among Indians was 0.3%; 52% of the 31 lesions occurred among *bidi* smokers (Mehta FS et al, 1971). The annual age adjusted incidence rate among smokers was 1.7 per 1,000; 0.7 per 1,000 in those who smoked and chewed (Gupta PC et al, 1980).

Natural History. Over a longer period 66% of the 44 lesions remained stationary, 34% regressed spontaneously and none showed malignant transformation. Palatal changes in reverse smokers (smoke with the burning end of a cigar/cigarette within the oral cavity), on the other hand, must be distinguished from this lesion and are multimorphic and precancerous, whereas leukokeratosis nicotina palati exhibits neither great variability nor malignant transformation (Table 2-4).

Palatal Changes Associated with Reverse Smoking

Reverse *chutta* (crude form of cigar) smoking practiced especially among females of Srikakulam district of Andhra Pradesh, recorded a prevalence of 8.8% of leukoplakia, 4.6% preleukoplakia and 17.9% leukokeratosis nicotina palati (Daftary et al, 1992). Palatal involvement was noted in 422 (85%) of the 497 leukoplakia cases and in 168 (57%) of the 296 preleukoplakias, and of course in all of the cases of leukokeratosis nicotina palati. Palatal changes associated with reverse smoking thus exhibited a spectrum of clinical changes, and it was not satisfactory to group them under leukoplakia, preleukoplakia or leukokeratosis nicotina palati. Accordingly, a new classification for palatal changes encompassing the entire spectrum of clinical components was proposed by Mehta FS et al, 1977.

Epidemiology. The annual age-adjusted incidence rates of palatal changes (encompassing all components) was 24.9 per 1,000 among men and 39.6 per 1,000 among women and the peak incidence was in the 55–64 year age group (Srikakulam data).

Clinical Aspect. Palatal changes comprise several components:

- ***Keratosis***—diffuse whitening of the entire palatal mucosa
- ***Excrescences***—1–3 mm elevated nodules, often with central red spots
- ***Patches***—well defined, elevated white plaques
- ***Red areas***—well defined reddening of the palatal mucosa
- ***Ulcerated areas***—crater-like areas covered by fibrin
- ***Nonpigmented areas***—areas of palatal mucosa that are devoid of pigmentation.

Histological Features. Hyperorthokeratosis, epithelial dysplasia and inflammatory cells in the connective tissue were observed in 87%, 23% and 55% of the biopsies collected from Srikakulam district (Daftary et al, 1992). Melanin deposits were noted in the lamina propria of most of them. The epithelium was atrophic in 60% of biopsies from red areas. Epithelial dysplasia was observed in 52% of red areas, 25% of excrescences, 20% of ulcerations, 10% of patches and in 19% of nonpigmented areas.

Natural History. In a six-year follow-up study, palatal changes remained stationary in 75% of individuals; regressed in 14% and were variable in 11%, i.e. they regressed, recurred and regressed again (Gupta PC et al, 1980). The regression rates were higher when the habit was discontinued or reduced substantially. Malignant transformation was observed for 0.3% of the palatal lesions. In a 10-year intervention study in the same area, the malignant potential of various components of palatal changes was evaluated: red areas and patches were found to exhibit a high potential for malignant transformation.

Palatal Erythema

This lesion is marked by a diffused erythematous hard palate, occasionally extending to the soft palate.

Epidemiology. Of the 69 lesions observed among 7,216 tobacco users, 87% occurred among smokers, especially *bidi* smokers.

Clinical Aspects. This lesion occurs either independently or sometimes with other lesions. About 10% of the lesions were associated with palatal papillary hyperplasia and 25% with central papillary atrophy of the tongue and bilateral commissural leukoplakias. This triad of lesions is comparable to the **multifocal candidiasis** described in western literature.

Natural History. The highest percentage of persistent lesions (60%) was seen among people who did not give up their smoking habits, while the highest percentage (75%) of regressed lesions occurred among those who discontinued or reduced smoking substantially. These observations clearly indicate that palatal erythema is caused by smoking, particularly *bidi* smoking. None of the lesions progressed to cancer.

Table 2-4: Classification of oral mucosal lesions

Based on different habits the lesions can be grouped broadly as shown:
Predominantly associated with smoking
Leukoedema
Leukokeratosis nicotina palati
Palatal erythema
Central papillary atrophy of tongue
Predominantly associated with chewing
Paan chewer's lesion
Oral lichen planus-like lesion
Oral submucous fibrosis
Associated with smoking and chewing (mixed habit)
Leukoplakia and preleukoplakia
Oral lichen planus
Oral squamous carcinoma

Central Papillary Atrophy of the Tongue

This lesion has also been described in the literature as median rhomboid glossitis and localized atrophy of the tongue papillae. It consists of a well-defined, oval, pink area in the center of the dorsum of the tongue devoid of lingual papillae.

Epidemiology. The prevalence of this lesion in the general population was 1%; it was present among 2.2% *bidi* smokers, 1.6% cigarette smokers and 0.3% of nonsmokers of tobacco. In a 10-year follow-up study from India, the annual age-adjusted incidence rate among smokers was 1.5 per 1000 as compared to 0.8 per 1,000 among nonsmokers.

Etiology. It is considered to be due to candidal infection, smoking or both (bidi smoking). Interestingly, very few women had this lesion due perhaps to the rarity of smoking among women.

Histologic Features. This lesion was marked by the absence of tongue papillae, the presence of slight parakeratinization of the epithelial surface, long slender rete ridges and occasional pseudoepitheliomatous hyperplasia. Chronic inflammatory cell infiltrate, chiefly of lymphocytes, was usually present within the epithelium and in the lamina propria. Candidal hyphae were observed in the superficial layers of epithelium in the majority of cases.

Natural History. The highest percentage of regressed lesions (87%) was seen in those who stopped their habits. None of the lesions progressed to cancer.

Lesions Associated with Betel Quid Chewing
(Paan-chewer's lesion)

This lesion consists of a thick brownish black encrustation on the buccal mucosa at the site of placement of the buccal quid (Fig. 2-10). It is often seen among heavily addicted betel quid chewers. It could be scrapped off with a piece of gauze; it regresses spontaneously; more frequently when the habit is discontinued.

Epidemiology. The annual age-adjusted incidence rate of this lesion was 28 per 1,000 among male chewers and 17.4 per 1,000 among female chewers (Gupta PC et al, 1980).

Figure 2-10. Tobacco pouch keratosis.
A white, wrinkled change of the mucosa in the mandibular buccal vestibule secondary to the use of chewing tobacco *(Courtesy of Dr Regazi JA, Dr Sciubba JJ and Dr Pogrd MA).*

Histologic Features. These lesions showed pale staining parakeratin-like surface layers of epithelium, containing round nuclear remnants, ballooning and vacuolated cells and epithelial hyperplasia.

Natural History. It is a specific entity and rarely progresses to leukoplakia. Malignant transformation was not observed in these lesions.

Oral Lichen Planus-like Lesion
(Lichenoid reaction)

A characteristic lesion consisting of white, wavy, parallel, nonelevated striae that do not criss-cross (as in lichen planus) is observed in habitual betel quid chewers. Sometimes, these striae radiate from a central erythematous area at the site of placement of the betel quid.

Epidemiology. The prevalence of this lesion among 5,099 individuals in Ernakulam, Kerala was 0.7%. About 89% of the lesions occurred among betel quid chewers and 11% among people with mixed habits. The annual age-adjusted incidence rates among men and women were 0.7 and 2.2 per 1,000 respectively. The peak incidence for women was in the 45–54 year age group. The incidence was zero among smokers and nonusers of tobacco; and 4.3 per 1,000 among women who chewed. This lesion is thus entirely associated with betel quid chewing.

Clinical Aspects. The lesion always occurs on the buccal mucosa and mandibular groove, areas which are in intimate contact with the betel quid.

Histologic Features. The lesion shows parakeratinized, atrophic epithelium, liquefaction degeneration of the basal cell layer and a band-like inflammatory cell infiltrate containing lymphocytes and plasma cells. Unlike lichen planus, this lesion shows hyperparakeratosis, and plasma cells in the juxtaepithelial region.

Natural History. Although the histological features are similar to those of oral lichen planus, in view of its complete association with betel quid chewing, it is regarded as a specific entity. No malignant transformation has been reported.

Oral Submucous Fibrosis

Oral submucous fibrosis (OSF) is a chronic, progressive, scarring disease, that predominantly affects people of South-East Asian origin. This condition was described first by Schwartz (1952) while examining five Indian women from Kenya, to which he ascribed the descriptive term "atrophia idiopathica (tropica) mucosae oris". Later in 1953, Joshi from Bombay (Mumbai) redesignated the condition as oral submucous fibrosis, implying predominantly its histological nature. The WHO definition for an oral precancerous condition—a generalised pathological state of the oral mucosa associated with a significantly increased risk of cancer—accords well with the characteristics of OSF.

Clinical Features. The onset is insidious, over a two to five years.

Prodromal Symptoms (Early OSF). This includes a burning sensation in the mouth when consuming spicy food, appearance of blisters especially on the palate, ulcerations or recurrent generalized inflammation of the oral mucosa, excessive salivation, defective gustatory sensation and dryness of the mouth. There are periods of exacerbation manifested by the appearance of small vesicles in the cheek and palate. The intervals between such exacerbation vary from three months to one year. Focal vascular dilatations manifest clinically as petechiae in the early stages of the disease. This may be part of a vascular response due to hypersensitivity of the oral mucosa towards some external irritant like arecanut products. Petechiae are observed in about 22% of OSF cases (Rajendran, 1994), mostly on the tongue followed by the labial and buccal mucosa with no sign of blood dyscrasias or systemic disorders. Pain in areas where submucosal fibrotic bands are developing when palpated is a useful clinical test. Histologically, they revealed a slightly hyperplastic epithelium, sometimes atrophic with numerous dilated and blood-filled capillaries juxtaepithelially (Figs. 2-11, 2-12). The inflammatory cells seen are mainly lymphocytes, plasma cells and occasional eosinophils. The presence together of large numbers of lymphocytes and fibroblasts as well as plasma cells in moderate numbers, suggests the importance of a sustained lymphocytic infiltration in the maintenance of the tissue reaction in OSF.

Advanced OSF. As the disease progresses, the oral mucosa becomes blanched and slightly opaque, and white fibrous bands appear. The buccal mucosa and lips may be affected at an early stage, although it was thought that the palate and the faucial pillars are the areas involved first. The oral mucosa is involved symmetrically (with possible exception) and the fibrous bands in the buccal mucosa run in a vertical direction. The density of the fibrous deposit varies from a slight whitish area on the soft palate, causing no symptoms, to a dense fibrosis, causing fixation and shortening or even deviation of the uvula and soft palate. The fibrous tissue in the faucial pillars ranges from a slight submucosal accumulation in both pillars to a dense fibrosis extending deep into the pillars with strangulation of the tonsils. It is this dense fibrosis, involving the tissues around the pterygomandibular raphae, that causes varying degrees of difficulty in mouth opening. A factor which seems to be overlooked by many investigators while recording the extent of mouth opening is the acuteness of oral symptoms (persistent/recurrent glossitis and stomatitis) at the time of recording. Sometimes the fibrosis spreads to the

Figure 2-11. Advanced OSF with difficulty in opening the mouth.

(A) Horizontal fibrosis traversing at the junction of hard and soft palate. **(B)** Involvement of pterygomandibular raphae compounding the difficulty of mouth opening. **(C)** Carcinoma developed on the palate.

pharynx and down to the piriform fossae. Upon palpation, a circular band can be felt around the entire *rima oris* (mouth orifice), and these changes are quite marked in the lower lip. All observers have noted impairment of tongue movement in patients with advanced OSF with significant atrophy of the tongue papillae. With progressing fibrosis, the stiffening of certain areas of the mucosa occurs leading to difficulty in opening the mouth, inability to whistle or blow out a candle and difficulty in swallowing. When the fibrosis involves the nasopharynx, the patient may experience referred pain to the ear and a nasal voice as one of the later signs in some patients.

Epidemiology. Numerous published reports on OSF allow an informed appraisal of its geographic distribution, together with data on the percentage prevalence. An epidemiological assessment of the prevalence of OSF among Indian villagers, based on baseline data, recorded a prevalence of 0.2% (n = 10,071) in Gujarat, 0.4% (n = 10,287) in Kerala, 0.04% (n = 10,169) in Andhra Pradesh, and 0.07% (n = 20,388) in Bihar. The prevalence among 101,761 villagers in the state of Maharashtra (central India) was 0.03%. In a 10-year follow-up study of oral precancer, Gupta et al, in 1980, calculated the incidence rate of OSF in Ernakulam, Kerala: 8 for men and 19 for women per 100,000. Variations in the prevalence figures are common between different studies, probably because of differences in the clinical criteria for diagnosis. While some investigators adhere to the earlier signs and symptoms, others looked for fibrous bands as the diagnostic criterion. According to Pindborg 1989, if only the fibrous band was the criterion for diagnoses, the prevalence rate would have been about 1.6%. Prevalence by gender varies widely in the different published studies. The general female preponderance may be related to factors like oral habits, deficiency states of iron, vitamin B complex among many other conditions prevalent in Indian women.

Etiology. There is compelling evidence to implicate the habitual chewing of arecanut with the development of OSF. It occurs predominantly in the Indian subcontinent where the habit is more prevalent. The frequency of this habit in population affected by OSF ranged from 34–100% (Bhonsle RB et al, 1987). This has been reported to be higher among OSF patients than in the general population. In a study of 100,000 villagers in Maharashtra (India), 4.2% of females who chewed areca nut and did not use tobacco suffered from OSF. Thus chewing areca nut may be an important factor in the etiology of OSF. Previous studies on the pathogenesis of OSF have suggested that the occurrence may be due to:

- Clonal selection of fibroblasts with a high amount of collagen production during the long-term exposure to areca quid ingredients (Meghji S et al, 1987).
- Stimulation of fibroblast proliferation and collagen synthesis by arecanut alkaloids (Harvey W et al, 1986).
- By fibrogenic cytokines secreted by activated macrophages and T lymphocytes in the OSF tissues (Haque MF et al, 2000).
- By decreased secretion of collagenase (Shieh TY et al, 1992).
- Deficiency in collagen phagocytosis by OSF fibroblasts (Tsai CC et al, 1999).
- By production of collagen with a more stable structure (collagen type I trimer) by OSF fibroblasts (Kuo MYP et al, 1995).
- By stabilization of collagen structure by (+) catechin and tannins from the areca nut (Scutt A et al, 1987).
- And by an increase in collagen cross-linkage as caused by upregulation of lysyl oxidase by OSF fibroblasts (Ma RH et al, 1995).

Genetic susceptibility may also be associated with OSF because raised frequencies of HLA-A10, – B7 and – DR3 are found in OSF patients compared to normal subjects. Further HLA-typing done by the use of the polymerase chain reaction (PCR) also demonstrates significantly increased frequencies of HLA-A24, DRB1-11 and DRB3-0202/3 antigens in 21 OSF patients when compared with the English controls (Saeed B et al, 1997).

Pathology

Structural and microstructural changes. The epithelial changes in the different stages of OSF are predominantly hyperplasia (early) and atrophy (advanced), associated with an increased tendency for keratinizing metaplasia. The epithelial atrophy reported by Pindborg et al, (1966) is the marked epithelial change in advanced OSF, which contrasts with the predominantly hyperplastic epithelium (Figs. 2-13, 2-14) of early OSF. Lesions involving the palate showed predominantly orthokeratosis and those of the buccal mucosa, parakeratosis. The high mitotic count in parakeratotic epithelium, which is more common with OSF, and the association with parakeratotic leukoplakia and atrophic epithelial changes predisposes OSF to malignancy.

Subepithelial changes. On the basis of the histopathological appearance of stained (H&E) sections, OSF can be grouped into four clearly definable stages: very early, early, moderately advanced and advanced. These stages are based not only on the amount and nature of the subepithelial collagen, but also on the following criteria taken together:

Figure 2-13. Advanced stage with fibrosis of lamina propria and submucosa: Van Gieson stain.

Figure 2-14. Early oral submucous fibrosis.
Note the sparing of lamina propria from fibrosis: Van Gieson stain.

- Presence or absence of edema
- Physical state of the mucosal collagen
- Overall fibroblastic response (number of cells and age of individual cells)
- State of the blood vessels
- Predominant cell type in the inflammatory exudate.

A vascular response due to inflammation, apart from the connective tissue repair process, has been very commonly found in OSF. Normal, dilated and constricted blood vessels have been seen often in combination, in the same section. The apparent narrowing of the smaller vessels appears first in the upper mucosa and spreads gradually to the larger, deeper vessels. Persistent dilatation has also been seen in many moderately advanced and advanced biopsies. A rise in mast cells occurs in the earlier stages of the tissue reaction but in advanced stages, the counts are fewer in number.

The inflammatory cells seen are mainly lymphocytes and plasma cells. The connective tissue in advanced stages is characterized by the submucosal deposition of extremely dense and avascular collagenous tissues with variable numbers of chronic inflammatory cells. Epithelial dysplasia without carcinoma is found in 10–15% of cases submitted for biopsy and carcinoma is found in at least 5% of sampled cases. The excessive fibrosis in the mucosa seems to be the primary pathology in OSF. The atrophic changes in the epithelium are secondary.

Biological Studies on Individuals and Tissues from OSF

Blood chemistry and hematological variations. Deficiency of vitamin B_{12}, folate and iron can affect the integrity of the oral mucosa. Significant hematological abnormalities have been reported in OSF, including an increased erythrocyte sedimentation rate (ESR), anemia and eosinophilia, increased gammaglobulin, a decrease in serum iron and an increase in total iron binding capacity (TIBC). The percentage saturation of transferrin also decreased and a significant reduction in total serum iron and albumin was found. The role of iron deficiency anemia as the cause or the effect of the disorder is doubtful. A rise in serum mucoproteins, mucopolysaccharides and antistreptolysin titer 'O' (measured in Todd's unit) has also been reported. A significant depression of the lactate dehydrogenase isoenzyme ratio (LDH IV/LDH II) is reported at the tissue level in OSF. A significant alteration in the serum copper and zinc ratio is also reported with a reduction in zinc content.

Chromosomal instability has long been associated with the neoplastic process and the quantitative assay of sister chromatid exchange (SCE) provides an easy, rapid and sensitive method for studying chromosome/DNA instability and its subsequent repair processes. This increase may be attributed to the genotoxic effect of the constituents of betel quid. The role of areca nut alkaloids in this regard may be significant.

AgNOR. Silver-binding nucleolar organizer region proteins (AgNORs) comprise a simple and reproducible cytological test indicative of the proliferative status of cells, particularly of epithelial and hematopoetic origin. It was found that the pooled mean AgNOR count in clinically advanced OSF was higher than in moderately advanced cases. Counting of AgNORs may be useful as a predictor of the biological behavior of OSF.

Immunological studies. Because of a possible immunological connection, the fact that the disease has been reported in subjects who do not practice the betel habit and the inability to prove a dose and effect relationship in all cases, the question arose whether there is a predisposition for the disease. In this respect, the finding by Canniff et al (1981) that the human leukocyte antigens (HLA) A10, B7 and DR3 occurred significantly more frequently in OSF, is important. Later van Wyk et al (1994), investigated the frequency of HLA in areca nut chewers with and without OSF and comparing them to a control comprising people with a similar background (South African Indians) they were unable to detect specific frequencies as was found by Canniff and coworkers. Thus, the problem of a possible predilection remains unanswered. In addition, studies on the relationship between systemic disease and OSF also proved negative.

Cell kinetic studies. Investigations carried out in the UK and South Africa found that the growth of OSF fibroblasts is normal. However, when fibroblasts are exposed to the alkaloids of areca nut their proliferation rate, according to certain workers, increases; a finding in contrast to others' results. The second group found a dose-dependent inhibition of growth by alkaloids (van Wyk et al, 1995). These studies prompt one to propose that the connective tissue changes in OSF are probably not due to increased fibroblast proliferation. On the other hand, OSF fibroblasts can play a role in overproduction of collagen. The UK group (Scutt A et al, 1987) found that collagen formation by fibroblasts increases when exposed to nut extracts and alkaloids, a finding which has been questioned recently by Jeng et al (1996), whose findings were contradictory. Thus it would seem that OSF fibroblasts have the capability to produce collagen in excess, but what triggers it, is controversial. Ma et al (1995) discovered increased lysyl oxidase activity in fibroblasts cultured from OSF patients. Lysyl oxidase, an extracellular metalloenzyme of copper, is secreted by fibroblasts and initiates cross-linking of collagen

which makes it relatively resistant to digestion by mammalian collagenase. Therefore, increased lysyl oxidase activity can result in collagen accumulation. Recently Trivedy et al (1997) demonstrated that the copper content in areca nut is relatively high and that it is released in the mouth with chewing. Other reasons proposed for an excessive accumulation of collagen are decreased collagenase activity in OSF mucosa and reduced phagocytosis by OSF fibroblasts, recently shown by Taiwanese researchers. In both instances, accumulation of collagen is enhanced. Unfortunately, none of these findings give an answer for the persistence of the disease, or for the continuing deposition of excessive collagen after stoppage of the habit. To conclude, the effect of the areca nut on cells is the trigger resulting, initially among others, in excessive accumulation of collagen which is followed by a permanent change possibly in the fibroblast population, characterized by a continued abnormal accumulation of collagen. The mechanism of this permanent change is not known at present.

Management. The reduction or even elimination of the habit of areca nut chewing is an important preventive measure. At least in the early stages of OSF, it could probably slow the progress of the disease. To improve current treatment regimens of OSF, the following strategies have been proposed:

1. ***Nutritional support.*** Mainly for high proteins and calories and for vitamin B complex and other vitamins and minerals.
2. ***Immunomodulatory drugs.*** Local and systemic applications of glucocorticoids and placental extracts are commonly used. These also prevent or suppress inflammatory reaction, thereby preventing fibrosis by decreasing fibroblastic proliferation and deposition of collagen.
3. ***Physiotherapy.*** This includes measures such as forceful mouth opening and heat therapy. Heat has been commonly used and the results have been described as satisfactory.
4. ***Local drug delivery.*** Local injections of corticosteroids and placental extract have been tried, in addition to hyaluronidase, collagenase and similar substances which break down intercellular cement substances and also decrease collagen formation.
5. ***Combined therapy.*** With peripheral vasodilators (nylidrin hydrochloride), vitamins D, E and 'B' complex, iodine, placental extract, local and systemic corticosteroids and physiotherapy claim a high success rate in OSF management. The evaluation of the merits and disadvantages of individual items in treatment is not possible due to the use of combined treatment protocols; unavoidable at present because of the empirical nature of each approach.
6. ***Surgical management.*** Measures such as forcing the mouth open and cutting the fibrotic bands have resulted in more fibrosis and disability. Submucosal resection of fibrotic bands and replacement with a partial thickness skin or mucosal graft have also been attempted along with procedures such as bilateral temporalis myotomy. At a retrospective glance, surgery seems to be a poor option in the overall management of the disease. Controlled studies of different regimens in the management of OSF are needed. They will not be easy to organize because of the

Interventions for the management of OSF

Objectives. To assess the effectiveness of interventions for the management of pain and restricted jaw opening or movement occurring as a result of oral submucous fibrosis.

Selection Criteria. Randomised controlled trials comparing surgical interventions, systemic or topical medicines or other interventions to manage the symptoms of OSF.

Data Collection and Analysis. Two authors independently assessed trial quality and extracted trial data. Disagreements were resolved by consultation with a third author. Attempts were made to contact study authors where necessary for clarification and for additional information.

Main Results. Two trials, involving 87 participants, evaluated lycopene in conjunction with intralesional injections of a steroid, and pentoxifylline in combination with mouth stretching exercises and heat. Only two of the primary but none of the secondary outcomes of this review were considered in these trials and provided a limited amount of reliable data. The data in one trial were based on inadequately defined evaluations of outcomes, and in the other trial are likely to be skewed due to a substantial number of withdrawals and therefore were not entered into the RevMan analyses. There were no reports of toxicity to the interventions but some side effects, which were mostly gastric irritation to pentoxifylline, were noted.

Authors' Conclusions. The lack of reliable evidence for the effectiveness of any specific interventions for the management of OSF is illustrated by the paucity, and poor methodological quality, of trials retrieved for this review.

The review authors found two studies which evaluated the effectiveness of lycopene, an extract of tomato, in conjunction with intralesional injections of a steroid, and pentoxifylline in combination with mouth exercises and heat. These studies provided a limited amount of reliable data which did not permit any firm conclusions to be made.

Future research should aim to provide evidence for people to make informed decisions about whether these treatments are effective and should also explore treatment plans which include patient education aimed at cessation of the chewing habit.

number of items in current management protocols, but they should greatly increase our understanding of OSF.

MALIGNANT TUMORS OF THE EPITHELIAL TISSUE ORIGIN

Basal Cell Carcinoma

(Basal cell epithelioma, BCC, rodent ulcer)

The most common malignancy in humans, basal cell carcinoma develops most frequently on the exposed surfaces of the skin, the face and the scalp in middle-aged or elderly persons. People with fair complexion who have spent much of their lives out of doors are often victims of this lesion, but it is by no means confined to such persons. It is slow growing and rarely metastasizes, but it can cause significant local destruction and disfigurement if neglected or treated inadequately.

Etiology. Ultraviolet radiation is the most important and common cause of BCC. Shorter wavelength ultraviolet (UV) radiation (290–320 nm, sunburn rays) is believed to play a greater role than the longer wavelength ultraviolet A (UVA) radiation (320–400 nm, tanning rays). Thus chronic sun exposure is important in the development of BCC. A long latency period of 20–50 years is typical between the time of UV damage and clinical onset of BCC. X-ray exposure as well as chemical like arsenic has been associated with basal cell carcinoma development. A modest role has been ascribed to immunosuppression as well.

Syndromes like xeroderma pigmentosum (due to an inability to repair UV-induced DNA damage), and nevoid BCC syndrome are characterized by multiple basal cell carcinomas occurring in early age.

Ultraviolet-induced mutations in the TP53 tumor suppressor gene, which resides on chromosome 17p, have been implicated in some cases of BCC. In addition, data support mutation of a tumor suppressor gene on band 9q22 as causing nevoid BCC syndrome, an autosomal-dominant condition characterized by early and continued appearance of many BCCs.

Basal cell carcinoma is believed to arise from the pluripotential stem cell compartments of the basal layer of epidermis as well as follicular structures (hair follicle stem cells residing just below the sebaceous gland duct).

Clinical Features. Basal cell carcinoma occurs most frequently in persons in the fourth decade of life or later, but it has been reported as occurring in younger persons, even children. The male-to-female ratio is approximately 3:2. It is a disorder of white individuals, especially those with very fair skin. It is rare in individuals with dark skin.

Basal cell carcinoma is most frequently seen in the middle third of the face, but may occur anywhere on the sun-exposed part of skin. It is important to realize that this form of carcinoma does not arise from oral mucosa and thus is never seen in the oral cavity unless it arrives there by invasion and infiltration from a skin surface.

The subtypes of basal cell carcinoma are:

Nodular basal cell carcinoma. This is the most common variety of basal cell carcinoma. It begins as a small, slightly elevated papule with a central depression which ulcerates, heals over and then breaks down again. Very mild trauma may cause bleeding. One or more telangiectatic blood vessels are usually seen coursing over the borders around the central depression. It enlarges, but still evidences periods of attempted healing. Eventually, the crusting ulcer which appears superficial, develops a smooth, rolled border representing tumor cells spreading laterally beneath the skin. Untreated lesions continue to enlarge, infiltrate adjacent and deeper tissues and may even erode deeply into cartilage or bone.

Pigmented basal cell carcinoma. In addition to features seen in lesions of nodular basal cell carcinoma, lesions of pigmented BCC contain increased brown or black pigment and are seen more commonly in individuals with dark skin.

Cystic basal cell carcinoma. These lesions are translucent blue-gray cystic nodules that may mimic benign cystic lesions.

Superficial basal cell carcinoma. This variety presents as scaly patches or papules that are pink to red-brown in color, often with central clearing. A thread like border is common. Erosion is less common than in nodular variety. Superficial BCC is common on the trunk and has little tendency to become invasive. The papules may mimic psoriasis or eczema but are slowly progressive and not prone to fluctuate in appearance. The occurrence of numerous superficial BCCs may indicate arsenic exposure.

Micronodular basal cell carcinoma. This is an aggressive variety. It is less prone to ulceration, may appear yellow-white when stretched, and is firm to touch. It may have a seemingly well-defined border.

Morpheaform and infiltrating basal cell carcinoma. These are aggressive basal cell carcinoma subtypes with sclerotic (scar like) plaques or papules. The border is usually not well defined and often extends well beyond clinical margins. Ulceration, bleeding, and crusting are uncommon. It may be mistaken for scar tissue.

The differential diagnoses include actinic keratosis, Bowen's disease, keratoacanthoma, melanocytic nevi, sebaceous hyperplasia, seborrheic keratosis, squamous cell carcinoma.

Histologic Features. Tumor cells of nodular basal cell carcinoma, sometimes called basalioma cells, typically have large, hyperchromatic, oval nuclei with little cytoplasm and arranged in nests of varying size. Cells appear rather uniform, and mitotic figures are usually few in number. The cells at the periphery of these nests show palisading. Early lesions usually exhibit some connection to the overlying epidermis, but such contiguity may be difficult to appreciate in more advanced

lesions. Increased mucin is often present in the surrounding dermal stroma.

Cleft formation, known as retraction artifact, commonly occurs between BCC nests and stroma because of shrinkage of mucin during tissue fixation and staining. Some lobules may exhibit areas of pseudoglandular change, and this is the predominant change in adenoid basal cell carcinoma. In the nodulocystic variant, larger tumor lobules may degenerate centrally, forming pseudocystic spaces filled with mucinous debris.

In pigmented basal cell carcinoma, benign melanocytes in and around the tumor produce large amounts of melanin. These melanocytes contain many melanin granules in their cytoplasm and dendrites.

Superficial basal cell carcinoma appears as buds of basaloid cells attached to the undersurface of the epidermis. Nests of various sizes often are seen in the upper dermis which show typical palisading periphery.

The more aggressive morpheaform and infiltrating basal cell carcinomas exhibit growth patterns resulting in strands of cells rather than round nests. Morpheaform BCC arises as thin strands of tumor cells that are embedded in a dense fibrous stroma. The strands of infiltrating type tend to be somewhat thicker than those seen in morpheaform basal cell carcinoma, and have a spiky irregular appearance. Infiltrating basal cell carcinoma usually does not exhibit the scar like stroma seen in morpheaform type. Peripheral palisading and retraction are much less pronounced in morpheaform and infiltrating basal cell carcinoma and subclinical involvement is often extensive.

Another aggressive variant, micronodular basal cell carcinoma, appears as small nodular aggregates of basaloid cells. Retraction artifact tends to be less pronounced than in the nodular form and subclinical involvement is often significant.

Treatment and Prognosis. Each lesion must be considered separately when contemplating the choice of therapy. In general, equally good results may be expected from surgical excision of the tumor or from X-ray radiation. There is probably an equal number of failures or recurrences subsequent to each type of treatment. Some lesions stubbornly resist treatment and exhibit great propensity for recurrence and subsequent destruction of tissue.

The prognosis of basal cell lesions is good, since the neoplasm grows slowly, does not tend to metastasize and responds well to treatment. Most difficulties, which may lead to death by local invasion, are due to neglect on the part of the patient who fails to seek medical aid until the lesion is in a far-advanced state.

Epidermoid Carcinoma
(Squamous cell carcinoma)

Squamous cell carcinoma is defined as "a malignant epithelial neoplasm exhibiting squamous differentiation as characterized by the formation of keratin and/or the presence of intercellular bridges" (Pindborg JJ et al, 1997).

The epidermoid carcinoma is the most common malignant neoplasm of the oral cavity. Although it may occur at any intraoral site, certain sites are more frequently involved than others. Because of the differences in clinical appearance, the nature of the lesion and particularly the prognosis, it is well to describe the tumors individually, as they may arise in these various areas.

Epidemiology. The incidence of squamous cell carcinomas of the oral cavity differs widely in various parts of the world and ranges from approximately 2–10 per 100,000 population per year. Such differences can, to some extent, be explained on the basis of environmental differences or lifestyle and habits among certain populations, such as betel quid chewing, snuff dipping or the habit of reverse smoking. High incidence countries include those in South Asia such as Sri Lanka, India, Pakistan and Bangladesh; Bas-Rhin and Calvados regions in France; countries in central and eastern Europe; and Brazil. The incidence of oral carcinoma in blacks is somewhat lower than in whites, which is mainly due to the low incidence of lower lip cancer in blacks.

In most parts of the world the male-female ratio is approximately 2 : 1 for oral carcinoma, except for carcinoma of the vermilion border of the lower lip. In the latter site there is a strong male predominance. Oral squamous cell carcinomas are mainly found after the fourth decade.

South-East Asian scenario. In India, oral cancer, constituting 9.8% of an estimated 644,600 incident cancer cases in 1992, ranks first among all cancer cases in males and is the third most common among females in many regions, with age-standardized incidence rates from 7–17/100,000 persons/ year; the incidence rate being higher than the western rate of 3–4/100,000/ year (Fig. 2-15).

Significant geographic variation is noted in the incidence of oral cancer, with high rates reported for the Indian subcontinent and parts of Asia (male incidence rates in excess of 10 per 100,000 per annum). In India, cancer of the oral cavity (ICD-9, 141, 143–145) is one of the five leading sites of cancer in either gender. The age standardized incidence rates (ASR) vary from 6.2 per 100,000 in Bangalore to 16.1 per 100,000 in Bhopal among urban males, and from 3.5 in Delhi to 7.8 per 100,000 in Chennai among urban females. On the basis of the cancer registry data, it is estimated that annually 75,000–80,000 new oral cancer cases develop in India. In India, the majority of oral cancers are unequivocally associated with tobacco-chewing habits, and usually preceded by premalignant lesions, most often a persistent leukoplakia or oral submucous fibrosis (SMF). Oral leukoplakias and SMF have been reported to show an increased risk of conversion to malignant transformation varying from 0.13–6%, and the risk further increased to 14% or higher in dysplastic lesions.

Of the areas of the oral cavity, the mortality rate is lowest for lip cancer (0.04 per 100,000) and highest for the tongue (0.7 per 100,000). More than 90% of oral cancers occur in patients over the age of 45. The incidence increases steadily with age until 65, when the rate levels off.

However, studies have shown that between 16 and 62% of oral carcinomas are associated with leukoplakic lesions when diagnosed, and an Indian house-to-house survey

showed that about 80% of oral cancers were preceded by oral precancerous lesions or conditions. Others consider the vast majority of oral cancers to arise from otherwise clinically normal mucosa.

National Cancer Registry Programme. The National Cancer Registry Programme (NCRP) was initiated in 1982, with three population-based (existing Mumbai registry and new registries at Bangalore and Chennai), and three hospital-based registries (at Chandigarh, Dibrugarh and Thiruvananthapuram). Further expansion saw the initiation of urban population-based cancer registries at Bhopal and Delhi; rural population-based cancer registry at Barshi (Maharashtra); and hospital cancer registries at Mumbai, Bangalore and Chennai. The Chandigarh registry functioned till 1992. At present the network has six population-based and five hospital-based cancer registries. Coordinating units at Bangalore and Delhi, with the help of a steering committee, carry out the monitoring and coordination of activities. Data from cancer registries helped in highlighting the magnitude and common sites of cancer in India, and was useful in planning the National Cancer Control Programme (Table 2-7).

Network of National Cancer Registry Programme. In 1994, the crude incidence rates of cancer in India varied between 57.5 and 78.6 per 100,000 men (Fig. 2-16); and between 57.7 and 89.7 per 10,000 women in urban registry areas (Fig. 2-17).

The age standardized incidence rates range from 98.7–138.3 per 100,000 men (Fig. 2-18); and from 08.0–143.4 per 100,000 women in urban areas (Fig. 2-19). The crude incidence rate for cancers at all sites in rural Barshi was reported to be 32.9 per 100,000 men and 49.7 per 100,000 women. The age standardized incidence rate in Barshi was 41.1 and 56.3 per 100,000 men and women, respectively (Tables 2-5, 2-6, 2-7).

Etiology. The use of tobacco in its various forms, including smokeless tobacco, is regarded as the main cause of oral cancer, particularly when associated with the use of excess alcohol. High exposure to ultraviolet light increases the chance of developing cancer of the lower lip. Diets with low levels of vitamins A and C or inadequate consumption of vegetables and fruits may contribute to the risk of oral cancer.

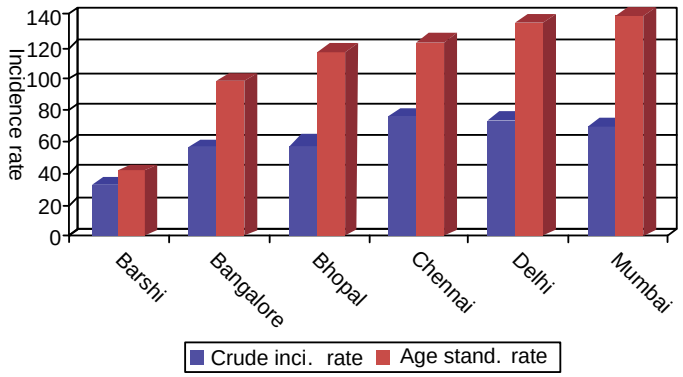

Figure 2-16. Incidence rate of cancer in India, men (1994).

Patients who are immunosuppressed, e.g. renal and homograft recipients and HIV-infected patients, have a higher incidence of subsequent cancer development, particularly of the lower lip. Furthermore, a number of rare conditions predispose to the development of oral cancer, such as xeroderma pigmentosum, Fanconi's anemia, and Bloom's syndrome.

In some patients with oral cancer, especially in females, none of the aforementioned factors or cofactors seem to be present, which makes the etiology of the development of oral cancer incompletely understood.

Although much circumstantial evidence currently exists, the literature still lacks unequivocal evidence linking HPV and oral cancer. When all anatomic sites are considered, the prevalence of HPV in oral cancer does not appear to be higher than the prevalence of HPV in clinically normal mucosa.

Epidemiological findings also lend further support to a causal relationship between HPV and oral cancer, particularly for oropharyngeal tumors:

- The risk of oral cancer has been shown to increase in the presence of HPV infection.
- Certain sexual risk factors known to be associated with cervical cancer for women have been shown to be associated with oral cancer in men.
- HPV positive oropharyngeal tumors appear to represent a distinct clinical and histopathological entity with improved prognosis.

However, it is difficult to ignore the highly preferential association of HPV with tonsillar carcinoma, as well as the finding of high-risk HPV type 16 in these tumors. It is also possible that this area is more predisposed to epithelial injury which facilitates the subsequent viral infection.

Sunlight, in cases of lip cancer, appeared to be of only minor etiologic significance. This is the generally accepted reason for its occurrence preponderantly in fair-skinned outdoor male workers who are affected by exposure of the lower lip to the sun, whereas the upper lip is partially protected. The lesser rate of occurrence in females may be due to lower exposure to sunlight and the partial protection of their lips by lipstick.

Trauma and dental irritation were not found to be significant etiologic factors in oral cancer. In this regard, Monkman and his associates have also carried out a thorough review of the literature relating cancer to trauma and found no evidence to suggest that single uncomplicated trauma can cause cancer. They also found it debatable whether trauma can aggravate or accelerate existing malignancies. However, they concluded that trauma, in combination with other factors, may act as a co-carcinogen and that there was adequate evidence suggesting that metastatic spread of malignant tumors can be affected by trauma.

Genetic Basis of Oral Cancer

Evidence suggests that oral cancer results from genetic damage.There is increased risk of oral cancer associated with exposure to genetic mutagens in tobacco, alcohol and betel quid. Gene mutations have been detected in oral SCC in chromosomes 3p, 4q, 6p, 8p, 9p, 11q, 13q (retinoblastoma [Rb] tumor suppressor gene), 14q, 17p (p53 tumor suppressor gene), 18q (deleted in colon cancer [DCC] tumor suppressor gene) and 21q.1113 The genetic hypothesis predicts a role for hyperactive oncogenes (growth promoting genes) in oral carcinogenesis. Oncogenes encode many of the signal-transmitting proteins (for example, EGFr, ras, cytoplasmic kinases, c-myc) via which cells respond to external growth signals. Normal cells, with normal oncogenes, will not commit themselves to another round of DNA replication and cell division without stimulation from such external signals. However, with oncogene mutation, the mutant oncoprotein may send a growth-stimulatory signal to the nucleus, regardless of events taking place in the cell's

As discussed, the ras oncoprotein lies on the internal aspect of the membrane-bound EGFr and is involved in the transmission of the EGF growth-stimulatory signal to the nucleus (Fig. 2-20). In the inactive state, ras binds guanosine diphosphate (GDP).When cells are stimulated by EGF, inactive ras becomes activated by exchanging GDP for guanosine triphosphate (GTP). Active ras activates the Raf protein and subsequently the other cytoplasmic kinases (MEK, MAPK) in a cascade-like manner (Fig. 2-20). After activating Raf, active ras returns to the inactive state due to its intrinsic guanosine triphosphatase (GTPase) activity. GTPase hydrolyses GTP to GDP, thereby releasing a phosphate group and returning the ras protein to its inactive GDP-bound state. The intrinsic GTPase activity of activated ras is amplified by binding of GTPase- activating proteins (GAPs). Under normal circumstances, this mechanism ensures that ras is active for only a brief period of time following EGF stimulation and that cell proliferation is tightly regulated by EGF. However, the control of ras activity changes dramatically with mutation of the ras oncogene. Mutant ras protein can bind GAPs, however GTPase activity is not amplified. Hence, mutant ras is trapped in its active GTP-bound form which continues to activate Raf, thus sending a proliferation signal to the nucleus even in the absence of binding between EGF and its receptor on the cell surface. In addition, hyperactive ras may stimulate the transcription of bcl-2 which blocks caspase 3 activation and hence blocks apoptotic cell death. Many studies have shown ras oncogene mutation and ras oncoprotein overexpression in oral SCC. Furthermore, oral premalignant lesions and oral cancer may be associated with upregulated EGF receptor expression. Oral cancer may, therefore, result from mutation of an oncogene in the EGF pathway. The mutant oncoprotein sends a continuous growth signal to the nucleus resulting in continuous oral keratinocyte proliferation and tumor development.

Under normal circumstances, the p53 tumor suppressor protein detects DNA damage (such as ras oncogene mutation) and halts progression through the cell cycle. Following DNA damage, there is an increase in the level of p53 which, in turn, stimulates the transcription of p21 (Fig. 2-20). The p21 tumor suppressor protein is a CDK inhibitor and blocks the phosphorylation of pRb, thereby blocking the release of E2F transcription factors and blocking DNA replication.The p21 tumor suppressor protein also binds and deactivates proliferating cell nuclear antigen (PCNA) (Fig. 2-20). PCNA is a toroidal-shaped protein that encircles and slides along DNA. PCNA tethers the DNA polymerase catalytic unit to the DNA template and is therefore essential for DNA replication. Binding of p21 to PCNA inhibits the interaction between PCNA and DNA polymerase, thereby, blocking DNA replication. Hence p53, acting via p21, puts the brakes on DNA replication and cell division in cells with damaged DNA. In some instances, p53 will trigger apoptosis (programmed cell death) in cells with damaged DNA. p53 stimulates the transcription of Bax which blocks the activity of bcl-2 (Fig. 2-20). bcl-2 normally blocks the activation of caspase 3, a central mediator of the apoptosis cell death pathway. When bcl-2 activity is blocked by Bax, caspase 3 activity is unchecked and apoptotic cell death proceeds (Fig. 2-20). p53 also represses the transcription of bcl-2 which

further contributes to caspase 3 activity and apoptosis in cells with damaged DNA.

However, if the p53 gene is mutated, the protection offered by the p53 tumor suppressor protein against DNA damage (for example, ras oncogene mutation) is lost. Both alleles of the tumor suppressor gene must be mutated for the tumor suppressor protein to become non-functional. A cell which is 'heterozygous' for a tumor suppressor gene has one normal allele and one mutant allele and the cell is clinically normal. If a cell becomes homozygous for the mutant allele, that is 'loses heterozygosity', cancer may develop. In familial cases of retinoblastoma, children inherit one mutant allele of the Rb tumor suppressor gene and the other allele is normal. Only one somatic mutation is required to inactivate the single normal allele of the Rb gene and for retinoblastoma to develop. In sporadic cases, both normal alleles of the Rb tumor suppressor gene in a single retinoblast are lost by somatic mutation resulting in retinoblastoma. In the Li–Fraumeni cancer susceptibility syndrome, children inherit one mutant allele of the p53 tumor suppressor gene and the other allele is normal. Again, only one somatic mutation is required to inactivate the single normal allele of the p53 gene and patients with this syndrome are at high risk of developing carcinomas, sarcomas, lymphomas and brain tumors. Most oral cancers are sporadic and therefore both normal alleles of the p53 tumor suppressor gene in a single oral keratinocyte are lost by somatic mutation. In this context, the tumor suppressor genes are 'recessive', as both alleles must be damaged for transformation to occur. In contrast, the oncogenes (for example, ras) are 'dominant', as mutation of only one allele results in transformation.

Mutation of the p53 tumor suppressor gene is the most common genetic lesion in human neoplasia and p53 is mutated in up to 80% of oral cancers. In oral SCC, p53 mutation correlates with a history of heavy smoking and is associated with increased epithelial cell proliferation. Mutation of p53 may precede or accompany the transition from oral precancer to cancer. A common p53 mutation in many tumors is deletion of one allele accompanied by a mutation in the central DNA-binding domain of the remaining allele. Consequently, the mutant p53 protein is unable to stimulate p21 or Bax transcription and cells with damaged DNA (for example, mutated ras oncogene) continue to divide, passing on their gene mutations to subsequent generations (Table 2-8).

By way of a simple example, oral cancer may result from an activating mutation of the ras oncogene and a simultaneous deactivating mutation of the p53 tumor suppressor gene in an oral keratinocyte. In this scenario, oral cancer would evolve from an oral keratinocyte that has received three genetic 'hits' from mutagens in tobacco, alcohol, betel quid or some other source. The first 'hit' would inactivate one allele of the p53 tumor suppressor gene. The second 'hit' would inactivate the other allele of the p53 tumor suppressor gene. The third 'hit' would activate apoptosis. As discussed, oral cancer may result from mutation in other oncogenes in the EGFr/ras/kinase cascade/c-myc signalling pathway and cumulative tumor suppressor gene the ras oncogene.The order of these 'hits' is probably important, as ras oncogene mutation in the mutations, presence of at least one functional allele of p53 would be expected to result in cell cycle arrest and which correlates with the stages of carcinogenesis from normal mucosa, to squamous hyperplasia (9p), to dysplasia (3p, 17p) to carcinoma *in situ* (11q, 13q, 14q) to invasive carcinoma (6p, 8 and 4q).

Table 2-8: Proteins required for DNA replication

Enzymes required in nucleotide synthesis
• Initiator proteins: bind at replication origin
• DNA helicase: binds initiator proteins and opens the double helix
• Single strand DNA binding proteins (helix destabilizing proteins): stabilizes unwound single strand DNA
• DNA polymerase: polymerizes deoxyribonucleoside triphosphates (5'–3') on a single strand DNA template
• PCNA (proliferating cell nuclear antigen) - tethers DNA polymerase to the DNA template
• DNA primase: makes RNA primers for lagging strand replication
• DNA ligase: joins Okazaki fragments during lagging strand replication
• Proofreading exonuclease: provides base-paired terminus that primes DNA synthesis
• DNA topoisomerase: transient nick in DNA to allow free rotation during replication

Most of these proteins are enzymes which are newly transcribed with each round of cell division. Many of these proteins are transcribed by the E2F family of transcription factors (Fig.2-20).

surroundings. The subsequent autonomous proliferation of mutant oncogene-bearing cells result in tumor formation.

Clinical Presentations of Oral Cancer. Clinically, almost all oral cancers, except those in the earliest stages have two very characteristic features in the form of ulceration and an indurated margin. In different sites; however, there are certain variations.

Histologic Features. Considerable histologic variation is presented in intraoral epidermoid carcinomas, although in general they tend to be moderately well-differentiated neoplasms with some evidence of keratinization (Fig. 2-21 and Table 2-9). Highly anaplastic lesions do occur, but are uncommon; such lesions tend to metastasize early and widely and cause death quickly. The well-differentiated epidermoid carcinoma consists of sheets and nests of cells with obvious origin from squamous epithelium. These cells are generally large and show a distinct cell membrane, although intercellular

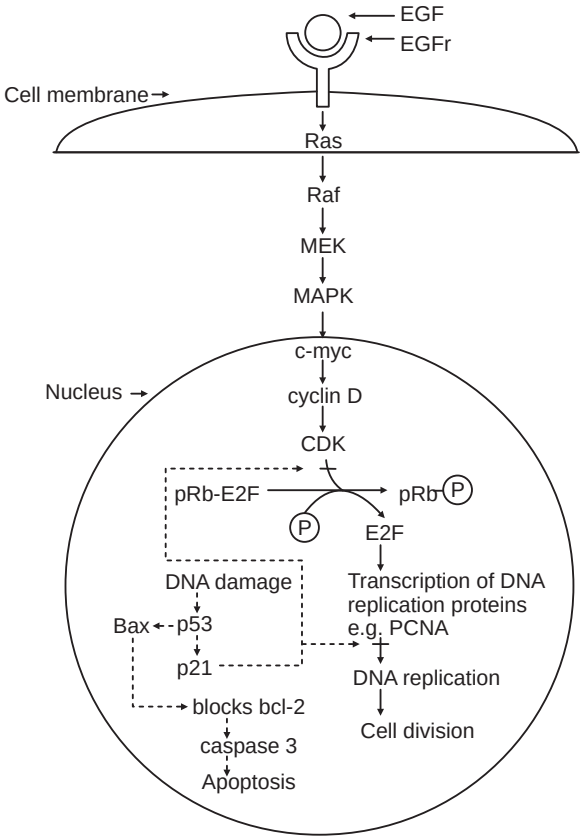

Figure 2-20. Oral cancer: Genetic basis
Normal oral keratinocyte division is stimulated by epidermal growth factor (EGF) binding the EGF receptor (EGFr) which activates ras. Active ras triggers the kinase cascade (Raf, MEK, MAPK) resulting in increased levels of c-myc in the nucleus. c-myc stimulates the transcription of cyclin D which activates cyclin-dependent kinase (CDK). Active CDK catalyzes the phosphorylation of the retinoblastoma tumor suppressor protein (pRb). Phosphorylated pRb releases the E2F transcription factors which are required for the transcription of DNA replication proteins including proliferating cell nuclear antigen (PCNA). DNA replication proceeds, followed closely by cell division.Cyclin D and most of the DNA replication proteins are degraded and must be newly transcribed with each round of cell division. DNA damage in oral keratinocytes is detected by p53. As a result, there is an increase in the level of p53 which stimulates the transcription of p21, a CDK inhibitor which blocks the phosphorylation of pRb. p21 also binds and deactivates PCNA. p53 stimulates the transcription of Bax which blocks the activity of bcl-2. Caspase 3 activity is therefore unchecked and apoptotic cell death proceeds. The dotted lines represent the apoptotic cell death pathway following DNA damage.

Pathophysiology

Allelic imbalances (loss of heterozygosity [LOH]) have been identified in tumor suppressor genes on the short arm of chromosome 3, p16 on chromosome 9, p53 on chromosome 17.

Damage to tumor suppressor genes may also involve damage to other genes involved in growth control, mainly those involved in cell signaling (oncogenes), especially some on chromosome 11 (PRAD-1) and chromosome 17 (Harvey *ras* [H-*ras*]). Changes in oncogenes can disrupt cell growth control, leading ultimately to the uncontrolled growth of cancer.

The molecular changes found in oral squamous cell carcinoma from Western countries (United Kingdom, United States, Australia), particularly p53 mutations, are infrequent in Eastern countries (India, South-East Asia), where the involvement of ras oncogenes is more common, suggesting genetic differences that might be involved in explaining the susceptibility of certain groups to oral squamous cell carcinoma.

The rare syndrome (Li–Fraumeni syndrome) is associated with defects in p53.

bridges or tonofibrils often cannot be demonstrated. The nuclei of the neoplastic cells are large and may demonstrate a good deal of variability in the intensity of the staining reaction. Nuclei which stain heavily with hematoxylin are referred to as hyperchromatic. In the well-differentiated lesion mitotic figures may be found, but they often do not appear to be especially numerous (Fig. 2-22). Many of these mitotic figures are atypical, although this may be obvious only to an experienced histopathologist. One of the most prominent features of the well-differentiated epidermoid carcinoma is the presence of individual cell keratinization and the formation of numerous epithelial, or keratin pearls of varying sizes. In a typical lesion, groups of these malignant cells can be found actively invading the connective tissue in a vagarious pattern.

Less well-differentiated epidermoid carcinomas lose certain features, so that their resemblance to squamous epithelium is less pronounced. The characteristic shape of the cells and their arrangement may be altered. The growth rate of the individual cells is more rapid, and this is reflected in the greater numbers of mitotic figures, the even greater variation in sizes, shape and tinctorial reaction and the failure to carry out the function of a differentiated squamous cell, the formation of keratin.

The poorly differentiated carcinomas bear little resemblance to their cell of origin and will often present diagnostic difficulties because of the primitive and uncharacteristic histologic appearance of the malignant, rapidly dividing cells. These cells show an even greater lack of cohesiveness and are extremely vagarious.

The recognition that different degrees of differentiation occur in the epidermoid carcinoma prompted Broders to suggest a system of grading tumors in which a grade I lesion was highly differentiated (its cells were producing much keratin), while grade IV was very poorly differentiated (the cells were highly anaplastic and showed practically no keratin formation). The fact that the same tumor may show different degrees of differentiation in varying areas has prompted the discontinuation of the grading system. Instead, most pathologists now modify the diagnosis of the neoplasm by a descriptive adjective indicative of its differentiation. The one advantage of grading a tumor is that the grade reflects the anaplasticity of the lesion, which in turn indicates the general rapidity of growth, the rapidity of metastatic spread, the general reaction to be expected after X-ray radiation and the prognosis.

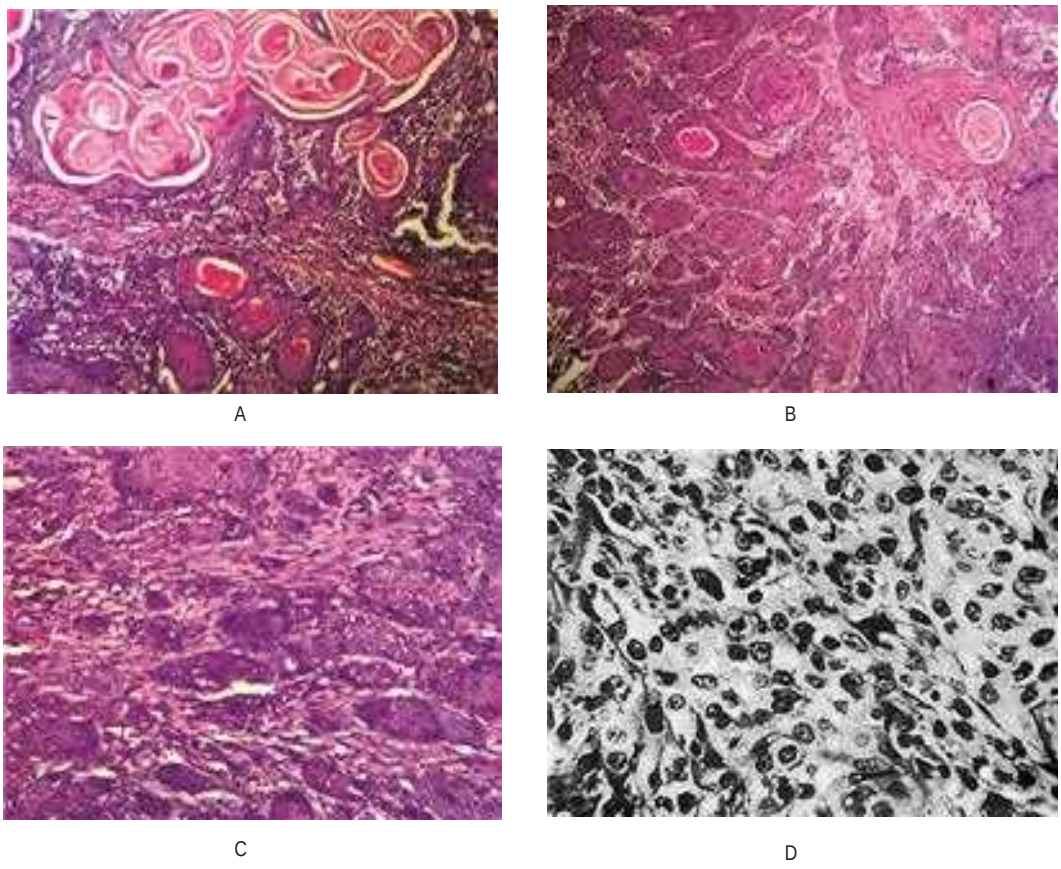

Figure 2-21. Epidermoid carcinoma.
Photomicrographs of various cases of epidermoid carcinoma illustrate **(A)** a highly differentiated carcinoma, **(B)** a well differentiated carcinoma, **(C)** a moderately differentiated carcinoma, and **(D)** a poorly differentiated carcinoma *(Courtesy of Dr G Sriram, Department of Oral and Maxillofacial Pathology, Meenakshi Ammal Dental College, Chennai).*

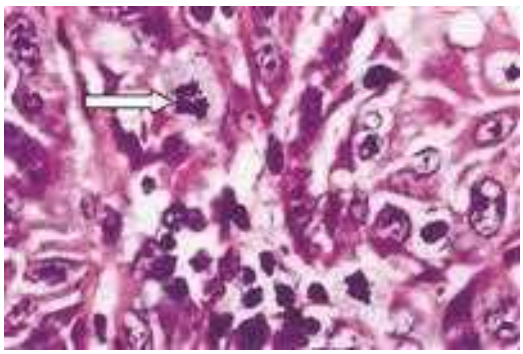

Figure 2-22. Increased number of mitotic figures per field (H&E stain).

This great advantage is still retained in the descriptive grading which is replacing the numerical grading system.

Metastases from intraoral carcinoma of different sites involve chiefly the submaxillary and superficial and deep cervical lymph nodes (Figs. 2-23–2-26). Occasionally, other nodes such as the submental, preauricular and postauricular nodes and supraclavicular nodes may be involved, but blood stream metastasis from oral cancer is uncommon. However, Gowen and de Suto-Nagy have reported on a series of 59 patients who died of carcinoma of the head and neck and were autopsied, with distant metastases being specifically sought. Surprisingly, 57% of these patients did have distant metastases; in the lung in 82% of the cases, in the liver in 45%, and in the bones in 23%.

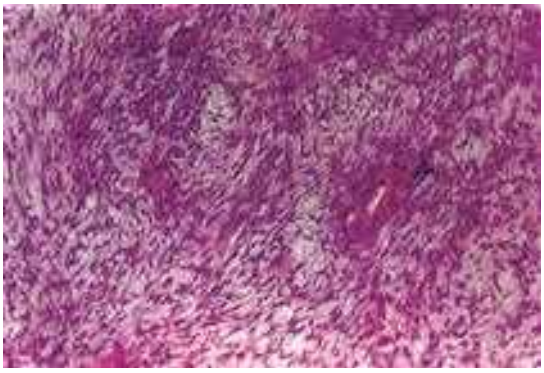

Figure 2-23. Squamous cell carcinoma with spindle metaplastic features.

Table 2-9: Histological classification of cancer and precancer of the oral mucosa

1. Carcinomas
   - Squamous cell carcinoma
   - Verrucous carcinoma
   - Basaloid squamous cell carcinoma
   - Adenoid squamous cell carcinoma
   - Spindle cell carcinoma
   - Adenosquamous carcinoma
   - Undifferentiated carcinoma
2. Benign lesions capable of microscopically resembling oral squamous cell carcinoma and oral verrucous carcinoma
   - Papillary hyperplasia
   - Granular cell tumor
   - Discoid lupus erythematosus
   - Median rhomboid glossitis
   - Keratoacanthoma
   - Necrotizing sialometaplasia
   - Juxtaoral organ of Chievitz
   - Chronic hyperplastic candidiasis
   - Verruciform xanthoma
   - Verruca vulgaris
   - Condyloma acuminatum
3. Precancerous lesions (clinical classification)
   - Leukoplakia
   - Erythroplakia
   - Palatal keratosis associated with reverse smoking
4. Precancerous lesions (histological classification)
   - Squamous epithelial dysplasia
   - Squamous cell carcinoma in situ
   - Solar keratosis
5. Benign lesions capable of resembling oral precancerous lesions
   - White lesions resembling leukoplakia
   - Red lesions resembling erythroplakia
   - Focal epithelial hyperplasia
   - Reactive and regenerative atypia
6. Precancerous conditions
   - Sideropenic dysphagia
   - Lichen planus
   - Oral submucous fibrosis
   - Syphilis
   - Discoid lupus erythematosus
   - Xeroderma pigmentosum
   - Epidermolysis bullosa

Carcinogen-metabolizing enzymes are implicated in some patients

1. Alcohol dehydrogenase (ADH) oxidizes ethanol to acetaldehyde, which is cytotoxic and results in the production of free radicals and DNA hydroxylated bases; alcohol dehydrogenase type 3 genotypes appear predisposed to oral squamous cell carcinoma.
2. Cytochrome p450 can activate many environmental procarcinogens. Ethanol is also metabolized, to some extent, by cytochrome p450 IIEI (CYP2E1) to acetaldehyde. Mutations in some tumor suppressor genes may be related to cytochrome p450 genotypes and predispose to oral squamous cell carcinoma.
3. Glutathione S transferase (GST) genotypes may have impaired activity; for example, the null genotype of GSTM1 has a decreased capacity to detoxify tobacco carcinogens. Some GSTM1 and GSTP1 polymorphic genotypes and GSTM1 and GSTT1 null genotypes have been shown to predispose to oral squamous cell carcinoma.
4. N-acetyltransferases NAT1 and NAT2 acetylate procarcinogens. N-acetyl transferase NAT1*10 genotypes may be a genetic determinant of oral squamous cell carcinoma, at least in some populations.
5. DNA repair genes are clearly involved in the pathogenesis of some rare cancers such as are seen in xeroderma pigmentosum but, more recently, evidence of defective DNA repair has also been found to underlie some oral squamous cell carcinoma.

   Immune defects may predispose to OSCC, especially lip cancer.

Metastatic Carcinoma

Mustard and Rosen have reported on the influence of lymph node metastasis on the survival rate of patients with oral cancer. In a series of 1,177 patients who did not have regional lymph node involvement at the time of diagnosis of their lesion,

Figure 2-24. Metastatic epidermoid carcinoma.
There is massive involvement of the cervical lymph nodes, which are firm, fixed and matted.

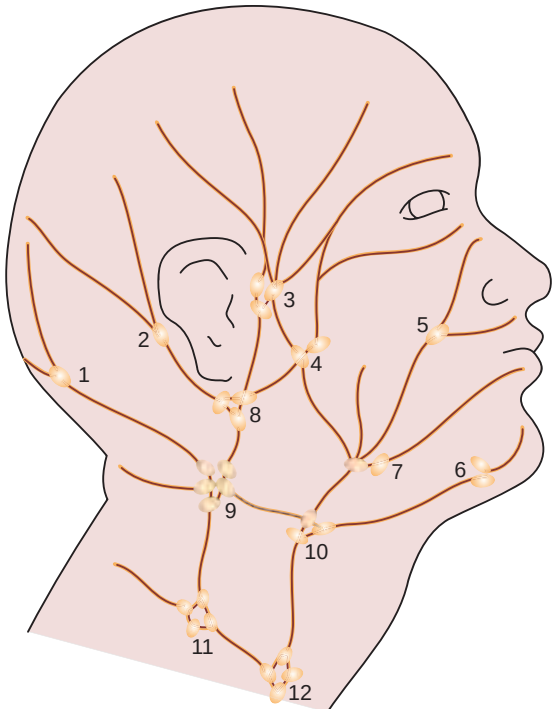

Figure 2-25. Regional lymphatic system of the head and neck, showing the various groups of lymph nodes.
1. Occipital nodes, 2. posterior auricular nodes, 3. anterior auricular (preauricular) nodes, 4. parotid nodes, 5. facial nodes, 6. submental nodes, 7. submaxillary nodes, 8. inferior auricular nodes, 9. lateral upper deep cervical nodes, 10. medial upper deep cervical nodes, 11. lateral lower deep cervical nodes and 12. medial lower deep cervical nodes.

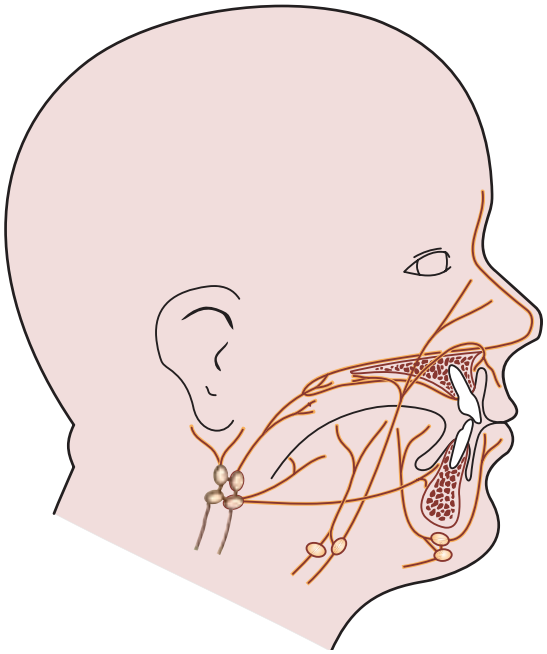

Figure 2-26. Regional lymphatic drainage of the oral structures.

64% lived for five years. However, of the group who did have lymph node involvement at the time of admission, only 15% survived for the same period.

TNM CLASSIFICATION OF LIP AND ORAL CAVITY CARCINOMAS

Rules for Classification

The classification applies only to carcinomas of the vermilion surfaces of the lips and of the oral cavity, including those of minor salivary glands. There should be histological confirmation of the disease. The following are the procedure for assessment of the T, N and M categories:

T category Physical examination and imaging
N category Physical examination and imaging
M category Physical examination and imaging.

Anatomical Sites and Subsites

Lip (ICD Coding)

1. External upper lip (vermilion border) (C00.0)
2. External lower lip (vermilion border) (C00.1)
3. Commissures (C00.6)

Oral Cavity

1. Buccal mucosa
   i. Mucosa of upper and lower lips (C00.3,4)
   ii. Cheek mucosa (C06.0)
   iii. Retromolar areas (C06.2)
   iv. Buccoalveolar sulci, upper and lower (vestibule of mouth) (C06.1)
2. Upper alveolus and gingiva (upper gum) (C03.0)
3. Lower alveolus and gingiva (lower gum) (C03.1)
4. Hard palate (C05.0)
5. Tongue
   i. Dorsal surface and lateral borders anterior to vallate papillae (anterior two-thirds) (C02.0,1)
   ii. Inferior (ventral) surface (C02.2)
6. Floor of mouth (C04).

Regional Lymph Nodes. The regional lymph nodes are the cervical nodes.

TNM Clinical Classification

T—Primary tumor

TX Primary tumor cannot be assessed
TO No evidence of primary tumor
Tis Carcinoma *in situ*
T1 Tumor 2 cm or less in greatest dimension
T2 Tumor more than 2 cm but not more than 4 cm in greatest dimension
T3 Tumor more than 4 cm in greatest dimension
T4 Lip: Tumor invades adjacent structures, e.g. through cortical bone, tongue, skin of neck
Oral cavity: Tumor invades adjacent structures, e.g. through cortical bone, into deep (extrinsic) muscle of tongue, maxillary sinus, skin.

N—Regional lymph nodes

NX Regional lymph nodes cannot be assessed

NO No regional lymph node metastasis
N1 Metastasis in a single ipsilateral lymph node, 3 cm or less in greatest dimension
N2 Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension, or in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension, or in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N2a: Metastasis in a single ipsilateral lymph node, more than 3 cm but not more than 6 cm in greatest dimension
N2b: Metastasis in multiple ipsilateral lymph nodes, none more than 6 cm in greatest dimension
N2c: Metastasis in bilateral or contralateral lymph nodes, none more than 6 cm in greatest dimension
N3 Metastasis in a lymph node, more than 6 cm in greatest dimension
Note: Midline nodes are considered ipsilateral nodes.

M—Distant metastasis
MX Presence of distant metastasis cannot be assessed
MO No distant metastasis
M1 Distant metastasis.

(pTNM pathological classification: The pT, pN and pM categories correspond to the T, N, and M categories).

Stage Grouping			
Stage 0	Tis	N0	M0
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T1 T2 T3	N1 N1 N0, N1	M0 M0 M0
Stage IV	T4 Any T Any T	N0, N1 N2, N3 Any N	M0 M0 M1

HISTOPATHOLOGICAL GRADING OF ORAL SQUAMOUS CELL CARCINOMA

Classic microscopic histopathologic alterations observed with squamous cell carcinoma include:

a. Enlarged nuclei as well as cell size
b. Large and prominent nucleoli
c. Increased nuclear/cytoplasmic ratio
d. Hyperchromatic (dark staining) nuclei
e. Dyskeratosis (premature keratinization of cells)
f. Increased and/or aberrant mitotic activity.

Based upon the above mentioned histopathologic features, squamous cell carcinoma can then be histologically graded. Although the grade of tumor does not substitute the staging protocol, it does serve as an important adjunctive in predicting the overall biological behavior of the tumor. In general, tumors that more closely resemble their native tissues are considered to be well differentiated and tend to have a better long-term prognosis. In contrast, tumors with abundant amounts of cellular and nuclear alterations with little or no resemblance to squamous epithelium or those that lack keratin production may be classified as poorly differentiated tumors. These lesions, also termed as anaplastic or high grade, have an increased propensity for regional metastasis and correlate to a poor prognosis. Additional features that favor a more aggressive nature include perineural spread, lymphatic invasion, and tumor extension beyond the lymph node capsule. Hematogenous spread is an uncommon mode of spread for carcinomas.

Criteria for the Diagnosis of Oral Epithelial Dysplasia

The diagnosis and grading of oral epithelial dysplasia is based on a combination of architectural and cytological changes (Barnes L et al, 2005), but evaluation of these is subjective and has been subject to considerable inter-and intra-observer variations in the grading of lesions. More recently, there has been an attempt to more carefully define the criteria for grading of epithelial dysplasia (Bouquot J et al, 2006, Brothwell DJ et al, 2003). The WHO classification (2005) recommends a more objective grading which does, to some extent, take account of levels of involvement of involved epithelium. The criteria for grading of oral epithelial dysplasia are summarized as follows:

Mild dysplasia (Grade-1). Demonstrates proliferation or hyperplasia of cells of the basal and parabasal layers which does not extend beyond the lower third of the epithelium. Cytological atypia is generally slight with only mild pleomorphism of cells or nuclei. Mitoses are not prominent, and when present are usually basally located and normal. Architectural (gross) changes are minimal.

Moderate dysplasia (Grade-2). Demonstrates a proliferation of atypical cells extending into the middle one third of the epithelium. The cytological changes are more severe than in mild dysplasia and changes such as hyperchromatism, and prominent cell and nuclear pleomorphism may be seen. Increased and abnormal mitoses may be seen, but these are usually located at the basal layers of the epithelium. Architectural changes may be seen in the lower half of the epithelium where there may be loss of basal polarity and hyperplasia leading to bulbous rete pegs. However, stratification and maturation are relatively normal, often with hyperkeratosis of the surface epithelium.

Severe dysplasia (Grade 3): There is abnormal proliferation from the basal layer into the upper third of the epithelium. Cytological and architectural changes can be very prominent. All the changes seen in mild and moderate dysplasia are present but in addition there is marked pleomorphism often with abnormal large nuclei and prominent or even multiple nucleoli present. Prominent and suprabasal mitoses are usually evident and abnormal tripolar or star shaped forms may be seen. Apoptotic bodies (cell death) may also be prominent. Architectural changes are severe, often with complete lack of

stratification and with deep abnormal keratinization and even formation of keratin pearls. Abnormal forms of rete pegs are usual and bulbous rete pegs are particularly significant in the diagnosis of severe dysplasia. Abnormal shaped rete pegs may also be seen, with lateral extensions or small branches. These are quite abnormal and may be the earliest signs of invasion. Occasional lesions may show prominent acantholysis with severe disruption of the architecture. Although the epithelium may be thickened, severe dysplasia is sometimes accompanied by marked epithelial atrophy (thinning). This is especially prominent in lesions from the floor of the mouth, ventral tongue or soft palate and may be a feature of lesions which have presented clinically as erythroplakia (red patch). In these cases there may be minimal evidence of stratification or keratinization, and atypical cells may be extended to the surface.

Carcinoma *in situ*. It is the most severe form of epithelial dysplasia and is characterised by full thickness cytological and architectural changes. In the oral cavity such changes are rare, and often, even in the presence of the most severe atypia, there is still an intact keratinised surface layer. Carcinoma *in situ* is thought by some to be a premalignancy but others regard it as evidence of actual malignant change but without invasion (Speight PM, 2010).

Histological Models and Scoring Systems

Many such models and scoring systems have been developed for predicting the biological behavior of oral squamous cell carcinoma. Broder's system (1920) was first established on the basis of the proportion of highly differentiated cells in the tumor. Although Broder's system was simple and widely used, it was a poor predictor for survival or metastasis. In 1973, Jakobsson et al, developed a multifactorial grading system which had the advantage of scoring tumor–host interactions and tumor characteristics, but eventually proved to be useful only when applied to tongue cancers. Later, Anneroth et al (1984) proposed a modification of Jakobsson system based on the assessment of six histomorphological parameters including degree of keratinization, nuclear pleomorphism, pattern of invasion, host response and mitotic activity. Bryne et al (1989) modified Anneroth's grading system and developed a malignancy grading focusing on the invasive front of the tumor. This method of grading appeared to be less time consuming in assessment of the neoplasm than that of Jakobsson et al, and Anneroth et al. Neverthless, this system was not sufficiently homogeneous to allow grading parameters to be assessed individually.

EMERGING TRENDS

An interesting pursuit in tumor biology would be studying the biologic behavior of neoplasms in general and follow the subtle differences that exists with individual tumors. Among the many variables would be consideration of the site, size, histologic grades, etiologic factors and stage of progression of individual neoplasms. This newer approach of carefully monitoring tumors comprise a separate area of 'biologic staging', which is currently gaining acceptance in clinical practice (Table 2-10). Another interesting trend currently being investigated is the use of the polymerase chain reaction (PCR) to determine if surgical margins obtained at the time of surgery that are histopathologically free of tumor contain a small amount of histologically undetectable tumor cells. Specifically, the use of PCR to detect specific p53 mutations identified in the primary tumor in the histopathologically negative surgical margin could be very useful, as these mutations would indicate the presence of residual (histopathologically undetected) tumor cells. It will be very important to establish whether the presence of submicroscopic tumor cells contributes to prognosis and clinical outcome. The recent development of *in situ* PCR will allow amplification of both DNA and RNA directly in tissue section; this technique should be extremely helpful in the future to localize tumor cells containing altered oncogenes or tumor suppressor genes. An improved understanding of the molecular biology of head and neck cancer may also contribute to future therapeutic improvements. Finally, molecular probes may be used to facilitate the early detection of secondary malignancies.

Table 2-10: Biomarker predictors in oral precancerous and cancerous lesions

Marker method	Detection	Target
Proliferation PCNA, Ki67, BrU Histone AgNORs	 IHC mRNA ISH Silver stain	 Cycling cells
Genetic Ploidy	 FC	 Aneuploid cells
Oncogenes C-myc	 IHC	 Cycling cells
Tumor suppressor p53 mutations	 IHC, PCR	 Cycling cells
Cytokeratin 8/19	IHC	Anaplasia
Blood group antigens	IHC	Anaplasia
Integrins/ECM ligands	IHC	Invasion and metastatic potential

IHC: immunohistochemistry, FC: flowcytometry, PCR: polymerase chain reaction, ISH: in-situ hybridization.

Under the current management, the strategy for head and neck cancer includes specialists from many disciplines and their concerted effort will promote the use of increasingly refined laboratory techniques for improved diagnosis and therapy. A good deal of current laboratory and clinical research is focusing on identifying the relative contributions of certain oncogenes and tumor suppressor genes on carcinogenesis, tumor stage, and clinical outcome. Although abnormalities of some oncogenes and tumor suppressor genes have been identified, their relative contribution and optimal use in diagnosis, prognosis, or treatment remain unknown. The same might be said for the role of Epstein-Barr, hepatitis, and herpes simplex viruses; further clinicolaboratory studies will be needed to define which are clinically relevant and when they should be

investigated. Genetic analysis at a molecular/chromosomal level is emerging as a science that may aid in identifying risk and possibly prevention as well. Finally, a reliable and predictable histopathology grading system should be developed to include, in addition to differentiation of tumor cells, such factors as basement membrane protein expression and invasion patterns, perineural invasion, and immunologic responses.

Carcinoma of Lip

Epidermoid carcinoma of the lip is a disease that occurs chiefly in elderly men. Furthermore, the lower lip is involved by this neoplasm far more commonly than the upper lip. Great numbers of cases have been reported in the literature, and the data of Cross, Guralnick and Daland on 563 patients with lip cancer may be cited to illustrate certain typical characteristics. In this large series, it was found that 98% of the patients were men and that the age of these patients at the onset of the disease ranged from 25–91 years, with the greatest incidence between 55 and 75 years and a mean of 62 years of age. Of the total group of lip cancers, 88.3% occurred on the lower lip, 3.3% on the upper lip and 8.3% on the labial commissures. The right and left sides were affected with equal frequency. In 636 cases reviewed by Schreiner, similar findings were reported. In his series 97% of the lesions occurred in men, and 96% were found on the lower lip. Nearly one-third of his cases occurred between the ages of 60 and 70 years.

Etiology. A number of possible etiologic factors have been suggested by the review of the records of many patients. One of the most common of these has been the use of tobacco, chiefly through pipe-smoking. The data of Cross and his coworkers indicate that 64% of their patients with lip cancer were pipe smokers, while a total of 94% habitually used tobacco in some form. These observations are in agreement with the data of Widmann, who, in a review of 363 cases of lip cancer, estimated an incidence of approximately 40% pipe smokers. Schreiner reported that 87% of his lip cancer patients were tobacco users. Although no conclusions may be drawn from such data because of the widespread use of tobacco in the general population, it appears suggestive that the heat, the trauma of the pipe stem and possibly the combustion end-products of tobacco may be of some significance in the etiology of lip cancer.

Syphilis is probably not as significant an etiologic factor in lip cancer as in certain other oral sites, since the incidence of lip cancer has been found to be low in syphilitic patients: 7.2% by Cross and his associates, 8% by Widmann and 3.6% by Schreiner. As indicated previously; however, the data of Wynder and his group indicated that syphilis was of etiologic significance in lip cancer.

Sunlight is generally considered to be important, as discussed previously, because the alterations which occur in skin and lips as a result of prolonged exposure to sun are characterized as preneoplastic. Ju has discussed this problem and constructed a profile of the lip cancer patient.

Poor oral hygiene is an almost universal finding in patients with lip cancer. Cross and his group pointed out that only approximately 8% of their entire series of patients had good or even fair oral hygiene. In addition, some patients indicate a history of trauma before the appearance of a lesion. They report not only a single traumatic experience, such as a cigarette burn or a cut, but also chronic trauma from jagged teeth and so forth. Unfortunately, it is difficult to assess scientifically the role of such factors in the etiology of cancer.

Leukoplakia has often been associated with the development of carcinoma. Since clinical leukoplakia is a fairly common lesion of the lip, it was only natural that the relationship should be investigated. Schreiner found leukoplakia present in only 2.4% of his 636 cases of lip cancer, while Cross and coworkers found leukoplakia associated with carcinoma in 14.5% of the cases in their series. This would indicate that the simultaneous occurrence of the two conditions is probably due to chance and that leukoplakia is not a common predecessor of lip cancer. However, in light of more recent studies dealing with the frequency of preneoplastic and neoplastic transformation in lesions of leukoplakia of the lip (q.v.), the interpretation of the above findings is uncertain.

Clinical Features. There is considerable variation in the clinical appearance of lip cancer, depending chiefly upon the duration of the lesion and the nature of the growth. The tumor usually begins on the vermilion border of the lip to one side of the midline. It often commences as a small area of thickening, induration and ulceration or irregularity of the surface. As the lesion becomes larger it may create a small crater like defect or produce an exophytic, proliferative growth of tumor tissue. Some patients have large fungating masses in a relatively short time, while in other patients the lesion may be only slowly progressive.

Carcinoma of the lip is generally slow to metastasize, and a massive lesion may develop before there is evidence of regional lymph node involvement. Some lesions; however, particularly the more anaplastic ones, may metastasize early. When metastasis does occur, it is usually ipsilateral and involves the submental or submaxillary nodes. Contralateral metastasis may occur, especially if the lesion is near the midline of the lip where there is a cross drainage of the lymphatic vessels.

Histologic Features. Most lip carcinomas are well-differentiated lesions, often classified as grade I carcinoma. This type of cancer tends to metastasize late in the course of the disease. In the series of Widmann, the following approximate distribution of graded lesions was found: grade I, 60%; grade II, 26%; grade III, 13%; grade IV, 2%.

Treatment and Prognosis. Carcinoma of the lip has been treated by either surgical excision or X-ray radiation with approximately equal success, depending to some degree upon the duration and extent of the lesion and the presence of metastases. Interestingly, in the series of Cross the overall cure rate of patients with lip cancer treated by surgery was approximately 81%, while in the series of Widmann the cure rate of patients with the same type of neoplasm treated by X-ray radiation was approximately 83%. This would indicate that either form of therapy, in skilled hands, will produce equally good results.

Many factors may influence the success or failure of treatment of lip carcinoma. The size of the lesion, its duration, the presence or absence of metastatic lymph nodes and the histologic grade of the lesion must all be considered carefully by the therapist in planning his/her approach to the neoplastic problem.

Carcinoma of Tongue

Cancer of the tongue comprises between 25 and 50% of all intraoral cancer. It is less common in women than in men except in certain geographic localities, chiefly the Scandinavian countries, where the incidence of all intraoral carcinoma in women is high because of the high incidence of a preexisting Plummer–Vinson syndrome. In a series of 441 cases of tongue cancer reported by Ash and Millar, 25% occurred in women and 75% in men, with an average age of 63 years. In a series of 330 cases of cancer of the tongue reported by Gibbel, Cross and Ariel the average age of the patient was 53 years, with a range of 32–87 years. Thus it is essentially a disease of the elderly, but it may occur in relatively young persons. To exemplify this latter point, a series of 11 patients less than 30 years of age, four of them less than 20 years, with carcinoma of the tongue has been reported by Byers. This group of patients represented approximately 3% of all patients seen at MD Anderson Hospital with epidermoid carcinoma of the tongue between 1956 and 1973 (418 cases).

Etiology. A number of causes of cancer of the tongue have been suggested, but in our present state of knowledge no precise statements can be made. A definite relation does appear to exist; however, between tongue cancer and certain other disorders. Many investigators have found syphilis, either an active case or at least a past history of it, coexistent with carcinoma of the tongue. In the series of Gibbel et al, 22% of patients with lingual cancer demonstrated a positive complement fixation or Kahn reaction, while in the general admission at their hospital only 5% of the patients had a positive reaction for syphilis. Martin reported that 33% of his patients with cancer of the tongue also had syphilis. The relationship can be explained on the basis of a chronic glossitis produced by the syphilis, chronic irritation long being recognized as carcinogenic under certain circumstances. This explanation implies a local effect of syphilis rather than a generalized or systemic effect. It should be pointed out that some studies do not confirm the theory of a relationship between syphilis and tongue cancer. Wynder has confirmed this relationship, but questioned whether the neoplasm might be related to the arsenic therapy, the treatment of choice before the advent of antibiotics, rather than to the syphilis itself. Meyer and Abbey have also questioned this relationship since they found only 15 patients (6%) who showed positive evidence of a history of syphilis in a survey of 243 cases of primary carcinoma of the tongue.

Leukoplakia is a common lesion of the tongue which has been observed many times to be associated with tongue cancer. Martin noted that 46% of his series of cancer patients had leukoplakia of the tongue, while Gibbel et al, found only a 10% incidence of leukoplakia in his series. It is not unusual to see typical lesions of carcinoma in leukoplakic areas; on the other hand, many lesions of leukoplakia appear to persist for years without malignant transformation, and many cases of carcinoma of the tongue develop without evidence of preexisting leukoplakia.

Other factors which have been thought to contribute to the development of carcinoma of the tongue include poor oral hygiene, chronic trauma and the use of alcohol and tobacco. Poor hygiene and the use of alcohol and tobacco are so prevalent as nearly to preclude the possibility of drawing conclusions about a possible cause and effect relation. A considerable number of cases have been observed in which cancer of the tongue developed at a site exactly corresponding to a source of chronic irritation such as a carious or broken tooth or an ill-fitting denture. The work of Wynder and his group; however, suggests that these findings may be fortuitous.

Clinical Features. The most common presenting sign of carcinoma of the tongue is a painless mass or ulcer, although in most patients the lesion ultimately becomes painful, especially when it becomes secondarily infected. The tumor may begin as a superficially indurated ulcer with slightly raised borders and may proceed either to develop a fungating, exophytic mass or to infiltrate the deep layers of the tongue, producing fixation and induration without much surface change (Fig. 2-27A–C).

The typical lesion develops on the lateral border or ventral surface of the tongue. When, in rare cases, carcinoma occurs on the dorsum of the tongue, it is usually in a patient with a past or present history of syphilitic glossitis. In a series of 1,554 cases of carcinoma of the tongue reported by Frazell and Lucas, only 4% occurred on the dorsum. The lesions on the lateral border are rather equally distributed between the base of the tongue, the anterior third and the mid portion, although in the above series 45% of cases occurred on the middle third. Lesions near the base of the tongue are particularly insidious, since they may be asymptomatic until far advanced. Even then the only presenting manifestations may be a sore throat and dysphagia. The specific site of development of these tumors is of great significance, since the lesions on the posterior portion of the tongue are usually of a higher grade of malignancy, metastasize earlier and offer a poorer prognosis, especially because of their inaccessibility for treatment.

Metastases occur with great frequency in cases of tongue cancer. In 302 patients on whom information was available, Gibbel and his group reported that cervical metastases from tongue lesions were present in 69% at the time of admission to the hospital. The metastatic lesions may be ipsilateral, bilateral, or because of the cross lymphatic drainage, contralateral in respect to the tongue lesion.

Treatment and Prognosis. The treatment of cancer of the tongue is a difficult problem, and even now no specific statements can be made about the efficacy of surgery in comparison to that of X-ray radiation. As in other areas, it will probably be found that the judicious combination of surgery and X-ray will be of greatest benefit to the patient.

A

B

C

Figure 2-27. Epidermoid carcinoma of tongue.
Early to advanced.

Many radiotherapists prefer the use of radium needles or radon seeds to X-ray radiation because they are able with these devices to limit the radiation to the tumor, sparing adjacent normal tissue. Metastatic nodes are highly complicating factors, but treating them without controlling the primary lesion is useless.

The prognosis of cancer in this location is not good. Although statistics vary between series, the five-year cure rate is generally conceded to be below 25%. Martin reported a 22% survival in 556 patients with tongue cancer, while Gibbel et al, found only a 14% survival among 213 patients. Frazell and Lucas reported an overall five-year cure rate of 35% on a series of 1,321 patients with tongue cancer.

The most significant factor affecting prognosis of these patients is the presence or absence of cervical metastases. Thus the studies of Gibbel and his associates showed an 81% survival rate if no metastases ever developed, 43% if no metastases were present at the time of hospital admission, and only 4% if metastases were present at the time of admission or developed subsequent to admission. The necessity for early diagnosis thus becomes obvious, and the role of the dentist in recognizing cancerous lesions is, of course, of paramount importance.

Carcinoma of Floor of Mouth

Carcinoma of the floor of the mouth represents approximately 15% of all cases of intraoral cancer and occurs in the same age group as other oral cancers. The average age of the patient was 57 years in the series of Tiecke and Bernier, 67 years in the series of 110 cases reported by Ash and Millar and 63 years in the group of 100 cases reported by Ballard and his associates. In the latter report, 81% of the lesions occurred in men, while 93% of the patients were men in the series of Ash and Millar.

Smoking, especially a pipe or cigar, has been considered by some investigators to be important in the etiology of cancer in this location. In the series of Ballard and his coworkers, 50% of the patients were classified as heavy smokers, 33% as heavy drinkers and 28% as heavy smokers and heavy drinkers. Nevertheless, little evidence has been gathered to suggest an obvious cause-and-effect relation with regard to tobacco or other factors such as alcohol, poor oral hygiene or dental irritation. Leukoplakia does occur in this location and there is evidence to indicate that epithelial dysplasia and malignant transformation in the leukoplakia occur here with greater frequency than in other oral sites.

Clinical Features. The typical carcinoma in the floor of the mouth is an indurated ulcer of varying size situated on one side of the midline. It may or may not be painful. This neoplasm occurs far more frequently in the anterior portion of the floor than in the posterior area. Because of its location, early extension into the lingual mucosa of the mandible and into the mandible proper as well as into the tongue occurs with considerable frequency (Fig. 2-28). Carcinoma of the floor of the mouth may invade the deeper tissues and may even extend into the submaxillary and sublingual glands. The proximity of this tumor to the tongue, producing some limitation of motion of that organ, often induces a peculiar thickening or slurring of the speech.

Metastases from the floor of the mouth are found most commonly in the submaxillary group of lymph nodes, and since the primary lesion frequently occurs near the midline where a lymphatic cross drainage exists, contralateral metastases

Figure 2-28. Epidermoid carcinoma of floor of mouth.

are often present. Of 95 cases of carcinoma of the floor of the mouth reviewed by Ash and Millar, 21% presented lymph node involvement at the time of admission, while an additional 23% subsequently developed lymphadenopathy. Thus the total incidence of metastasis was 44%. This corresponds to the incidence of 42% metastatic lymph node involvement in the series reported by Tiecke and Bernier and 58% by Martin and Sugarbaker. Fortunately, distant metastases are rare.

Treatment and Prognosis. The treatment of cancer of the floor of the mouth is difficult and all too frequently unsuccessful. Large lesions, because of the anatomy of the region, usually are not a surgical problem. Even small tumors are apt to recur after surgical excision. For this reason, X-ray radiation and the use of radium often give far better results than surgery. The problem is complicated, however, if there is concomitant involvement of the mandible.

The prognosis for patients with carcinoma of the floor of the mouth is fair. The net five-year survival of 86 patients with cancer in this location reviewed by Ash and Millar was 43%. All patients in this series were treated by some form of radiation. Martin and Sugarbaker reported a five-year survival rate of 21% in their series of 103 patients.

Carcinoma of Buccal Mucosa

Reported studies of carcinoma of the buccal mucosa reveal exceptional variation in incidence, the widest differences being accounted for by studies from countries other than the United States. In the series of Krolls and Hoffman, cancer of the buccal mucosa comprised 3% of the total cases of intraoral carcinoma. Like most cancers of the oral cavity, cancer of the buccal mucosa is approximately 10 times more common in men than in women and occurs chiefly in elderly persons. In the study of Tiecke and Bernier, the average age at occurrence of carcinoma of the buccal mucosa was 58 years.

Etiology. The etiology of carcinoma of the buccal mucosa is no better understood than that of carcinoma of other areas of the oral cavity. Several factors appear to be of indisputable significance, however; these include the use of chewing tobacco and the habit of chewing betel nut, which is widespread in many countries in the Far East. It is a fairly common clinical observation that carcinoma of the buccal mucosa develops in the area against which a person has habitually carried a quid of chewing tobacco for years while the opposite cheek may be normal, the patient never having rested the tobacco there. Although this is only presumptive evidence of a cause-and-effect relation; it has been recognized so frequently that it appears to be more than a coincidental finding. A special form of neoplasm known as 'verrucous carcinoma' (q.v.) occurs almost exclusively in elderly patients with a history of tobacco chewing. Since the betel nut quid contains tobacco as well as other substances, including slaked lime, the high incidence of cancer in persons addicted to its use may be explained on a similar basis.

Leukoplakia is a common predecessor of carcinoma of the buccal mucosa. It is usually of extremely long duration and may or may not necessarily be associated with the use of tobacco. Chronic trauma in the form of cheek biting and dental irritation such as that from jagged teeth does not appear to be associated with the development of carcinoma, although focal areas of leukoplakia sometimes occur when these conditions exist.

Clinical Features. There is considerable variation in the clinical appearance of carcinoma of the buccal mucosa. The lesions develop most frequently along or inferior to a line opposite the plane of occlusion. The anteroposterior position is variable, some cases occurring near the third molar area, others anteriorly towards the commissure.

The lesion is often a painful ulcerative one in which induration and infiltration of deeper tissues are common. Some cases, however, are superficial and appear to be growing outward from the surface rather than invading the tissues. Tumors of this latter type are sometimes called exophytic or verrucous growths.

The incidence of metastases from the usual epidermoid carcinoma of the buccal mucosa varies considerably, but is relatively high. Tiecke and Bernier reported that 45% of the patients in their study exhibited metastases at the time of presentation for treatment. This is similar to the incidence of approximately 50% reported by Richards. The most common sites of metastases are the submaxillary lymph nodes.

Treatment and Prognosis. The treatment of carcinoma of the buccal mucosa is just as much of a problem as that of cancer in other areas of the oral cavity. In early cases, it is probable that similar results may be obtained by either surgery or X-ray radiation. The combined use of these two forms of treatment undoubtedly also has a place in the therapy of this tumor.

The prognosis of this neoplasm depends upon the presence or absence of metastases. The findings of Modlin and Johnson indicate that the five-year survival rate for patients with cancer of the buccal mucosa approximates 50%, but in another series Martin reported only a 28% survival.

Carcinoma of Gingiva

Carcinoma of the gingiva constitutes an extremely important group of neoplasms. The similarity of early cancerous lesions of the gingiva to common dental infections has frequently led to delay in diagnosis or even to misdiagnosis. Hence institution of treatment has been delayed, and the ultimate prognosis of the patient is poorer.

Martin reported that approximately 10% of all malignant tumors of the oral cavity occur on the gingiva. In the study of Krolls and Hoffman, 11% of the intraoral carcinomas occurred on the gingiva, while Tiecke and Bernier found a similar incidence of 12% in their series. In the group reported by Martin, one patient was only 22 years old, but the average age of the patients was 61 years. This is essentially a disease of elderly persons, since only 2% of the tumors occurred in patients under the age of 40 years. In the same group of patients, 82% were men and only 18% were women. This is similar to the gender distribution found in oral cancer in other locations.

Etiology. The etiology of carcinoma of the gingiva appears to be no more specific or defined than that in other areas of the oral cavity. Syphilis does not appear to be as significant a factor here as it is in carcinoma of the tongue, and the relation to the use of tobacco is indefinite. Since the gingiva, because of calculus formation and collection of microorganisms, is in nearly all persons the site of a chronic irritation and inflammation lasting over a period of many years, one may speculate the possible role of chronic irritation in the development of cancer of the gingiva. Occasionally, cases of gingival carcinoma appear to arise after extraction of a tooth. If such cases are carefully examined, however, it may usually be ascertained that the tooth was extracted because of a gingival lesion or disease or because the tooth was loose. In fact, the tooth was extracted because of the tumor, which, at the time of surgery, went unrecognized or undiagnosed.

An unusual situation arises in some instances after extraction of a tooth in that a carcinoma appears to develop rapidly and proliferate up out of the socket. Those cases which appear to represent such a phenomenon probably are due to carcinoma of the gingiva growing down along the periodontal ligament and then proliferating suddenly after the dental extraction.

Clinical Features. It is generally agreed that carcinoma of the mandibular gingiva is more common than the involvement of the maxillary gingiva, although the distribution of cases varies considerably between different series. In 47 cases reported by Tiecke and Bernier, 81% of the tumors were found on the mandibular gingiva and only 19% on the maxillary gingiva. Martin, however, reported a more equal distribution of 54% on the mandibular gingiva and 46% on the maxillary gingiva. Data on the exact position in the dental arch at which carcinoma is most apt to develop are insufficient to draw valid conclusions.

Carcinoma of the gingiva usually is manifested initially as an area of ulceration which may be a purely erosive lesion or may exhibit an exophytic, granular or verrucous type of growth (Fig. 2-29). Many times, carcinoma of the gingiva does not have the clinical appearance of a malignant neoplasm. It may or may not be painful. The tumor arises more commonly in edentulous areas, although it may develop in a site in which teeth are present. The fixed gingiva is more frequently involved primarily than the free gingiva.

Figure 2-29. Carcinoma of the gingiva.
The mild overgrowth of the gingiva over the maxillary central incisors in this 25-year-old girl resembled inflammatory gingival hyperplasia. Microscopic examination of the gingivectomy specimen revealed epidermoid carcinoma. This is an unusual clinical appearance, age and location for this neoplasm, but many early cases are difficult to recognize *(Courtesy of Harold R Schreiber and Charles A Waldron. J Periodontol, 29: 196, 1958)*.

The proximity of the underlying periosteum and bone usually invites early invasion of these structures. Although many cases exhibit irregular invasion and infiltration of the bone, superficial erosion arising apparently as a pressure phenomenon sometimes occurs. In the maxilla, gingival carcinoma often invades into the maxillary sinus, or it may extend onto the palate or into the tonsillar pillar. In the mandible, extension into the floor of the mouth or laterally into the cheek as well as deep into the bone is rather common. Pathologic fracture sometimes occurs in the latter instance (Fig. 2-30).

Metastasis is a common sequela of gingival carcinoma. Cancer of the mandibular gingiva metastasizes more frequently than cancer of the maxillary gingiva. In most series of cases, metastases to either the submaxillary or the cervical nodes eventually occur in over 50% of the patients regardless of whether the involvement is maxillary or mandibular.

Treatment and Prognosis. The use of X-ray radiation for carcinoma of the gingiva is fraught with hazards because of the well-known damaging effect of the X-rays on bone. In general, treatment of carcinoma in this location is a surgical problem.

The prognosis of cancer of the gingiva is not particularly good. In the series of 105 cases reported by Martin, only 26% of the patients were alive and free of the disease five years after treatment. It is of great significance that in this same series there were no five-year survivals if the patient presented lymph node metastases at the time of admission. This again illustrates the great need for early diagnosis of these neoplasms.

Figure 2-30. Pathologic fracture of mandible caused by the invasion of epidermoid carcinoma arising on the alveolar ridge.

Carcinoma of Palate

Epidermoid carcinoma of the palate is not a particularly common lesion of the oral cavity. It exhibits approximately the same percentage of occurrence as carcinoma of the buccal mucosa, floor of the mouth and gingiva. The palate was the primary site of 9% of the intraoral epidermoid carcinomas reported by Krolls and Hoffman. In a study by Tiecke and Bernier, of 38 palatal tumors in which the site was specific, 53% occurred on the soft palate, 34% on the hard palate and 13% on both. Ackerman, however, stated that epidermoid carcinoma of the hard palate is a rare finding. New and Hallberg found an incidence of only 0.5% of cases of epidermoid carcinoma of the hard palate among approximately 5,000 cases of intraoral carcinoma. (Accessory salivary gland tumors of the hard palate appear to be three to four times more common than epidermoid carcinoma).

Clinical Features. Palatal cancer usually manifests itself as a poorly defined, ulcerated, painful lesion on one side of the midline (Fig. 2-31). It frequently crosses the midline, however, and may extend laterally to include the lingual gingiva or posteriorly to involve the tonsillar pillar or even the uvula. The tumor on the hard palate may invade into the bone or occasionally into the nasal cavity, while infiltrating lesions of the soft palate may extend into the nasopharynx.

The epidermoid carcinoma is almost invariably an ulcerated lesion, whereas the tumors of accessory salivary gland origin, even the malignant lesions, are often not ulcerated, but are covered with an intact mucosa. This fact may be of some aid in helping to distinguish clinically between these two types of neoplasms.

Metastases to regional lymph nodes occur in a considerable percentage of cases, but there is little evidence to indicate whether such metastases are more common in carcinoma of the soft palate or in that of the hard palate.

Figure 2-31. Epidermoid carcinoma of palate.

Treatment and Prognosis. Both surgery and X-ray radiation have been used in the treatment of epidermoid carcinoma of the palate. Few large series of cases are available for analysis to aid in determining which form of therapy may be expected to give the greatest survival. Nor are any significant series of purely palatal carcinomas available to aid in the determination of overall survival rate of patients with this lesion. It does appear that the prognosis is somewhat comparable to that of carcinoma of the gingiva.

Carcinoma of Maxillary Sinus

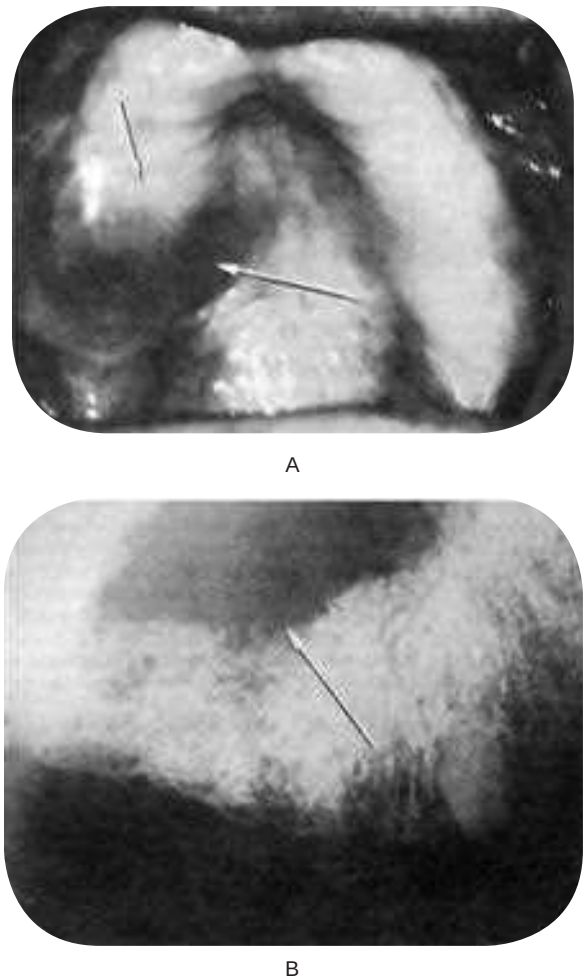
Antral carcinoma is an exceedingly dangerous disease. Although the actual incidence of the disease in respect to intraoral carcinoma cannot be determined, it does appear to be considerably less frequent than any other form of oral cancer. Seelig presented an excellent 10-year survey of the literature and described the chief findings in 624 cases of antral carcinoma; a review of this disease has also been reported by Chaudhry and his associates. Although nothing is known of the etiology of this particular neoplasm, Ackerman stated that chronic sinusitis does not seem to predispose to the development of carcinoma of the maxillary sinus. It might be pointed out here that, although most cases of carcinoma of the maxillary sinus are of the epidermoid type, occasional cases of adenocarcinoma occur, apparently originating from the glands in the wall of the sinus.

Clinical Features. One of the features which contribute to the deadly nature of this disease is that it is often hopelessly advanced before the patient is conscious of its presence. The dentist must be fully aware of the potentialities of this neoplasm and the various ways in which it may manifest itself clinically.

Available studies indicate that carcinoma of the antrum is somewhat more common in men and that, though it is chiefly a disease of elderly persons, occasional cases occur in young adults.

The first clinical sign of antral carcinoma is frequently a swelling or bulging of the maxillary alveolar ridge, palate or mucobuccal fold, loosening or elongation of the maxillary molars or swelling of the face inferior and lateral to the eye (Fig. 2-32). Unilateral nasal stuffiness or discharge is sometimes a primary complaint. In edentulous patients wearing maxillary dentures, loosening of or inability to tolerate the prosthetic appliance may occur before there is any visible clinical evidence of the disease.

The actual spread of the neoplasm which determines the clinical manifestations of the disease is reflected by the extent of involvement of the various walls of the antrum. In some cases, only the floor of the sinus is invaded so that the manifestations of the disease are associated solely with oral structures. If the medial wall of the sinus is involved, nasal obstruction may result. The involvement of the superior wall or roof produces displacement of the eye, while invasion of the lateral wall produces bulging of the check. Ulceration either into the oral cavity or on the skin surface may occur, but only late in the course of the disease.



A

B

Figure 2-32. Epidermoid carcinoma of the maxillary sinus.
(A) The alveolar ridge shows thickening, reddening and deformity, although there is no ulceration of the mucosa. **(B)** The radiograph reveals raggedness of the maxillary sinus and obvious bony alteration.

Metastases usually do not occur until the tumor is far advanced, but when they appear they involve the submaxillary and cervical lymph nodes. The lack of metastasis does not indicate a favorable course, since many patients die from local infiltration alone.

Treatment and Prognosis. Both surgery and X-ray radiation have been used to treat this form of neoplastic disease. If the cancer is confined to the antrum and inferior structures, hemimaxillectomy gives favorable clinical results in some cases. Radiation treatment frequently takes the form of radium needles inserted into the antrum or the tumor mass. This has proved effective in some cases, even though considerable invasion of adjacent structures has occurred.

The overall prognosis of patients with antral carcinoma is not good. In the series of Chaudhry and his associates, only 10% of 49 patients with carcinoma of the antrum lived for more than five years.

Verrucous Carcinoma

A warty variant of squamous cell carcinoma characterized by a predominantly exophytic overgrowth of well-differentiated keratinizing epithelium having minimal atypia and with locally destructive pushing margins at its interface with underlying connective tissue.

Verrucous carcinoma was originally described as a distinct entity on account of its clinical and microscopic features and its mode of behavior. Well differentiated, hyperplastic stratified squamous epithelium is organized into bulbous rete-ridges that exhibit little or no cytological atypia or mitotic activity. There may be a significant endophytic component and the invading margin is usually below the level of the surrounding mucosa. Deep surface invaginations are filled with keratin. The advancing epithelial border is broad and the basement membrane is generally intact. There is usually a heavy inflammatory cell reaction in the adjacent connective tissue. Local destruction of connective tissue occurs in advance of the deep epithelial border. Growth is generally slow and metastatic spread occurs late, if at all. There is a view that verrucous carcinomas may become more aggressive if irradiated.

Although most verrucous carcinomas can be distinguished from squamous cell carcinomas on the basis of their mode of growth, infrequent dysplasia and absence of metastases, there are occasionally foci of conventional squamous cell carcinomas within a verrucous carcinoma. Such lesions should be classified and treated as squamous cell carcinomas. Thorough sectioning of specimens is therefore, necessary to eliminate this possibility. Another hazard in diagnosis occurs when the extremely thick layers of keratin and hyperplastic epithelium are biopsied at insufficient depth to include underlying connective tissue.

The term verrucous hyperplasia describes an exophytic overgrowth of well differentiated keratinizing epithelium that is similar to verrucous carcinoma but without the destructive pushing border at its interface with the underlying connective tissue. Areas of verrucous hyperplasia may be encountered in association with verrucous carcinoma, squamous cell carcinoma or proliferative verrucous leukoplakia.

Exophytic papillary lesions that show epithelial dysplasia, possibly even carcinoma *in situ,* and relatively inconspicuous areas of invasive squamous cell carcinoma separate from the surface epithelium, should be distinguished from verrucous carcinomas and classified as papillary squamous cell carcinomas (Pindborg JJ et al, 1997).

Clinical Features. Verrucous carcinoma is generally seen in elderly patients, the mean age of occurrence being 60–70 years, with nearly 75% of the lesions developing in males, according to a review by Shafer of nearly 300 reported cases. The vast majority of cases occur on the buccal mucosa and gingiva or alveolar ridge, although the palate and floor of the mouth are occasionally involved.

The neoplasm is chiefly exophytic and appears papillary in nature, with a pebbly surface which is sometimes covered by a white leukoplakic film. The lesions commonly have rugae-like folds with deep clefts between them. Lesions of the buccal mucosa may become quite extensive before the involvement of deeper contiguous structures. Lesions on the mandibular ridge or gingiva grow into the overlying soft tissue and rapidly become fixed to the periosteum, gradually invading and destroying the mandible (Fig. 2-33A–C). Regional lymph nodes are often tender and enlarged, simulating metastatic tumor, but this node involvement is usually inflammatory. Pain and difficulty in mastication are common complaints, but bleeding is rare.

The term oral florid papillomatosis has been used by dermatologists to describe a lesion with not only a clinical and microscopic appearance similar to verrucous carcinoma but also a similar biologic behavior. For this reason, many authorities now believe that oral florid papillomatosis and verrucous carcinoma represent one and the same disease with no justification for continued use of the former term, since it fails to imply the neoplastic nature of the disease.

It is consistently reported that a very high percentage of patients with this disease are tobacco chewers. A small number of patients give no such history but, instead, use snuff or smoke tobacco heavily. Occasional patients deny the use of tobacco and these usually have ill-fitting dentures.

Histologic Features. The histologic features may be extremely deceptive, and many cases have been diagnosed originally as simple papillomas or benign epithelial hyperplasia because of the orderly and harmless appearance of the specimen. There is generally marked epithelial proliferation with downgrowth of epithelium into the connective tissue but usually without a pattern of true invasion. The epithelium is well differentiated and shows little mitotic activity, pleomorphism or hyperchromatism. Characteristically, cleft like spaces lined by a thick layer of parakeratin extend from the surface deeply into the lesion. Parakeratin plugging also occurs extending into the epithelium. The parakeratin lining the clefts with the parakeratin plugging is the hallmark of verrucous carcinoma. Even though the lesion may be very extensive, the basement membrane will often appear intact. When the lesions become infected, focal intraepithelial abscesses are often seen. Significant chronic inflammatory cell infiltration in the underlying connective tissue may or may not be present (Fig. 2-34).

Unfortunately, the diagnosis of verrucous carcinoma is often difficult even when the biopsy specimen is generous, and the pathologist will sometimes request a second biopsy.

Treatment and Prognosis. Verrucous carcinoma has been treated in several ways in the past, usually by surgery, X-ray radiation or a combination of the two. However, there have been some reports of anaplastic transformation of lesions occurring in patients treated by ionizing radiation. While the radiation appears to be the triggering mechanism, other factors contributing to or related to the transformation are unknown. Even though such an occurrence is uncommon, many investigators believe the treatment should be entirely surgical. Since the lesion is so slow-growing and late to metastasize, many cases can be treated by relatively conservative excision without a mutilating procedure. The prognosis is much better than for the usual type of oral epidermoid carcinoma.

A B C

Figure 2-33. Verrucous carcinoma.
The exophytic, verrucous nature of the lesion is evident *(A and B, Courtesy of Dr Charles A Waldron, and C, of Dr George G Blozis and Dr Mirdza E Neiders).*

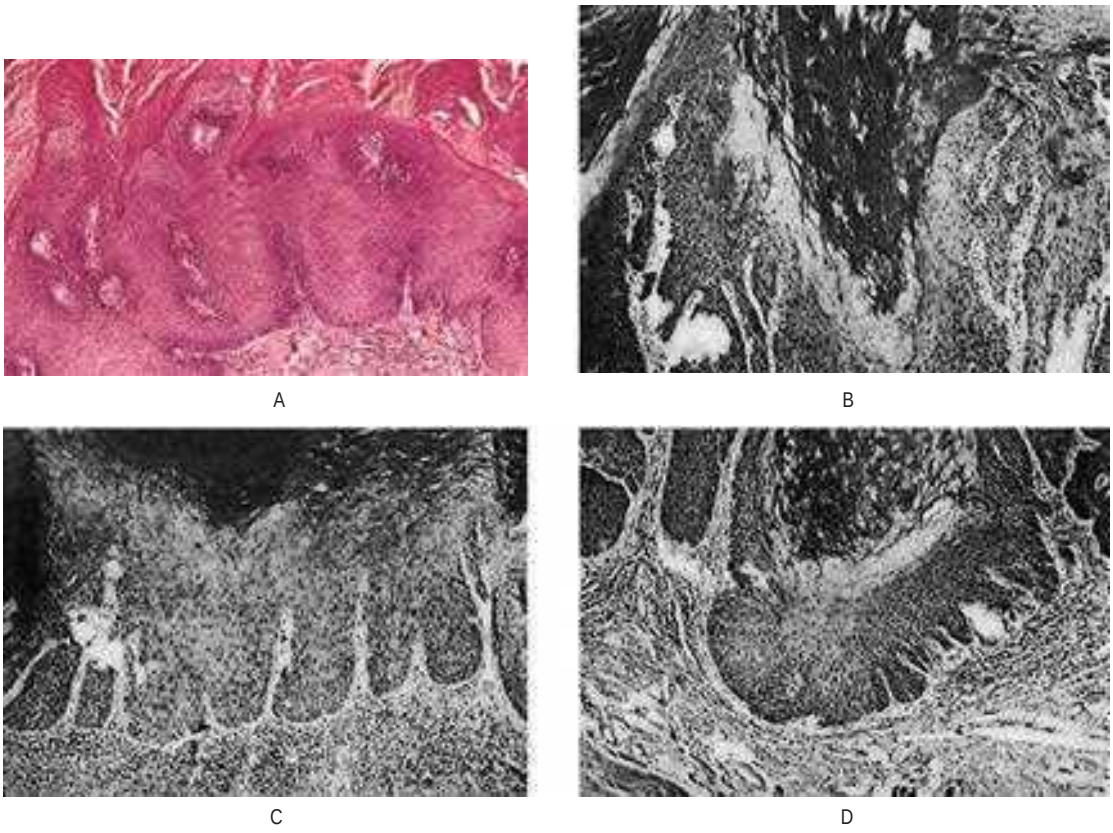


Figure 2-34. Verrucous carcinoma.
The tumor is exophytic and has a papilliferous surface. It is composed of proliferating sheets and groups of stratified squamous epithelium, which exhibit few cytological features of malignancy. There is a round cell infiltrate in the fibrous tissue stroma. It may turn invasive at a later stage. *(A, Courtesy of Dr Hari S, Noorul Islam College of Dental Science,Trivandrum)*

Spindle Cell Carcinoma

(Carcinosarcoma, pseudosarcoma, polypoid squamous cell carcinoma, Lane tumor)

A carcinoma within which there are some elements resembling a squamous cell carcinoma that are associated with a spindle cell component.

In a true spindle cell carcinoma, the malignant spindle shaped cells should be demonstrably of epithelial origin and derived from the squamous cell component of the carcinoma. This must be distinguished both from a squamous cell carcinoma that has provoked a reactive fibroblastic stromal proliferation and from a carcinosarcoma in which a squamous cell carcinoma is accompanied by a sarcoma of fibroblastic or other connective tissue cell type. Care should also be taken not to confuse a spindle cell carcinoma with a spindle cell malignant melanoma or with sarcomas of various types. Often the squamous cell carcinoma component in a spindle cell carcinoma is inconspicuous and multiple sections or blocks may be necessary to find it. Most of the neoplasm comprises of thin elongated cells amongst which there may be occasional pleomorphic cells. Mitotic figures, including abnormal forms, are usually not difficult to find. The behavior is similar to that of the more frequent and usual type of squamous cell carcinoma (Pindborg JJ et al, 1997).

Clinical Features. A series of 59 cases of the oral cavity has been reported by Ellis and Corio, who noted a predilection for occurrence in males, although this finding was somewhat biased because of the number of military cases involved. The mean age of occurrence of the lesion was 57 years, with a range of 29–93 years. The lesions developed with the greatest frequency on the lower lip (42%), tongue (20%) and alveolar ridge or gingiva (19%) with the remainder scattered at other sites.

The most common presenting findings were swelling, pain and the presence of a nonhealing ulcer. The initial lesion appeared either with a polypoid, exophytic or endophytic configuration. It is perhaps significant that 13 patients in this series were known to have a history of prior therapeutic radiation to the region where the tumor subsequently developed. The time interval from radiation to diagnosis of the tumor ranged from 1.5–10 years with a mean of about seven years.

Histologic Features. Spindle cell carcinoma is a bimorphic or biphasic tumor which, although almost always ulcerated, will show foci of surface epidermoid carcinoma or epithelial dysplasia of surface mucosa, usually just at the periphery and often quite limited. Proliferation and 'dropping-off' of basal cells to spindle cell elements is a common phenomenon. The tissue patterns making up the bulk of the tumor have

been categorized as either fasciculated, myxomatous or streaming. The cells, particularly in the fasciculated form, are elongated with elliptical nuclei, although pleomorphic cells are also common. The number of mitoses may vary from few to many. Giant cells, both benign-appearing of the foreign body type and the bizarre, pleomorphic, atypical cells may be found. Finally, an inflammatory cell infiltrate is often present. Osteoid formation within the tumor component is sometimes seen. Microscopic invasion of subjacent structures is evident, as it is with most epidermoid carcinomas of the oral cavity.

Numerous ultrastructural studies of the spindle cell carcinoma, such as those of Leifer and his associates, have been carried out in clarification of the histogenesis and pathogenesis of this lesion.

Treatment and Prognosis. Surgical removal of the tumor, with or without radical neck dissection, alone or in combination with radiation, or radiation therapy alone all have been used in the treatment of this disease. In the series reported by Ellis and Corio, those treated by surgery had the best survival rate although only nine of 18 patients treated in this fashion were alive and well. Radiation therapy appears ineffective. The presence of metastasis signals a poor prognosis, since 81% of the patients with recorded metastases in this study died of their disease. The value of chemotherapy is not known.

Adenoid Squamous Cell Carcinoma

(Adenoacanthoma, pseudoglandular squamous cell carcinoma)

A squamous cell carcinoma containing pseudoglandular spaces or lumina is an interesting tumor of the skin which also occurs with considerable frequency on the lips. It was originally described by Lever in 1947. This variant is produced as a result of acantholysis and degeneration within islands of a squamous cell carcinoma. The result is a pseudoadenocarcinomatous appearance, but there is no evidence of glandular differentiation or of secretory activity or products. There are insufficient reported cases to establish likely behavior.

Clinical Features. Adenoid squamous cell carcinoma is reported to occur as early as 20 years of age, although in the series of Johnson and Helwig, nearly 75% of the patients were 50 years of age or older. In their series, only 2% of the patients were females. Significantly, they found that 93% of the lesions were in the head and neck region.

The lesions on the skin appear as simply elevated nodules that may show crusting, scaling or ulceration. Sometimes there is an elevated or rolled border to the lesion.

A series of 15 cases of adenoid squamous cell carcinoma of the lips (11 lower, three upper, one unstated) has been reported by Jacoway and his associates, while Tomich and Hutton have reported two cases and discussed the lesion in detail. These lip lesions often appear clinically similar to epidermoid carcinoma, being described frequently as ulcerated, hyperkeratotic or exophytic.

There have been four cases of this lesion reported intraorally, two on the gingiva. The latter includes the first case reported from India by Sivapathasundharam B and Rohini S. However three of these lesions behaved in a very aggressive fashion, metastasized in at least two instances and the patient died in all three cases as a result of the tumor. Because of the aggressive nature of the lesions, these intraoral cases may not be identical to those of the skin and lips.

Histologic Features. There is a proliferation of surface dysplastic epithelium into the connective tissue as in the typical epidermoid carcinoma. However, the lateral or deep extensions of this epithelium show the characteristic solid and tubular ductal structures which typify the lesion. These duct like structures are lined by a layer of cuboidal cells and often contain or enclose acantholytic or dyskeratotic cells.

Treatment and Prognosis. The adenoid squamous cell carcinoma is generally treated by surgical excision. On only rare occasions does it metastasize or cause death of the patient. However, recurrence is relatively common (38% in the series of lip lesions reported by Jacoway and his coworkers, although it is possible that some of these may have been second lesions, since multiple adenoid squamous cell carcinomas in the same patient often occur).

Basaloid Squamous Cell Carcinoma

Basaloid squamous cell carcinoma is a form of carcinoma with a mixed composition of basaloid and squamous cells. This is a form of oral carcinoma in which the basaloid component comprises small cells with hyperchromatic nuclei and scant cytoplasm that are crowded together into lobulated sheets or strands focally connected to the surface epithelium. Cells at the periphery of the lobules are often palisaded; more centrally there may be cystic spaces, sometimes containing material resembling mucin, and focal squamous differentiation. Mitotic figures, including abnormal forms, and areas of necrosis are commonly seen. There is often hyalinization of the surrounding stroma and chronic inflammatory cell infiltration is variable. Confusion with ameloblastoma and adenoid cystic carcinoma is to be avoided; a focal squamous cell carcinoma component among the basaloid areas is the most important distinguishing feature. Most cases have been described in the larynx, hypopharynx and base of the tongue (Pindborg JJ et al, 1997).

Adenosquamous Carcinoma

A malignant tumor with histological features of both adenocarcinoma and squamous cell carcinoma. This tumor may arise from the ducts of minor salivary glands or from the overlying surface epithelium. The component identified as squamous cell carcinoma may be *in situ* or invasive, and the adenocarcinomatous component comprises glandular structures lined by basaloid, columnar or mucin-secreting cells. A distinction between adenosquamous carcinoma and high-grade mucoepidermoid carcinoma may be difficult, though in the former the glandular and squamous components are generally more distinct. Care must also be taken to distinguish

adenosquamous carcinoma from adenoid squamous cell carcinoma (Pindborg JJ et al, 1997).

Undifferentiated Carcinoma

Undifferentiated carcinoma is carcinoma that lacks evidence of squamous, glandular or other types of differentiation. Accurate diagnosis is almost certainly dependent upon the use of adjunctive diagnostic techniques.

Lymphoepithelioma and Transitional Cell Carcinoma

There is an unusual group of malignant neoplasms exhibiting many features in common which involves nasopharynx, oropharynx, tongue, tonsil and anatomically associated structures such as the nasal chamber and paranasal sinuses. These tumors arise from the mucosa of these areas, exhibit a relatively specific histologic pattern and react in a rather atypical fashion to X-ray radiation. This group of neoplasms consists of the lymphoepithelioma, transitional cell carcinoma and undifferentiated squamous cell carcinoma.

Regaud, and later Schminke as well as Ewing, described the lymphoepithelioma as a lesion occurring chiefly in the nasopharynx of young or middle-aged persons. It was found to be usually a small lesion which often did not manifest itself clinically before regional lymphadenopathy was apparent. Death of the patient was the frequent outcome of the disease even though the lesion was found to be radiosensitive.

Under the term 'transitional cell epidermoid carcinoma', Quick and Cutler reported a series of cases in which the lesions arose chiefly from the tonsil, base of the tongue and nasopharynx. It is in these areas that a transitional type of stratified epithelium is found, the schneiderian membrane. These tumors, then, occurred in areas similar to the sites of the lymphoepithelioma. It was noted, however, that this transitional cell carcinoma was extremely malignant, running a rapid clinical course, metastasizing widely and causing very early death.

Clinical Features. The primary lesion of the lymphoepithelioma or transitional cell carcinoma is usually very small, often completely hidden, usually slightly elevated and either frankly ulcerated or presenting a granular, eroded surface. The tumor is indurated and, in some instances, appears as an exophytic or fungating growth. Since the primary lesion usually remains small, the patient may not seek advice until metastasis to the regional lymph nodes has already occurred.

Scofield carried out an excellent study of 214 cases of malignant nasopharyngeal lesions, comprising transitional cell carcinoma, lymphoepithelioma and undifferentiated squamous cell carcinoma. He found that swelling of the regional lymph nodes was the most common presenting symptom of the observed patients, followed by sore throat, nasal obstruction, defective hearing or ear pain, headache, dysphagia, epistaxis and ocular symptoms. Differences in the median age of the patients were found, patients with transitional cell carcinoma averaging 44 years of age, those with lymphoepithelioma averaging only 26 years and those with undifferentiated squamous cell carcinoma, 56 years. Bloom published a review of cancer of the nasopharynx with particular reference to the significance of the histopathology of the lesions.

Histologic Features. The diagnosis of these neoplasms and their differentiation depends solely upon their microscopic structure.

Transitional cell epidermoid carcinoma consists of cells growing in solid sheets or in cords and nests. The individual cells are moderately large, round or polyhedral, and exhibit a lightly basophilic cytoplasm and indistinct cell outlines. The nuclei appear large and round, and they exhibit varying degrees of mitotic activity. Although a slight degree of intercellular bridging may be present, keratinization and pearl formation are completely lacking. The stroma exhibits little or no lymphocytic infiltration.

The lymphoepithelioma is made up of cells growing in a syncytial pattern with the stroma infiltrated by varying numbers of lymphocytes. The individual cells are large and polyhedral with indistinct outlines. The cytoplasm stains lightly eosinophilic. The nuclei appear large, oval and vesicular, and characteristically contain one or two large eosinophilic nucleoli.

Treatment and Prognosis. Because of the general inaccessibility of the majority of these lesions and their unusual property of being highly radiosensitive, X-ray radiation has been the most commonly accepted treatment. The response of this tumor to radiation is different from that of the epidermoid carcinoma found in these locations. Regional lymph node metastases also respond well to X-ray radiation. The complicating factor lies in the relative inability to treat the widespread metastases in the various organs.

The outlook for patients with these forms of neoplastic disease is poor. Since widespread metastases frequently occur before there is any clinical manifestation of disease, the unfavorable prognosis can be readily understood. In the series of Scofield the probability of five-year survival was calculated. He found that, after onset of symptoms, only 30% of treated patients suffering from transitional cell carcinoma or lymphoepithelioma would be alive in five years, while only 11% with squamous cell carcinoma in these areas would survive.

Nasopharyngeal Carcinoma

A tumor of the nasopharynx involving squamous epithelium, malignant in nature is widely prevalent in parts of south China (Cantonese) (98 per 100,000 of the population); where it is the commonest tumor in men and the second commonest in women. The tumor is rare in most parts of the world, though pockets occur in north and central Africa, Malaysia, Alaska, and Iceland. The most undifferentiated form of the tumor is always associated with EBV whereas the rarer, more differentiated forms are not consistently so. The evidence that EBV is involved in the pathogenesis is based on detection of multiple copies of the EBV genome can be detected in the malignant cells of 100% of undifferentiated

NPC. All the malignant cells express EBNA-1. Furthermore, infectious EBV particles can be recovered from NPC cell lines. And also 100% of sera from undifferentiated NPC patients have high-titer antibodies to EB-viral antigens.

Clinical Features. NPC is a tumor proven to have a genetic background mainly restricted to southern China, with intermediate frequency in some Negro and Mongoloid races and rare in Caucasians. Studies have shown that first-generation immigrants from south China retain the high incidence of the disease, with the later generations showing a decline in incidence. This suggests that environmental as well as genetic factors are involved. NPC is especially associated with certain HLA haplotypes, e.g. HLA A2. More genetic linkage studies demonstrated the presence of NPC susceptibility genes near the MHC locus. Environmental factors are thought to play a role, particularly the consumption of salted fish and foods containing nitrosamines.

The EBV associated undifferentiated type arises mainly in younger patients whereas the more differentiated types occur in older patients and constitute the bulk of the sporadic cases. The tumor most commonly arises in the posterior wall of the nasopharynx in the *fossa of Rosenmuller*, where it often remains silent and metastasize to the local lymph nodes. The most common presentation of NPC is bilateral enlargement of the glands in the neck. The primary tumor may be very small and difficult to locate. Less frequently, the patient may present with the symptoms of invasion by the primary tumor, e.g. nasal obstruction, postnasal discharge, epistaxis, partial deafness and cranial nerve palsies. If untreated, the disease is rapidly fatal due to the development of laryngeal and pharyngeal obstruction.

Histologic Features. Three types of NPC are recognized on histological appearance:

- Well differentiated squamous cell carcinoma
- Nonkeratinizing carcinoma
- Undifferentiated carcinoma.

Serum antibodies to EBV antigens can be used to confirm the diagnosis and monitor the progress of the disease.

Treatment. NPC is difficult to treat surgically because of the early metastasis to regional lymph nodes. The tumor is resistant to chemotherapy, and radiotherapy is the treatment of choice. However, because the tumor usually presents late, the prognosis is poor with a five-year survival rate of 20%. It may be possible to prevent the development of NPC with the use of an EBV vaccine at an early age.

Malignant Melanoma

Malignant melanoma is a neoplasm of epidermal melanocytes. It is one of the more biologically unpredictable and deadly of all human neoplasms. Although it is the third most common cancer of the skin (basal and squamous cell carcinomas are more prevalent), it accounts for only 3% of all such malignancies. However, it results in over 83% of all deaths due to skin cancer in the United States.

Cutaneous melanoma is increasing in incidence. The frequency of its occurrence is closely associated with the constitutive color of the skin, and depends on the geographical zone. Incidence among dark skinned ethnic groups is 1 per 100,000 per year or less, but among light-skinned Caucasians up to 50 and higher in some areas of the world. The highest incidence rates have been reported from Queensland, Australia with 56 new cases per year per 100,000 for men and 43 for women. In contrast, for Africans and Asians the annual incidence rate of malignant melanoma is only 0.2–0.4 per 100,000 population, affecting mainly the palms, soles, and mucous membranes. Cutaneous malignant melanoma is the most rapidly increasing cancer in whites. The annual increase in incidence rates has been estimated to be between 3 and 7%. These estimates suggest a doubling of rates every 10–20 years. These epidemiologic studies have supported the belief that sunlight is an important etiologic factor in cutaneous melanoma.

For many years, it was believed that many melanomas developed in preexisting pigmented nevi, particularly junctional nevi. However, Clark and his colleagues are of the opinion that junctional nevi are not histogenetically related to melanomas. It is quite possible that lesions which were interpreted as junctional nevi were, in fact, premalignant melanocytic dysplasias of some type, thus leading to the erroneous concept of malignant transformation of nevi. In support of this is a study by Jones and his colleagues in which 169 cases diagnosed as junctional nevi were studied retrospectively. Only 74 were actually junctional nevi, whereas 41 were actually melanomas in various phases of growth. The remainder were nevoid and non-nevoid pigmented lesions of various types. Melanomas may develop in or near a previously existing precursor lesion or in healthy-appearing skin. A malignant melanoma developing in healthy skin is said to arise de novo, without evidence of a precursor lesion. Certain lesions are considered to be precursor lesions of melanoma, including the common acquired nevus, dysplastic nevus, congenital nevus, and cellular blue nevus.

The following environmental and genetic factors are described in the etiology of malignant melanoma.

Environmental Factors

Sun exposure. The highest incidence of melanoma has been reported from areas with long hours of sunlight throughout most of the year. Studies reported lower risk for melanoma among people who resided in a low ultraviolet environment in childhood compared with those who resided in a high UV environment. Intermittent exposure to high intensity UV seems to be more detrimental than continual exposure in its causation. Exposure in childhood appears to be particularly important. Recreational activity leading to sunburns in adulthood, such as sailing, has also been incriminated as an etiological factor.

Artificial UV sources. Several case-control studies of melanoma risk and tanning lamp use have demonstrated a positive relation, suggesting that longer wave artificial UVA may play a part in the etiology of melanoma in addition to exposure to natural sunlight. The association of melanoma with PUVA (combination of psoralen (P) and long wave

ultraviolet radiation (UVA)) therapy has also been reported. This topic is still controversial, though, and further studies are needed.

Socioeconomic status. Several studies have reported that melanoma is more prevalent in those of high socioeconomic status. An explanation of this finding may be the fact that the latter can better afford holidays in areas of high UV intensity, as well as expensive outdoor hobbies like sailing, which increase the risk of melanoma due to intermittent intense sun exposure.

Fair skin, freckles, red hair. These phenotypic characteristics increase the risk of melanoma.

Number of melanocytic nevi. The total number of melanocytic nevi, dysplastic or bland, has been reported by several groups as a strong risk factor.

Genetic Factors

Familial melanoma. Between 2 and 5% of melanoma patients have a positive family history of melanoma in at least one first-degree relative. In approximately 30% of melanoma patients abnormalities on chromosome 9p21 are seen.

Xeroderma pigmentosum. In this genetically determined disorder, defective DNA repair mechanisms lead to excessive chronic UV damage and subsequent development of different sun-related skin tumors, including melanoma, in sun-exposed areas.

Risk factors for oral mucosal melanomas are unknown. These melanomas have no apparent relationship to chemical, thermal, or physical events (e.g. smoking, alcohol intake, poor oral hygiene, irritation from teeth, dentures, or other oral appliances) to which the oral mucosa is constantly exposed. Although benign, intraoral melanocytic proliferations (nevi) occur and are potential sources of some oral melanomas; the sequence of events is poorly understood in the oral cavity. Currently, most oral melanomas are thought to arise de novo.

In 1975, Clark and his coworkers presented an interesting concept regarding the developmental biology of cutaneous melanoma. They documented two phases in the growth of melanoma: the *radial-growth phase* and the *vertical-growth phase.*

Many genes are implicated in the development of melanoma, including CDKN2A (p16), CDK4 (chromosome 12q15), RB1, CDKN2A (p19), PTEN/MMAC1, and ras. CDKN2A (p16) appears to be especially important in both sporadic and hereditary melanomas. This tumor suppressor gene is located on band 9p21, and its mutation plays a role in various cancers. Variations in the melanocortin-1 receptor gene can also increase the risk of melanoma. The gene plays an important role in determining hair and skin color, and sensitivity to UV radiation. Interestingly, people who had olive and darker skin and who carried one or more variations of the gene had a higher than average risk for melanoma.

The radial-growth phase is the initial phase of growth of the tumor. During this period, which may last many years, the neoplastic process is confined to the epidermis. Neoplastic cells are shed with normally maturing epithelial cells and although some neoplastic cells may actually penetrate the basement membrane, they are destroyed by a host-cell immunologic response. The vertical-growth phase begins when neoplastic cells populate the underlying dermis. This takes place because of increased virulence of the neoplastic cells, a decreased host-cell response, or a combination of both. Metastasis is possible once the melanoma enters the vertical-growth phase. It is recognized that not all melanomas have both radial- and vertical-growth phases. Nodular melanoma (q.v.) exists only in the vertical-growth phase.

Cutaneous melanoma has been classified into a number of types. However, the most common types are: superficial spreading melanoma; nodular melanoma; lentigo maligna melanoma (Hutchinson's freckle); and acral lentiginous melanoma.

Clinical Features

Superficial spreading melanoma is the most common cutaneous melanoma in Caucasians. It accounts for nearly 65% of cutaneous melanomas. It exists in a radial-growth phase which has been called premalignant melanosis or pagetoid melanoma *in situ.* The lesion presents as a tan, brown, black or admixed lesion on sun-exposed skin, especially the back. It also occurs on the skin of the head and neck, chest and abdomen and the extremities. The radial-growth phase may last for several months to several years. The vertical-growth phase is characterized by an increase in size, change in color, nodularity and, at times, ulceration.

Nodular melanoma accounts for approximately 13% of cutaneous melanomas. It apparently has no clinically recognizable radial-growth phase, existing solely in a vertical-growth phase. It presents as a sharply delineated nodule with varying degrees of pigmentation. They may be pink (amelanotic melanoma) or black. They have a predilection for occurrence on the skin of the back and head and neck skin of men. In other cutaneous sites, there is an even gender distribution.

Lentigo maligna melanoma accounts for approximately 10% of cutaneous melanomas. It exists in a radial-growth phase which is known as **lentigo maligna** or **melanotic freckle of Hutchinson**. The melanotic freckle has been recognized as a clinicopathologic entity for nearly 100 years. However, the concept that it represents a melanoma in a radial-growth phase is much more recent. The lesion occurs characteristically as a macular lesion on the malar skin of middle-aged and elderly Caucasians. It occurs more often in women than in men. In an extensive series of 85 cases, Wayte and Helwig found an average age of 58 years in men and 55 in women. In a series studied by Clark and his colleagues, the median age was 70 years. Both studies showed a female gender predilection. The lesion can remain in the radial-growth phase for years. In Wayte and Helwig's study, the average duration in which an accurate history was possible was 14 years. Clark and Mihm

have documented a lentigo maligna for 50 years prior to the development of a vertical-growth phase. Nearly 53% of the lesions evolved into lentigo maligna melanoma, the vertical-growth phase of this form of melanoma.

Melanoma may occur as a primary lesion not only on the skin but also in the eye and on mucous membranes. It has also been reported as a primary lesion in the parotid gland, although melanomas in this site are usually metastatic to lymph nodes in the parotid region.

Acral lentiginous melanomas. Melanoma developing on the palms and soles, as well as on toes and fingers, represents only 10% of cases in whites, but over 50% of all melanomas on Black and Asian skin. The tumor is characterized by a macular, lentiginous pigmented area around a nodule. Mechanical stress may lead to erosion and ulceration. Subungual melanomas present as pigmentations of the nail bed and are often mistaken for subungual hematomas, and are thus commonly diagnosed at a late stage in development. They are extremely aggressive, with rapid progression from the radial to vertical growth phase.

Mucosal lentiginous melanomas develop from the mucosal epithelium that lines the respiratory, gastrointestinal, and genitourinary systems. These lesions account for approximately 3% of the melanomas diagnosed annually and may occur on any mucosal surface, including the conjunctiva, oral cavity, esophagus, vagina, female urethra, penis, and anus. Noncutaneous melanomas are commonly diagnosed in patients of advanced age. When compared to cutaneous melanomas, mucosal lentiginous melanomas appear to have a more aggressive course, although this may be because they are commonly diagnosed at a later stage of disease than the more readily apparent cutaneous melanomas.

Amelanotic melanoma presents as an erythematous or pink, sometimes eroded, nodule. This tumor is often confused for other tumors, and only the histological examination provides the right diagnosis.

The following criteria aid clinical diagnosis of melanoma **(ABCDE-rule):**

- Asymmetry—in which one half does not match the other half
- Border irregularity—with blurred, notched, or ragged edges
- Color irregularity—pigmentation is not uniform. Brown black, tan, red, white, and blue—can all appear in a melanoma
- Diameter—greater than 6 mm. Growth in itself is also a sign
- Elevation—a raised surface can also be a sign.

Oral Manifestations. Malignant melanoma is an uncommon neoplasm of the oral mucosa. Pliskin reviewed the literature on oral melanoma and found that they accounted for 1.6% of over 7,500 reported melanomas. Other authors have reported rates of 0.2–8%. Conley and Pack reported 26 cases of primary oral melanoma and McCaffrey, Neel and Gaffey reported on the 10 cases treated at the Mayo Clinic. Of epidemiologic interest is the fact that melanoma of the oral mucosa is one of the most common sites for the neoplasm in Japanese. Melanomas in Blacks are seldom found in the skin yet occur on mucous membranes and on the plantar skin.

Primary oral melanoma is nearly twice as common in men as in women. The overall age of occurrence is approximately 55 years, with most cases occurring between 40 and 70 years.

The oral melanoma exhibits a definite predilection for the palate and maxillary gingiva/alveolar ridge. Seventy-seven% of the cases in Pliskin's review occurred in these two sites. Cases are also recorded on the buccal mucosa, mandibular gingiva, tongue, lips and floor of the mouth. The lesion usually appears as a deeply pigmented area, at times ulcerated and hemorrhagic, which tends to increase progressively in size (Fig. 2-35A–C). Amelanotic melanoma accounts for 5–35% of oral melanomas which appear as a white, mucosa-colored, or red mass.

Significantly, focal pigmentation preceding the development of the actual neoplasm frequently occurred several months

A B C

Typical lesions involve the plate **(A)** and **(B)**, and the alveolar ridge **(C)** *(Courtesy of Sivakumar G, Sivapathasundharam B, Karthiga KS. Malignant melanoma of the oral cavity–case reports and review of literature. Indian J Dent Res, 2004, 15(2): 70–73).*

to several years before clinical symptoms appeared. For this reason it has been suggested that the appearance of melanin pigmentation in the mouth and its increase in size and in depth of color should be viewed seriously.

Although clinicopathologic correlation is well established for cutaneous melanomas, it is unfortunate that such correlation does not exist for oral melanomas. It is now apparent that melanomas of the oral mucosa can exist in radial- and vertical-growth phases but only a few such cases have been reported. Takagi and his coworkers were able to document a preexisting or concurrent melanosis in 62 of 94 cases of oral melanomas which they studied. Regezi, Hayward and Pickens evaluated three cases of oral melanoma in accordance with the established clinicopathologic parameters of cutaneous melanomas. They were able to classify one as a superficial spreading melanoma which had a preexisting melanosis for 11 years. The other two had histologic features consistent with lentigo maligna melanoma. However, since these lesions behaved much more aggressively, they were termed *acral-lentiginous melanomas* as suggested by Clark and his colleagues and by Reed.

Most dermatopathologists recognize the existence of lentigo maligna (melanotic freckle of Hutchinson) only on sun-damaged skin and do not accept its occurrence intraorally. It follows that lentigo maligna melanoma (melanoma arising in melanotic freckle of Hutchinson) cannot occur on oral mucosa, although such a case has been reported by Robinson and Hukill. In light of present knowledge, such a case would be called acral-lentiginous melanoma because of the clinicopathologic similarity of the oral lesion to those on palmar and plantar skin (Table 2-11).

Thus, oral melanomas may be expected to exist in superficial spreading, acral-lentiginous and nodular types. Batsakis and his associates and Hansen and Buchner have recently discussed the current concepts of oral mucosal melanomas relative to their cutaneous counterparts.

Table 2-11: Differential diagnosis for melanoma

Condition	Distinguishing characteristics
Seborrheic keratosis	"Stuck-on" appearance, symmetric, often multiple
Traumatized or irritated nevus	Returns to normal appearance within 7–14 days
Pigmented basal cell carcinoma	Waxy appearance, telangiectasias
Lentigo	Prevalent in sun-exposed skin, evenly pigmented, symmetric
Blue nevus	Darkly pigmented from dermal melanocytes, no history of change from melanoma
Angiokeratoma	Vascular tumors, difficult to distinguish
Traumatic hematoma	May mimic melanoma but resolves in 7–14 days
Venous lake	Blue, compressible, found on ears and lips
Hemangioma	Compressible, stable
Dermatofibroma	Firm growths of fibrous histiocytes, 'button-hole' when pinched
Pigmented actinic keratosis	Sandpapery feel; sun-exposed area

Histologic Features. The malignant cells often nest or cluster in groups in an organoid fashion; however, single cells can predominate. The melanoma cells have large nuclei, often with prominent nucleoli, and show nuclear pseudoinclusions due to nuclear membrane irregularity. The abundant cytoplasm may be uniformly eosinophilic or optically clear. Occasionally, the cells become spindled or neurotized in areas. This finding is interpreted as a more aggressive feature, compared with findings of the round or polygonal cell varieties.

The intraepithelial component (radial-growth phase) of superficial spreading melanoma is characterized by the presence of large, epithelioid melanocytes distributed in a so-called 'pagetoid' manner (Figs. 2-36, 2-37 A). This pagetoid spread within the epidermis is sometimes known as 'buckshot scatter'. As long as the malignant cells are confined to the epithelium, there is no host-cell response in the underlying connective tissue. When melanocytes penetrate basement membrane, a florid host-cell response of lymphocytes develops. Macrophages and melanophages may be present. The tumor cells are often destroyed by this cellular response. The vertical-growth phase is characterized by the proliferation of malignant epithelioid melanocytes in the underlying connective tissues (Fig. 2-37B). The cells may be arranged singly or in clusters. Melanin pigment is usually scanty.

Nodular melanoma also is characterized by large, epithelioid melanocytes within the connective tissue. However, small ovoid and spindle-shaped cells may be present. Melanin pigment is usually but not invariably present. The tumor cells may invade and ulcerate the overlying epithelium and penetrate the deep soft tissues.

Lentigo maligna (melanotic freckle of Hutchinson) has well-defined histologic features which have been discussed by Wayte and Helwig and by Clark and Mihm. The lesion is characterized

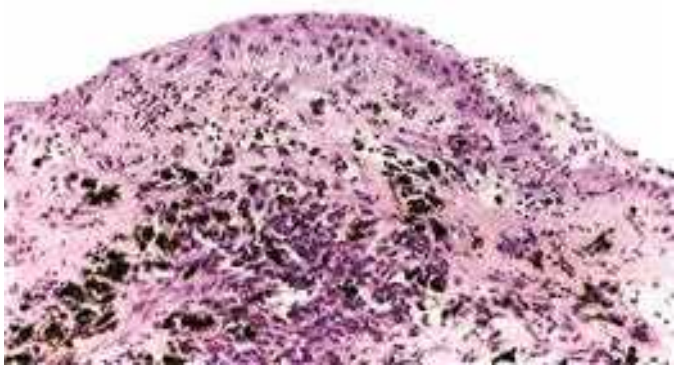

Figure 2-36. Vertical growth phase characterized by malignant melanocytes invading the underlying connective tissue
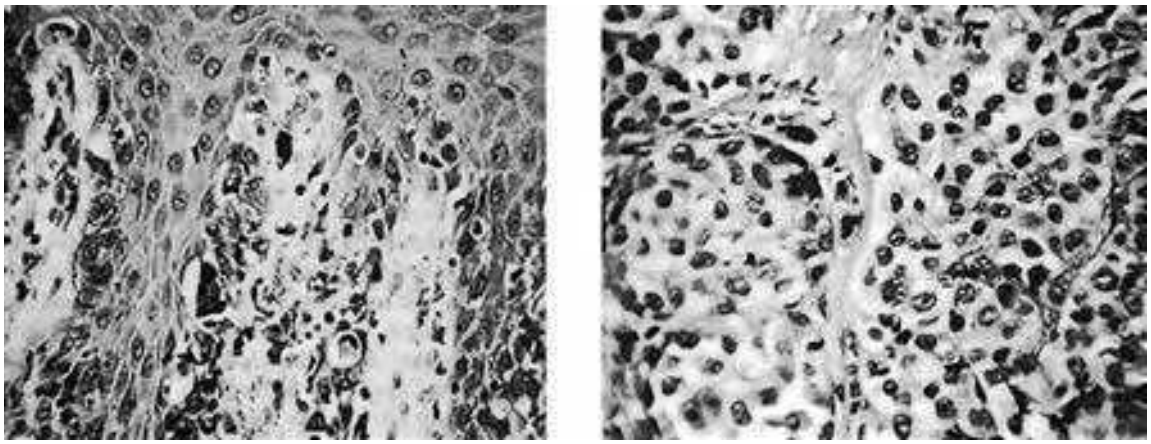
(Courtesy of Dr Hari S, Noorul Islam College of Dental Science,Trivandrum).



A B

Figure 2-37. Malignant melanoma.
(A) The radial-growth phase or premalignant melanosis is characterized by atypical melanocytes within the epithelium. **(B)** The vertical-growth phase is characterized by malignant epithelioid melanocytes invading the underlying connective tissue.

by increased numbers of atypical melanocytes within the basal epithelial layer. The epithelium is generally atrophic and the dermal collagen shows the effects of sun-damage (basophilic degeneration). If skin appendages are present, they are often involved with atypical melanocytes as well. In time, cords and nests of atypical melanocytes may be evident. Lentigo maligna melanoma is characterized by invasive spindle-shaped cells into the underlying dermis. A lymphohistiocytic infiltrate is usually present.

The acral-lentiginous melanoma is histologically similar to lentigo maligna melanoma. Coleman and his coworkers have studied 35 cases and have pointed out the salient histologic features. These are:

- A lentiginous radial-growth phase
- A deep vertical-growth phase composed predominantly of spindle-shaped cells
- Psoriasiform epidermal hyperplasia
- An intense host-cell response
- A prominent desmoplasia associated with the vertical-growth phase.

Although the majority of melanomas are diagnosed by routine light microscopy, ultrastructural study can be of value in diagnosing and distinguishing between various types of melanoma. As pointed out by Klug and Gunther, the three main types of cutaneous melanoma differ ultrastructurally in the number and size of melanosomes. Regezi, Hayward and Pickens studied an oral acral-lentiginous melanoma ultrastructurally and found premelanosomes and melanosomes similar to those found in normal melanocytes and nevus cells.

Less common histologic variants of melanoma such as desmoplastic, neurotropic, spindle cell and balloon cell melanomas exist. These have been discussed by Ainsworth and her colleagues.

Although immunohistochemical stains are usually not necessary for diagnosis, they are generally performed for confirmation. Both S-100 and homatropine methylbromide (HMB45) stains are positive in melanoma. The S-100 is highly sensitive, although not specific, for melanoma, while the HMB45 is highly specific and moderately sensitive for melanoma. The 2 stains, in concert, can be useful in diagnosing poorly differentiated melanomas. Vimentin is positive in most cases. Recently, microphthalmic transcription factor, tyrosinase, and melano A immunostains have been used to highlight melanocytes.

The lymph node metastasis is identified by using lymphoscintigraphy and a radioactive tracer (technetium-labeled sulfur colloid or human serum albumin).

Treatment and Prognosis. The treatment of cutaneous malignant melanoma is surgical excision. Although regional lymph node dissection is indicated when nodes are involved, prophylactic lymph node dissection is very controversial. The decision of the surgeon relative to elective node dissection should be based upon the thickness of the lesion and its specific anatomic location. In this regard, tumors greater than 0.75 millimeters in thickness and located in the so-called BANS (back, arm, neck and scalp) sites have a greater tendency to metastasize. On the other hand, melanomas of the skin of the face have a much more favorable prognosis.

Chemotherapy, immunotherapy and radiation therapy have been used in the treatment of cutaneous melanoma. The role of these modalities is discussed in the monograph on melanoma edited by Clark, Goldman and Mastrangelo.

The treatment of oral melanoma has been and still is surgical excision. Jaw resection and lymph node dissection is indicated in cases involving bone and regional lymph nodes. Other forms of therapy such as cryosurgery, radiation, chemotherapy and

immunotherapy have been employed on occasion but none have significantly improved the dismal prognosis of melanoma in the oral cavity.

There are both clinical and histologic factors which are of great prognostic significance in cutaneous melanomas. According to McGovern, clinical features with prognostic significance are the gender and age of the patient and the site of the lesion. Women have a much better survival rate up to the age of 50 years and then the rate declines.

Histologic features which are of prognostic significance are histologic type and depth of invasion. Nodular melanoma and superficial spreading melanoma have much poorer prognosis than lentigo maligna melanoma. In fact, McGovern believes that lentigo maligna melanoma should be considered as a separate entity because of its better prognosis. In 1999, Clark and his colleagues related prognosis to the anatomic level of invasion at the time of diagnosis. In 1970, Breslow proposed that the actual thickness of the tumor as measured in millimeters by an ocular micrometer correlated well with prognosis. It is now recognized that tumors less than 0.75 mm in thickness rarely metastasize or cause death, regardless of the location on skin.

Unfortunately, oral mucosal melanomas have a far worse prognosis than cutaneous melanomas. According to Pliskin, the five-year survival rate for such tumors is approximately 7%. Batsakis and his colleagues have pointed out that establishment of prognostic indicators for oral mucous membrane melanomas has not kept pace with those which have been established for cutaneous melanomas.

The level of tumor invasion is another important indicator of the prognosis of MM. The **Clark system** is generally used to grade tumor invasion based on the deepest histologic cutaneous structure the tumor infiltrates. Table 2-12 depicts five-year survival (FYS) rates for MM based on the Breslow and Clark grading systems.

Table 2-12: Malignant melanoma classification and five-year survival (FYS) rates

Clark system	FYS rate (percentage)
Level I: Tumor *in situ* Tumor is confined to the epidermis and is entirely above the basement membrane	100–98
Level II Invasive cells are only present in the papillary dermis. The tumor is usually still considered to be in the radial growth phase	96–72
Level III Tumor cells are found throughout the papillary dermis with impingement on the reticular dermis. The tumor has entered the vertical growth phase	90–46
Level IV Tumor cells are clearly seen between the collagen bundles of the reticular dermis	67–31
Level V	
Tumor cells show invasion of the subcutaneous fat.	48–12

Breslow system*	FYS rate (in percentage)
0.00 – 0.76 mm	98 – 99
0.76 – 1.49 mm	85
1.50 – 2.49 mm	84
1.50 – 2.49 mm	84
4.00 mm	44

** Total tumor thickness as measured from the outermost layer of the stratum granulosum to the deepest identifiable point of tumor invasion in the dermis.*

BENIGN TUMORS OF CONNECTIVE TISSUE ORIGIN

Oral Fibroma and Fibromatoses Fibroma
(Irritation fibroma, focal fibrous hyperplasia)

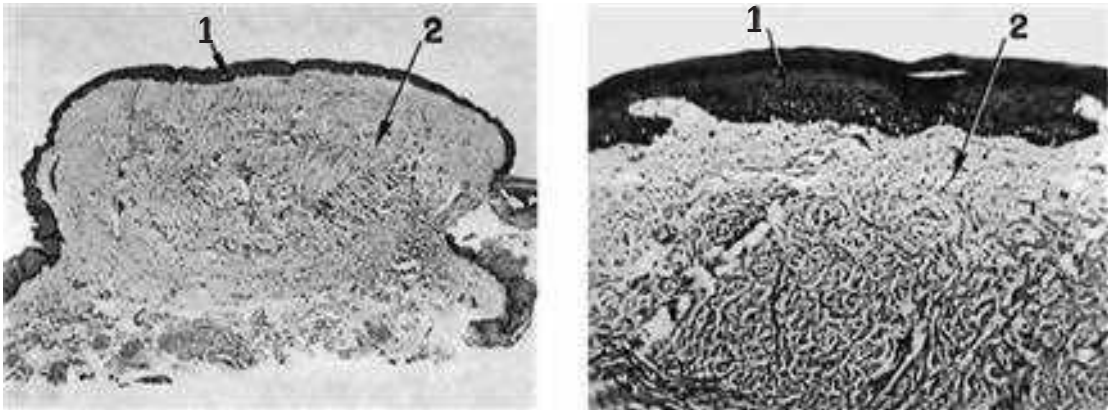
This connective tissue tumor is the most common benign soft tissue neoplasm occurring in the oral cavity. Most fibromas represent reactive focal fibrous hyperplasia due to trauma or local irritation. Although the term focal fibrous hyperplasia more accurately describes the clinical appearance and pathogenesis of this entity, it is not commonly used. It is intimately related to fibrous hyperplasia and, in many instances, is histologically indistinguishable from it.

Clinical Features. A fibroma may occur at any oral site, most commonly it is seen on the buccal mucosa along the plane of occlusion. Other frequent sites are the gingiva, buccal mucosa, the tongue, lips and the palate.

The fibroma appears as an elevated nodule of normal color with a smooth surface and a sessile or, occasionally, pedunculated base. The tumor may be small or, in rare instances, may range up to several centimeters in diameter. Projecting above the surface, the tumor sometimes becomes irritated and inflamed and may even show superficial ulceration or hyperkeratosis. It is nearly always a well-defined, slowly growing lesion that occurs at any age, but is most common in the third, fourth and fifth decades. Females are affected twice as frequently as males.

The clinical differential diagnosis of a fibroma includes giant cell fibroma, neurofibroma, peripheral giant cell granuloma, mucocele, and benign and malignant salivary gland tumors.

Histologic Features. The fibroma consists of bundles of interlacing collagenous fibers interspersed with varying numbers of fibroblasts or fibrocytes and small blood vessels. The surface of the lesion is covered by a layer of stratified squamous epithelium which frequently appears stretched and shows shortening and flattening of the rete pegs (Fig. 2-38). If trauma to the tissue has occurred, vasodilatation, edema and inflammatory cell infiltration are variably present. Areas of diffuse or focal calcification or even ossification are found in some fibromas, chiefly those occurring on the gingiva, and these lesions have sometimes been called 'peripheral ossifying fibroma', 'ossifying fibroid epulis', 'peripheral cementifying fibroma' or 'peripheral odontogenic fibroma' (q.v.).



A B

Figure 2-38. Fibroma.
(A) The low-power photomicrograph illustrates the typical sessile base, the thin surface epithelium (1) and coarse bundles of collagen (2) comprising the bulk of the tumor. **(B)** The high-power photomicrograph shows the relative acellularity of the connective tissue.

It is interesting to note that the fibroma, a true neoplasm of connective tissue origin, is microscopically similar to the condition known as inflammatory hyperplasia, an increased bulk of connective tissue which forms as part of an inflammatory reaction. In few situations is the distinction between the two general processes, hyperplasia and neoplasia, as poorly defined as it is here. Hyperplasia is usually considered to be a self-limiting process which is not etiologically related to neoplasia. Both processes, however, are typified by an increase in the number of cells brought about by increased mitotic activity. Hyperplastic tissue sometimes, but not invariably, regresses after the removal of the stimulus or irritant. Neoplastic tissue shows no such regression.

This distinction between hyperplasia and neoplasia is not clearcut, and cases occur intraorally in which there is focal or diffuse proliferation of tissue obviously due to irritation which does not regress after removal of the irritant. The tissue appears identical with that in other cases which do regress when the irritant is removed. This suggests that the processes of hyperplasia and neoplasia may not be as completely dissociated as previously considered and that a true oral neoplasm may result from chronic irritation.

Many persons think, however, that a great number of the lesions of the oral cavity diagnosed as fibromas are, in reality, simply examples of focal or localized hyperplasia, resulting from inflammation, and that the true fibroma is much rarer than is presently believed. There is no doubt that the pyogenic granuloma (q.v.), if left untreated, will undergo eventual healing by sclerosis and will then microscopically resemble the fibroma.

Treatment and Prognosis. The treatment for the fibroma, or focal inflammatory hyperplasia as the case may be, is conservative surgical excision. Seldom does the lesion recurs.

Fibromatoses

Fibromatoses, sometimes referred to as juvenile or aggressive fibromatoses, represent a group of infiltrating fibrous proliferations with a biologic behavior and microscopic appearance intermediate between those of benign lesions and fibrosarcomas.

Clinical Features. The head and neck region, particularly the submandibular area, is a common site of involvement. However, intraoral lesions are rare. The age of affected patients varies from 0–51 years, but in 74% of patients, fibromatosis is diagnosed before they are aged 10 years. No significant gender predilection is apparent.

A desmoplastic fibroma is considered to be the intraosseous counterpart of the soft-tissue fibromatosis. A desmoplastic fibroma appears as a firm, painless, poorly demarcated mass that is either rapidly or slowly growing. The mass is locally aggressive, blends into surrounding structures, and causes resorption of the underlying bone when it is present.

Fibromatosis has to be differentiated clinically from low-grade fibrosarcoma, nodular fasciitis, reactive fibrous hyperplasia, fibrous histiocytoma, and neurofibroma.

Histologic Features. Histologically, fibromatosis is characterized by a poorly delineated, infiltrating cellular proliferation of mature spindle cells arranged in streaming and interlacing fascicles. Collagen production is prominent. Infiltration of the adjacent structures is common at the periphery, but cellular atypia is not present.

Treatment and Prognosis. The treatment is wide excision. The recurrence rate of 24% for intraoral fibromatoses is recorded.

Giant Cell Fibroma

Giant cell fibroma is an oral tumor first described in 1974 by Weathers and Callihan as a distinctive entity. The distinctive histologic appearance sets it apart from a conventional fibroma.

Clinical Features. It appears as an asymptomatic sessile or pedunculated nodule that is less than 1 cm in diameter. Often, it has a bosselated or somewhat papillary surface. Most cases are diagnosed in persons aged 10–30 years, and no gender

predilection exists. The most common site is the mandibular gingiva, followed by the maxillary gingiva, the tongue, and the palate.

The clinical differential diagnoses include squamous papilloma, irritation fibroma, pyogenic granuloma, and peripheral giant cell granuloma.

Histologic Features. Microscopically, a giant cell fibroma is an unencapsulated mass of loose fibrous connective tissue that contains numerous characteristic large, plump, spindle-shaped and stellate fibroblasts, some of which are multinucleated. These cells are easily observed in the peripheral areas of the lesion, whereas the more central areas contain typical fusiform fibroblasts. The surface epithelium is corrugated and atrophic; in contrast to an irritation fibroma, a giant cell fibroma has thin, elongated rete ridges.

The origin of stellate and multinucleate cells is not well known. Few studies showed positive immunostaining for vimentin. This suggests that the stellate and multinucleate cells of GCF have a fibroblast phenotype.

Treatment and Prognosis. Conservative excisional biopsy is curative, and its findings are diagnostic. Recurrence is rare.

Myofibroma and Myofibromatosis

The terms myofibroma (if solitary) or myofibromatosis (if multicentric) are applied to the tumors which show predominant myofibroblasts. Myofibroblasts have features of both fibroblasts and smooth muscle cells.

Clinical Features. The tumors are benign and similar to fibromatosis but less aggressive. Tumors of the myofibroblasts may occur in either gender and in patients of all ages, with a mean patient age of 26.6 years.

Myofibroblastic tumors are most common in the head and neck region, including oral and perioral sites, than in other areas. Intraoral lesions occur mainly on the tongue, lips, and buccal mucosa. Tumors have also been described in the dermis, soft tissues, viscera, and bone. Jaw lesions, usually mandibular lesions, generally appear as well-defined unilocular or multilocular radiolucencies. Oral lesions appear as firm submucosal nodules or exophytic masses with a diameter of 0.3–5.0 cm. Although lesions are most often asymptomatic, they may be tender or even painful.

The clinical differential diagnosis for oral myofibroma includes irritation fibroma, peripheral giant cell fibroma, neurofibroma, leiomyoma, and benign and malignant neoplasms of the minor salivary glands.

Histopathologic Features. Histologically, all cases showed a biphasic pattern that consisted of fascicles of spindle cells with abundant eosinophilic cytoplasm that resembled smooth muscle, in addition to a population of more primitive spindled cells associated with a hemangiopericytoma like vascular pattern.

Treatment and Prognosis. Treatment for oral myofibromas is conservative excision. The recurrence rate is low, and spontaneous regression is reported.

Peripheral Ossifying Fibroma

(Peripheral odontogenic fibroma, peripheral cementifying fibroma, calcifying or ossifying fibroid epulis, peripheral fibroma with calcification)

There are numerous histologically different types of focal overgrowths which may occur on the gingiva, such as the peripheral giant cell granuloma, the giant cell fibroma, the pyogenic granuloma, the simple fibroma (which may be simply a healed pyogenic granuloma in many cases) and the present lesion, which in the past has been known by a variety of names indicated above. The terms most frequently used have been the 'peripheral ossifying fibroma' and the 'peripheral odontogenic fibroma'. In as much as the latter term has been used for a lesion described by the World Health Organization in their classification of odontogenic tumors as a totally different entity, the term peripheral ossifying fibroma will be used here for that relatively common gingival lesion characterized by a high degree of cellularity usually exhibiting bone formation, although occasionally cementum-like material or rarely dystrophic calcification may be found instead.

Some investigators believe that the lesion is nevertheless odontogenic in origin, being derived from the periodontal ligament, especially since it only occurs on the gingiva and may contain oxytalan fibers. At the present time, however, its exact derivation is still uncertain. Despite the similarity in terminology, it is not considered to be the extraosseous counterpart of the central ossifying fibroma. An attempt at clarification of the terms 'peripheral ossifying fibroma' and 'peripheral odontogenic fibroma' has been published recently by Gardner.

Clinical Features. The peripheral ossifying fibroma can occur at any age, although it appears to be somewhat more common in children and young adults. In a study of 365 cases by Cundiff, 50% of the lesions occurred between the ages of five and 25 years with the peak incidence at 13 years, while the mean age was 29 years. Most reported series of cases show a predilection for occurrence in females by a ratio ranging from 2 : 1 to 3 : 2. In addition, the lesions are approximately equally divided between the maxilla and the mandible. In the series reported by Cundiff, over 80% of the lesions in both jaws occurred anterior to the molar area. A series of 185 cases of 'peripheral fibroma with calcification' were also reported by Bhaskar and Jacoway with very similar clinical data.

The clinical appearance of the lesion is characteristic but not pathognomonic. It is a well-demarcated focal mass of tissue on the gingiva, with a sessile or pedunculated base (Fig. 2-39A). It is of the same color as normal mucosa or slightly reddened. The surface may be intact or ulcerated. It most commonly appears to originate from an interdental papilla.

Radiographic Features. In the vast majority of cases, there is no apparent underlying bone involvement visible on the radiograph. However, on rare occasions, there does appear to be superficial erosion of bone.

Histologic Features. The surface of the peripheral ossifying fibroma exhibits either an intact or, more frequently, an

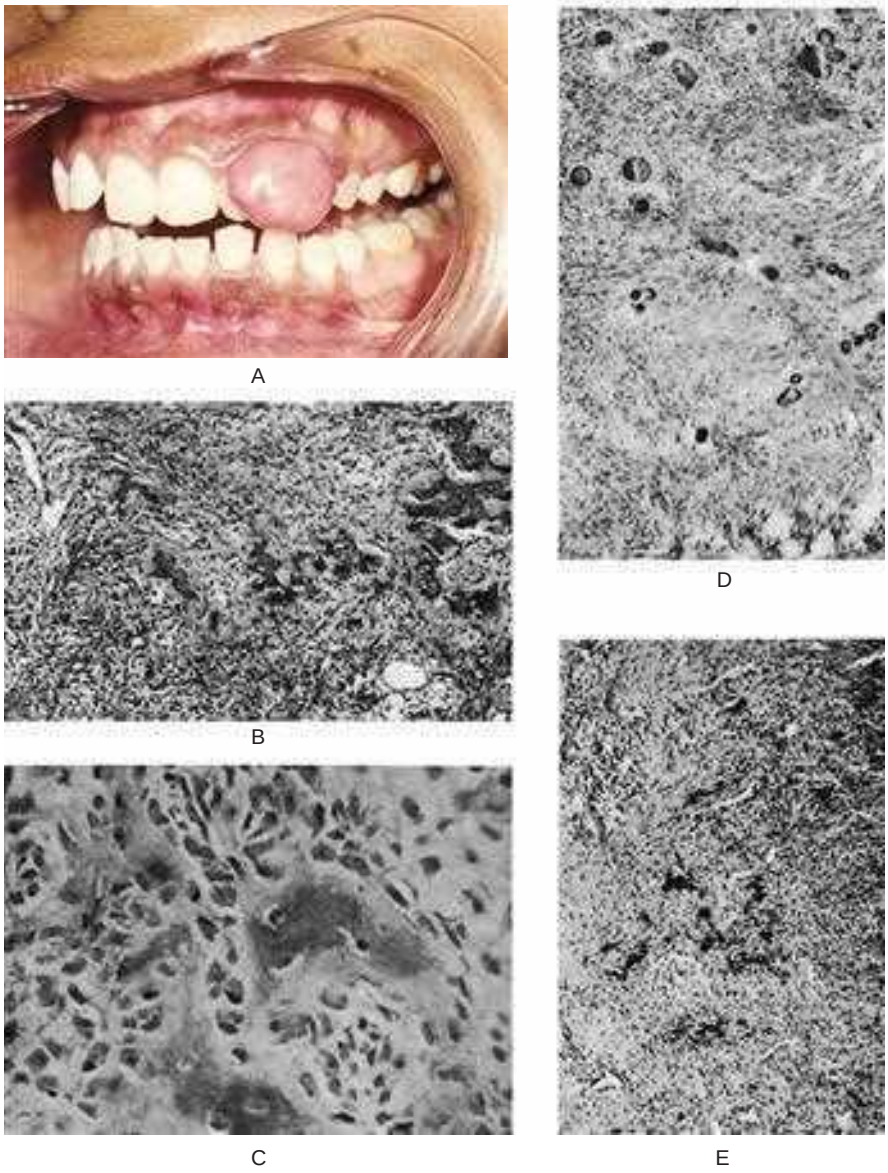


Figure 2-39. Peripheral ossifying fibroma.
The sessile lesion on the gingiva **(A)** is histologically a very cellular lesion which also exhibits most frequently irregular trabeculae of osteoid or bone (**[B]** in low power, **[C]** high power), but occasionally presents cementum-like droplets **(D)** or even dystrophic calcification **(E)**. *(A, Courtesy of Dr Vandhana KL, Department of Periodontics, College of Dental Sciences, Davangere)*.

ulcerated layer of stratified squamous epithelium. The bulk of the lesion is composed of an exceedingly cellular mass of connective tissue comprising large numbers of plump proliferating fibroblasts intermingled throughout a very delicate fibrillar stroma. The lesion is quite characteristic in its high degree of cellularity in contrast to the usual simple fibroma. In addition, vascularity is not nearly as prominent a feature of this lesion as in the pyogenic granuloma. Several forms of calcification occur in this particular lesion and will vary in amount from case to case. The calcification may be in the form of single or multiple interconnecting trabeculae of bone or osteoid (either mature lamellar bone or immature cellular bone), although less commonly globules of calcified material closely resembling acellular cementum, or a diffuse granular dystrophic calcification may be found (Fig. 2-39B, C, D, and E). Significantly, the degree of cellularity of the lesions is usually greatest in the areas of the bone cementum of calcification.

On occasion, areas will be found containing multinucleated giant cells which, with the surrounding tissue, bear considerable resemblance to some areas of the peripheral giant cell granuloma.

Treatment and Prognosis. The lesions should be surgically excised and submitted for microscopic examination for confirmation of diagnosis. The extraction of adjacent teeth is seldom necessary or justified. However, the lesions do recur with some frequency and, in fact, repeated recurrences are not uncommon. In the series of Cundiff, 16% of the cases

recurred, while in a series of 50 cases reported by Eversole and Rovin, the recurrence rate was 20%.

Central Ossifying Fibroma of Bone
(Central fibro-osteoma)

The ossifying fibroma of bone is a central neoplasm of bone which has caused considerable controversy because of confusion of terminology and criteria of diagnosis. It now appears that this represents a definite entity which should be separated from fibrous dysplasia of bone and the other fibro-osseous lesions which do not represent true neoplasms. This concept has been discussed by Pindborg, by Waldron and by many others.

There is a remarkable similarity in clinical features between this lesion and the central cementifying fibroma, a tumor accepted by most investigators as being odontogenic in origin. There is also considerable similarity and even overlap in the histologic features of these two lesions. For these reasons, it has been suggested that:

- These are two separate benign tumors, identical in nature except for the cell undergoing proliferation, the osteoblast with bone formation in one case, or the cementoblast with cementum formation in the other case; or
- These represent simply two facets of the same basic tumor. Further investigation will be necessary to clarify the relationship, or lack of it, between the central ossifying fibroma and the central cementifying fibroma.

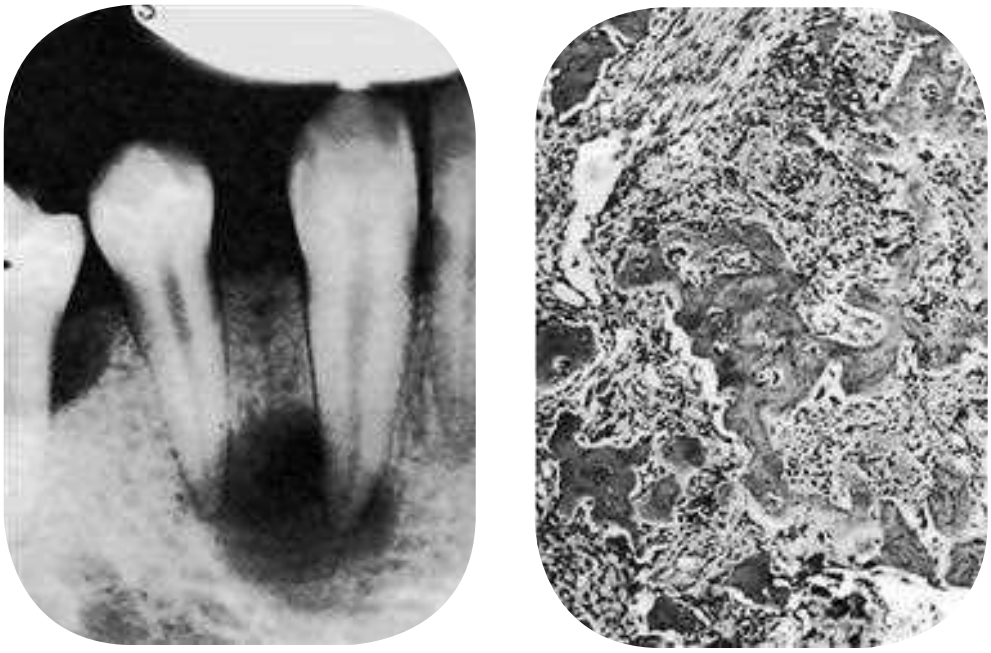
Clinical Features. The central ossifying fibroma may occur at any age, but is far more common in young adults. The age range of occurrence in a series of 31 cases presented by Shafer was nine to 52, with a mean of 33 years of age. Langdon and his associates reported similar findings. Either jaw may be involved, but there appears to be a predilection for the mandible. In the series of Shafer, there were 26 cases in the mandible but only five in the maxilla. A marked predilection for occurrence in females was also noted: 26 cases compared to only five in males. In addition, there was an unusually high incidence of lesions in blacks; 13 cases contrasted to 18 cases in white patients.

The lesion is generally asymptomatic until the growth produces a noticeable swelling and mild deformity; displacement of teeth may be an early clinical feature. It is a relatively slow growing tumor and may be present for some years before discovery. Because of the slow growth, the cortical plates of bone and overlying mucosa or skin are almost invariably intact.

Radiographic Features. The neoplasm presents an extremely variable radiographic appearance depending upon its stage of development. Yet despite the stage of development, the lesion is always well circumscribed and demarcated from the surrounding bone, in contrast to fibrous dysplasia.

In its early stages, the central ossifying fibroma paradoxically appears as a radiolucent area with no evidence of internal radiopacities (Fig. 2-40A). As the tumor bone apparently matures, there is increasing calcification, so that the radiolucent areas becomes flecked with opacities until, ultimately, the lesion appears as a relatively uniform radiopaque mass. Displacement of adjacent teeth is common, as well as impingement upon other adjacent structures.

Histologic Features. The lesion is composed basically of many delicate interlacing collagen fibers, seldom arranged in discrete bundles, interspersed by large numbers of active,



A B

Figure 2-40. Central ossifying fibroma of bone.

proliferating fibroblasts. Although mitotic figures may be present in small numbers, there is seldom any remarkable cellular pleomorphism. This connective tissue characteristically presents many small foci of irregular bony trabeculae (Fig. 2-40B) which may bear some similarity to the bizarre Chinese-character shape of the bony trabeculae in fibrous dysplasia of bone (q.v.).

As the lesion matures, the islands of ossification increase in number, enlarge and ultimately coalesce. This, with the probable increase in degree of calcification, accounts for increasing radiopaqueness of the lesion on the radiograph.

Treatment and Prognosis. The lesion should be excised conservatively, and recurrence is rare.

Peripheral Giant Cell Granuloma

(Peripheral giant cell epulis, peripheral giant cell reparative granuloma)

Peripheral giant cell granuloma has an unknown etiology, with some dispute as to whether this lesion represents a reactive or neoplastic process. However, most authorities believe peripheral giant cell granuloma is a reactive lesion. Since the lesion does not appear to be truly a 'reparative' one, this term reparative granuloma has been deleted from the name in the past few years.

The use of the term 'epulis' in connection with this or any other oral tumor is to be deplored. By definition, the word means only a growth on the gingiva and is entirely nonspecific. Since it gives no hint as to the true nature of a lesion, the term should be discarded.

The etiology of peripheral giant cell granuloma is unknown, but local irritation due to dental plaque or calculus, periodontal disease, poor dental restorations, ill-fitting dental appliances, or dental extractions has been suggested to contribute to the development of the lesion.

Clinical Features. Although the lesion may be found in very young children as well as in dentulous or edentulous elderly persons, most patients were in fourth to sixth decades of life and the mean age of patients at the time of diagnosis is typically 38–42 years. It was found that females were affected almost twice as frequently as males — 65% compared to 35%. A similar gender predilection has been found for the central giant cell granuloma. Lesions are generally asymptomatic and have a relatively rapid growth rate, often attaining a size of 1 cm within a few months.

Peripheral giant cell granuloma may vary considerably in clinical appearance. It always occurs on the gingiva or alveolar process, most frequently anterior to the molars, and presents itself as a pedunculated or sessile lesion that seems to be arising from deeper in the tissue than many other superficial lesions of this area such as the fibroma or pyogenic granuloma, either of which it may resemble clinically. Thus it seems to originate from either periodontal ligament or mucoperiosteum. The lesion also varies widely in size, but usually is between 0.5 and 1.5 cm in diameter. It is most often dark red, vascular or hemorrhagic in appearance, and it commonly exhibits surface ulceration.

In the edentulous patient, the lesion may appear sometimes as a vascular, ovoid or fusiform swelling of the crest of the ridge, seldom over 1–2 cm in diameter (Fig. 2-41A). Or there may be a granular mass of tissue which seems to be growing from the tissue covering the slope of the ridge. The color of these lesions varies, but is usually similar to that of lesions in dentulous patients. Ulceration is less common in the edentulous situation. A slight predilection for the mandible is observed in most reported series.

Histologic Features. The microscopic appearance of the giant cell lesion is unique. It consists of a nonencapsulated mass of tissue composed of a delicate reticular and fibrillar connective tissue stroma containing large numbers of ovoid or spindle-shaped young connective tissue cells and multinucleated giant cells. The giant cells in some instances resemble osteoclasts and in other cases are considerably larger than the typical osteoclast. Capillaries are numerous, particularly around the periphery of the lesion, and the giant

The lesion in edentulous patients produces a circumscribed growth, causing expansion of the alveolar ridge, **(A)**. The radiograph shows ragged loss of bone with peripheral 'cuffing', **(B)**.

cells sometimes may be found within the lumina of these vessels. Foci of hemorrhage, with liberation of hemosiderin pigment and its subsequent ingestion by mononuclear phagocytes, as well as inflammatory cell infiltration, are also characteristic features. Spicules of newly formed osteoid or bone are often found scattered throughout the vascular and cellular fibrous lesion (Fig. 2-42B).

A histochemical study of this lesion has been reported by Shklar and Cataldo with distinct differences observed in different multinucleated giant cells with respect to the distribution of tyrosine and sulfhydryl groups.

The origin of the giant cells has never been established. Although their resemblance to osteoclasts is sometimes striking, seldom are they seen carrying out the ascribed normal resorptive function of such cells. Geschickter and Copeland suggested that the giant cells might be derived from proliferating giant cells associated with the resorption of deciduous tooth roots. Thus they suppose the lesion to be concerned with the transition from the deciduous to the permanent dentition. Unfortunately, such association of lesions is present in only a few cases even though the tumor is a rather common one in youngsters. Such a theory would account for the predominance of the lesions anterior to the permanent molars.

There has been considerable support for another theory of origin from endothelial cells of capillaries. There is some basis in fact for such an idea, the chief being the common occurrence of the giant cells within vascular channels, suggesting that they arise here through fusion of endothelial cell. This suggested to earlier workers that the tumor was a malignant metastasizing one, and they applied to it the term 'giant cell sarcoma' or, in some cases, 'myeloid sarcoma'.

A recent study of the giant cells in the peripheral giant cell granuloma by electron microscope has been reported by Sapp. He found that these giant cells ultrastructurally contained a sufficient number of features in common with osteoclasts to conclude that they represent a slightly modified form of that cell. In addition, he reported that the stromal cells were structurally compatible with the various stages of differentiating osteoprogenitor cells.

Laboratory studies are generally not necessary. Serum calcium level or a parathyroid hormone assay may be indicated to rule out the rare possibility of brown tumor for lesions that are particularly large and recurrent, may be associated with systemic signs of hyperparathyroidism.

Radiographic Features. The intraoral radiograph may or may not exhibit evidence of involvement of the bone underlying the lesion. In edentulous areas the peripheral giant cell granuloma characteristically exhibits superficial erosion of the bone with pathognomonic peripheral 'cuffing' of the bone as seen in the radiograph (Fig. 2-41B). When the tumor occurs in areas in which teeth are present, the radiograph may reveal superficial destruction of the alveolar margin or crest of the interdental bone, but this is by no means invariably present.

Treatment and Prognosis. Conservative excision is typically curative, although the lesion must be completely removed to prevent recurrence. Prognosis is excellent. A recurrence rate of 10–15% has been reported in most series; however, recurrences are typically managed easily with additional surgery.

Central Giant Cell Granuloma and Giant Cell Tumor of Bone

Central giant cell granuloma (CGCG) is an uncommon, benign, and proliferative lesion whose etiology is not defined. It was Jaffe who first introduced the term central giant cell reparative granuloma to distinguish this lesion from the giant cell tumor of long bones. However, since a reparative response was quite rare and most of these lesions were found to be destructive rather than reparative, the word 'reparative' was omitted from that term.

Clinical Features. Though central giant cell granuloma may be seen in all age group, it is much more common in the young, especially those under 30 years of age. It is somewhat more common in females than in males. The gender distribution of 38 cases reported by Waldron and Shafer was approximately 2 to 1, females over males. A study of 34 cases

(*Source: Waldron CA, Shafer WG: The central giant cell reparative granuloma of the jaws. Am J Clin Pathol, 45: 437, 1966*).

by Austin, over 60% of the cases occurred before the age of 30 years. Furthermore, 60% of their cases were under the age of 20 years. Either jaw may be involved, but the mandible is affected more often. Two-thirds of their cases occurred in the mandible, and only one-third in the maxilla. The lesions are more common in the anterior segments of the jaws and, not uncommonly, cross the midline (Fig. 2-43).

The lesion may present no signs or symptoms and may be discovered accidentally, but sometimes, central giant cell granuloma may lead to an expansion of the cortex and perforation, mobility, displacement, and root resorption of associated tooth. The borders of the lesions may be regular or diffuse.

Depending on clinical and radiographic features, central giant cell granuloma can be classified into two types. The first type of lesion is **nonaggressive,** slow growing, does not show root resorption or cortical perforation, and often shows new bone formation. The second type is an **aggressive** type which grows quickly, shows pain, cortical perforation, and root resorption. On the other hand, although the clinical, radiographic and histologic features of CGCG have been extensively evaluated, the dimensional features of these lesions have not been clearly defined.

Radiographic Features. Central giant cell granuloma is essentially a destructive lesion, producing a radiolucent area with either a relatively smooth or a ragged border, and sometimes showing faint trabeculae. Definite loculations are often present, particularly in larger lesions. The cortical plates of the bone are often thin and expanded and may become perforated by the mass. Displacement of the teeth by the lesion is seen with some frequency. The appearance of the giant cell granuloma is not pathognomonic and may be confused with that of many other lesions of the jaw, both neoplastic and non-neoplastic (Fig. 2-44 A–F).

Histologic Features. Central giant cell granuloma is made up of a loose fibrillar connective tissue stroma with many interspersed proliferating fibroblasts and small capillaries. The collagen fibers are not usually collected into bundles; however, groups of fibers will often present a whorled appearance. Multinucleated giant cells are prominent throughout the connective tissue, but not necessarily abundant (Fig. 2-45). These giant cells vary in size from case to case and may contain only a few or several dozen nuclei. In addition, there are usually numerous foci of old extravasated blood and associated hemosiderin pigment, some of it phagocytized by macrophages. Foci of new trabeculae of osteoid or bone also are often seen, particularly around the periphery of the lesion.

There is a debate whether the giant cells are fibroblast origin or from monocyte/macrophages. Recent study by Itonaga et al, indicate that the giant cells in CGCG of the jaw are osteoclast like and formed from monocyte/macrophage precursors which differentiate into osteoclasts.

Treatment and Prognosis. The treatment of the giant cell granuloma is curettage or surgical excision. The lesions so treated almost invariably fill in with new bone and heal with no difficulty. Occasional lesions recur, but this is seldom sufficient cause for more radical procedures. X-ray radiation is contraindicated.

Giant Cell Tumor of Bone
(Osteoclastoma)

Giant cell tumor of bone is a distinctive neoplasm of undifferentiated cells. Multinucleated giant cells apparently result from fusion of the proliferating mononuclear cells, and although they are a constant and prominent part of this tumor, the giant cells are probably of less significance than the mononuclear cells. The exact cell of origin of this neoplasm is still unknown. Several immunohistochemical studies have suggested that the mononuclear cells are of histiocytic origin and that the giant cells arise from their fusion.

Malignant giant cell tumor cannot be diagnosed with assurance unless evidence of ordinary benign giant cell tumor exists within the lesion or has been demonstrated previously at the same site. If the stromal cells of a tumor that has many benign giant cells are malignant throughout with features of osteosarcoma, malignant fibrous histiocytoma, or fibrosarcoma, the tumor probably has no relationship to giant cell tumor.

Figure 2-44. Central giant cell granuloma.
Various cases all show the radiolucent, expansile, multilocular nature of the lesion.

The benign giant cells are but an incidental and confusing component. The clinical correlative studies reported by Troup and coworkers in 1960 have fortified this concept.

Clinical Features. The 568 cases of giant cell tumor reported from Mayo Clinic files represented 5.12% and 22.7% of the benign tumors. In many series, female patients are predominant. Approximately 84% of the neoplasms occurred in patients older than 19 years, with a peak incidence in the third decade of life (Unni KK, 1996). Pain of variable severity is almost always predominant symptom. More than three-fourths of the patients had noted swelling of the affected region. Less common symptoms were weakness, limitation of motion of the joint and pathologic fracture.

Histologic Features. The basic proliferating cell has round-to-oval or even spindle-shaped nucleus in the field that is diagnostic of true giant cell tumor. The nucleus is surrounded by an ill-defined cytoplasmic zone, and discernible intercellular substance is absent. Mitotic figures can be found, sometimes numerous. Mitotic activity has no prognostic significance. The giant cells are usually scattered uniformly throughout the lesion. They usually contain 40–60 nuclei. Areas of infarct-like necrosis are common in giant cell tumors. Some tumors are almost completely necrotic. The necrosis is not associated with an inflammatory response. Small collections of foam cells are common. Grading of giant cell tumors has no prognostic significance (Fig. 2-46).

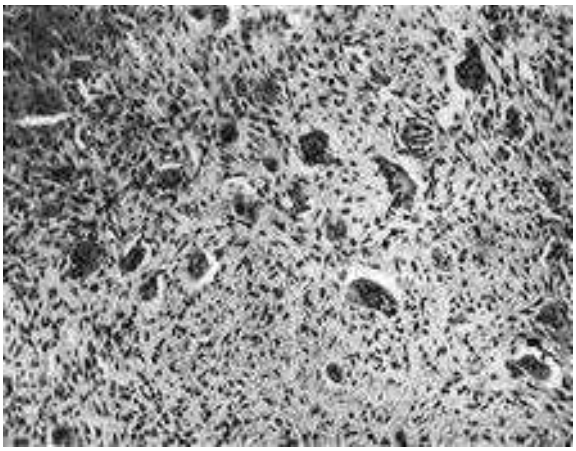

Figure 2-45. Central giant cell granuloma.

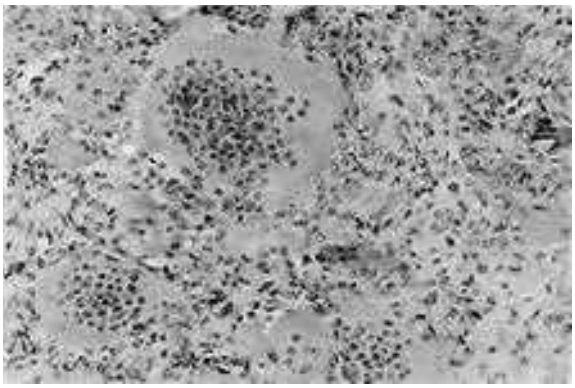

Figure 2-46. Giant cell tumor.
Typical appearance of a benign giant cell tumor. Giant cells with varying numbers of nuclei are arranged more or less uniformly within a background of mononuclear cells *(Courtesy of Dr KK Unni).*

Treatment. Removal of the tumor by curettage is the most widely accepted therapy. Recurrence may be seen as late as seven years. Secondary malignant change is usually to pure fibrosarcoma or osteosarcoma.

Aneurysmal Bone Cyst

The aneurysmal bone cyst is an interesting solitary lesion of bone which was separated as a distinct entity in 1942 by Jaffe and Lichtenstein. Since their original account, many cases have been reported in the literature, although the first cases occurring in the jaws were not described until 1958.

Features that make it logical to exclude aneurysmal bone cyst from the neoplastic category include the observation that the lesion has been known to regress after incomplete removal. The cause of this strange process in bone is unknown but several examples apparently arose after a fracture. It is similar to and probably related to other reactive non-neoplastic processes, including giant cell reparative granuloma of the jaws, traumatic reactions in periosteum and bone and even florid heterotopic ossification. Aneurysmal bone cyst may arise de novo in bone; that is, a definite preexisting lesion cannot be demonstrated in the tissue. Rarely malignant tumors of bone contain such benign areas as well. Obviously, recognition of an underlying process is important.

Clinical Features. The aneurysmal bone cyst is generally a lesion of young persons, predominantly occurring under the age of 20 years, with no significant predilection for either gender. The lesion can be encountered in adults. A history of traumatic injury preceding development of the lesion may often be obtained.

Cases of aneurysmal bone cyst have been observed in nearly every part of the skeleton, although over 50% of all cases occur in the long bones and vertebral column. Lesions are also seen frequently in the clavicle, rib, innominate bone, skull and bones of the hands and feet as well as other sites.

The lesions are usually tender or painful, particularly upon motion, and this soreness may limit movement of the affected bone. Swelling over the area of bone involvement is also common.

Gross findings at the time of operation are characteristic. Upon entering the lesion, excessive bleeding is encountered, the blood 'welling up' from the tissue. The tissue has been described as resembling a blood-soaked sponge with large pores representing the cavernous spaces of the lesion. In manometric studies by Biesecker and his associates, some of the cysts had elevated vascular pressures as high as arteriolar levels.

Four phases of pathogenesis are recognized, as follows:

- Osteolytic initial phase.
- Active growth phase, which is characterized by rapid destruction of bone and a subperiosteal blow out pattern.
- Mature stage, also known as stage of stabilization, which is manifested by the formation of a distinct peripheral bony shell and internal bony septa and trabeculae that produce the classic soap-bubble appearance.
- Healing phase, with progressive calcification and ossification of the cyst and its eventual transformation into a dense bony mass with an irregular structure.

Oral Manifestations. The aneurysmal bone cyst occurs with some frequency in the jaws, although many probably are misdiagnosed as some other bone lesion (Fig. 2-47A). In a review of the literature, Neumann-Jensen and Praetorius found 26 reported cases in the jaws, 17 in the mandible and nine in the maxilla. Of these, the average age of occurrence was 18 years with a range of 6–69 years, although only two patients were over 22 years of age. There was a slight predilection for occurrence in females, 14–19, where the gender was known.

Radiographic Features. The radiographic picture of the lesion is often distinctive. The bone is expanded, appears cystic with a honeycomb or soap-bubble appearance in many cases, and is eccentrically ballooned (Fig. 2-47B). The cortical bone may be destroyed, and a periosteal reaction may be evident.

Histologic Features. The aneurysmal bone cyst consists of a fibrous connective tissue stroma containing many cavernous or sinusoidal blood-filled spaces. These spaces may or may not show thrombosis. Young fibroblasts are numerous in

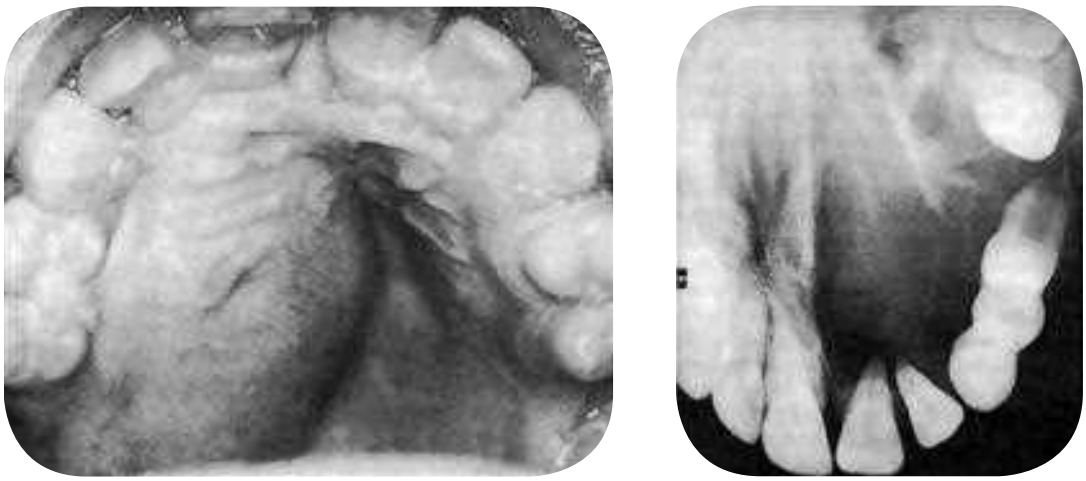

Figure 2-47. Aneurysmal bone cyst.
The large palatal swelling is a result of the underlying destructive, expansile mass *(Courtesy of Dr Jack Todd)*.

the connective tissue stroma, as well as multinucleated giant cells with a patchy distribution similar to that in the giant cell granuloma. But in the latter lesion the cavernous spaces are not found. Varying amounts of hemosiderin are present and, invariably, new osteoid and bone formation (Fig. 2-48A–D).

Pathogenesis. The nature of this lesion is still controversial despite the many cases that have been studied and reported. Lichtenstein has proposed that the aneurysmal bone cyst arises as a result of a persistent local alteration in hemodynamics, leading to increased venous pressure and subsequent development of a dilated and engorged vascular bed in the transformed bone area. Resorption of bone then occurs, to which the giant cells are related, and this is replaced by connective tissue, osteoid and new bone.

An alternative explanation of the lesion is that it represents an exuberant attempt at repair of a hematoma of bone, similar to the central giant cell granuloma. But in the case of the aneurysmal bone cyst, it is postulated that the hematoma maintains a circulatory connection with the damaged vessel. This would produce a slow flow of blood through the lesion and account for the clinical 'welling' of blood when the lesion is entered. Thus the only real difference between this aneurysmal cyst and the giant cell granuloma is that in the latter lesion damaged blood vessels fail to retain a circulatory connection with the lesion.

It is most significant that Biesecker and his associates have reported that 32% of their series of aneurysmal bone cysts had an accompanying benign primary lesion of bone. On this basis, they have proposed a new hypothesis for the etiology and pathogenesis of this lesion—namely, that a primary lesion of bone initiates an osseous, arteriovenous fistula and thereby creates, via its hemodynamic forces, the secondary reactive lesion of bone, the aneurysmal bone cyst.

This occurrence of aneurysmal bone cyst secondary to or in association with other osseous lesions has been confirmed by other investigators. For example, Levy and his associates reported 57 cases of aneurysmal bone cyst with which the most commonly associated lesion was the solitary or unicameral bone cyst (16 cases), the osteoclastoma or benign giant cell tumor (14 cases) and osteosarcoma (12 cases). Other associated lesions included the nonosteogenic fibroma, benign osteoblastoma, hemangioendothelioma and hemangioma of bone. Five aneurysmal bone cysts were secondary to fracture or other bone trauma.

Hillerup and Hjrting-Hansen have summarized the different theories on the etiology and pathogenesis of the aneurysmal bone cyst, simple bone cyst and central giant cell granuloma of the jaws. They suggested that these three lesions have a common dysvascular etiology and that local environmental factors within the bone may differentiate the pathogenesis.

Treatment and Prognosis. Surgical curettement or excision is the treatment of choice, although low doses of radiation have also been used. The possibility of radiation sarcoma is always a potential hazard, however, and the propriety of treatment of benign lesions by radiation has been seriously questioned on this basis. Recurrence in bones other than the jaws has been reported variously in between 21 and 59% of cases. However, no lesion in the jaws is known to have recurred.

Lipoma

It is a relatively rare intraoral tumor, although it occurs with considerable frequency in other areas, particularly in the subcutaneous tissues of the neck.

This is a benign, slow-growing neoplasm composed of mature fat cells. It appears that the cells of the lipoma differ metabolically from normal fat cells even though they are histologically similar. Thus a person on a starvation diet will lose fat from normal fat depots in the body, but not from the lipoma. Furthermore, fatty acid precursors are incorporated at

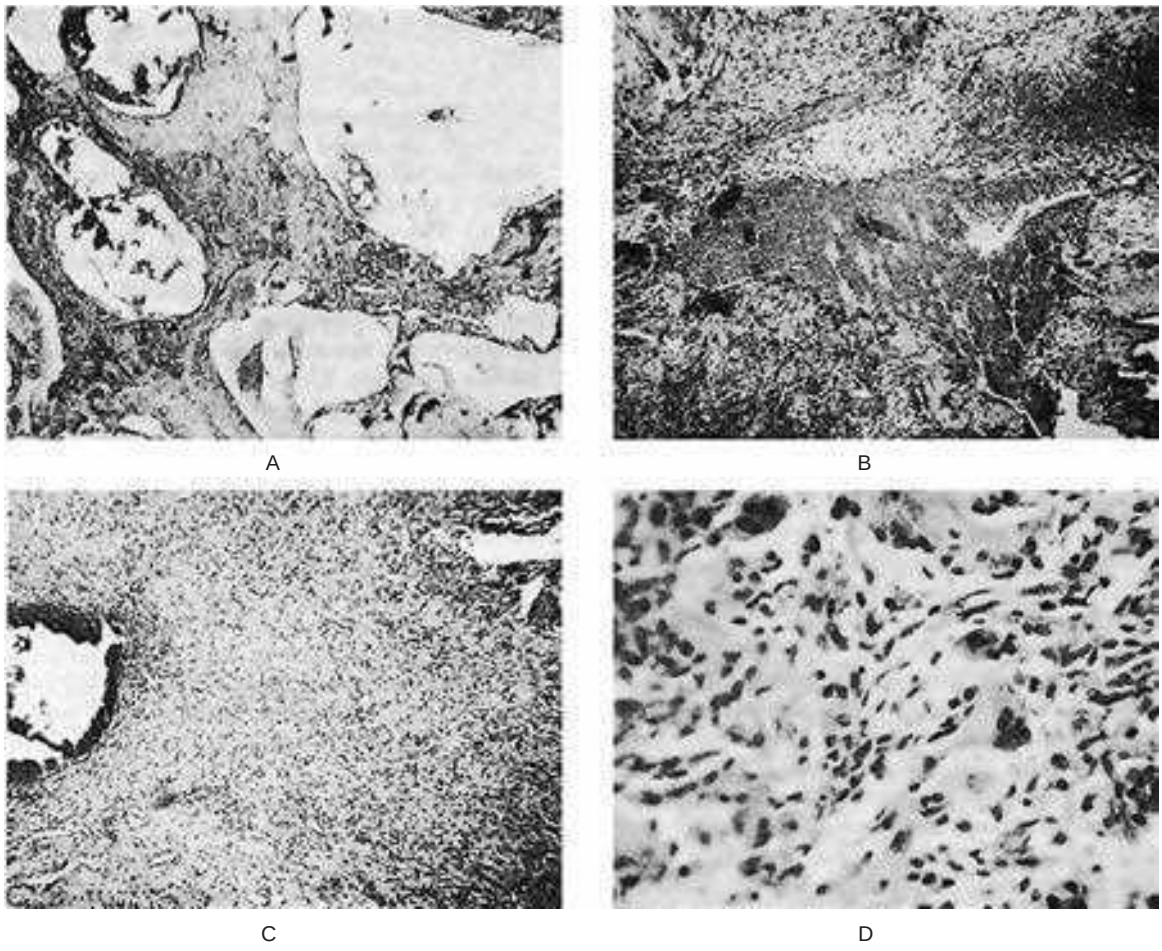

Figure 2-48. Aneurysmal bone cyst.
The photomicrographs illustrate the sinusoidal blood spaces, connective tissue, osteoid and giant cells.

a more rapid rate into lipoma fat than into normal fat while lipoprotein lipase activity is reduced.

The lipoma is a very common benign tumor of adipose tissue, but its presence in the oral and oropharyngeal region is relatively uncommon, with a prevalence rate of only 1/5,000 adults. The first description of an oral lesion was provided in 1848 by Roux in a review of alveolar masses; he referred to it as a 'yellow epulis'. While most lesions are developmental anomalies, those which occur in the maxillofacial region usually arise late in life and are presumed to be neoplasms of adipocytes, occasionally associated with trauma. Few lipomas show rearrangement of **12q, 13q, 6p** chromosomes.

Clinical Features. It is usually found in adults and there is no gender predilection. In most cases the size of the lesion is less than 3 cm at the time of diagnosis, but can increase up to 5–6 cm over a period of years. The tumor has been reported to occur in a variety of locations, including the tongue, floor of the mouth, buccal mucosa, gingiva, and mucobuccal or labial folds. Morphologically intraoral lipomas can be classified as **diffuse form** affecting the deeper tissues, and a **superficial** and **encapsulated form**.

Superficial form appears as a single or lobulated, painless lesion attached by either a sessile or a pedunculated base (Fig. 2-49A). There is a yellow surface discoloration and well-encapsulated, lipoma are freely movable beneath the mucosa. The epithelium is usually thin, and the superficial blood vessels are readily visible over the surface. The lipoma is yellowish, and relatively soft to palpation. Lesions in deeper tissues produce only a slight surface elevation which tend to be more diffuse than the superficial type of lipoma. When palpated, the diffuse form feels like fluid, sometimes leading to a mistaken tentative diagnosis of 'cyst'. Since this diffuse form often occurs in areas in which some fat is normally present, the diagnosis of lipoma depends upon the recognition of simply an overabundance of this tissue. Thus the diagnosis is essentially a clinical one.

Multiple head and neck lipomas have been observed in neurofibromatosis, Gardner syndrome, encephalocraniocutaneous lipomatosis, multiple familial lipomatosis, and Proteus syndrome. Generalized lipomatosis has been reported to contribute to unilateral facial enlargement in hemifacial hypertrophy.

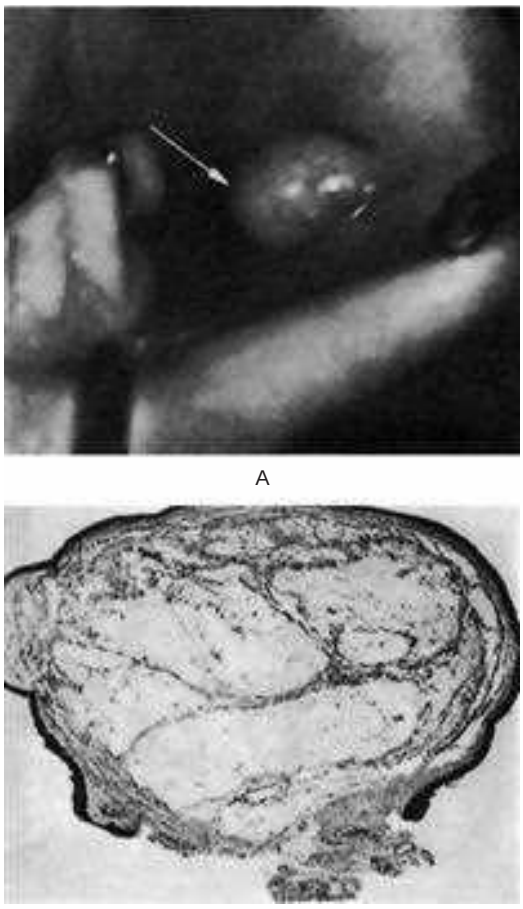

Figure 2-49. Lipoma.
The circumscribed mass on the buccal mucosa **(A)** is composed chiefly of adult fat cells with occasional connective tissue septa coursing through the lesion **(B)**.

Histologic Features. The lipoma is composed predominantly of mature adipocytes, possibly admixed with collagenic streaks, and is often well demarcated from the surrounding connective tissues. A thin fibrous capsule may be seen and a distinct lobular pattern may be present. Quite often, however, lesional fat cells are seen to 'infiltrate' into surrounding tissues, perhaps producing long, thin extensions of fatty tissue radiating from the central tumor mass. When located within striated muscle this infiltrating variant is called intramuscular lipoma **(infiltrating lipoma)**, but extensive involvement of a wide area of fibrovascular or stromal tissues might best be termed **lipomatosis**.

Occasional lesions exhibit excessive fibrosis between the fat cells **(fibrolipoma)**, excess numbers of small vascular channels **(angiolipoma)**, a myxoid background stroma **(myxoid lipoma, myxolipoma)**, or areas with uniform spindle-shaped cells interspersed between normal adipocytes (spindle cell lipoma). When spindle cells appear somewhat dysplastic or mixed with pleomorphic giant cells with or without hyperchromatic, enlarged nuclei, the term **pleomorphic lipoma** is applied. When the spindled cells are of smooth muscle origin, the term **myolipoma** may be used, or **angiomyolipoma** when the smooth muscle appears to be derived from the walls of arterioles.

Rarely, chondroid or osseous metaplasia may be seen in a lipoma (**osteolipoma,** ossifying lipoma, chondroid lipoma, ossifying chondromyxoid lipoma). When bone marrow is present, the term **myelolipoma** is used. Also on rare occasions, isolated ductal or tubular adnexal structures are scattered throughout fat lobules, in which case the term **adenolipoma** is applied. **Perineural lipoma** has also been reported.

On occasion, lipoma of the buccal mucosa cannot be distinguished from a herniated buccal fat pad, except by the lack of a history of sudden onset after trauma. Otherwise, lipoma of the oral and pharyngeal region is not difficult to differentiate from other lesions, although spindle cell and pleomorphic types must be distinguished from liposarcoma. When metaplastic calcified tissue is present, the lesion may be confused with soft tissue chondroma or soft tissue osteoma.

The benign neoplasm of brown fat, **hibernoma,** has been reported in the oral/pharyngeal region only rarely.

Lipoblastoma

This is a rare related lesion originally described by Vellios and his associates in 1958. It is probably not a true neoplasm but rather a continuation of the normal process of fetal fat development carried into postnatal life. It is characterized clinically by the occurrence in infants of solitary or multiple soft-tissue masses developing at various sites such as the buttock, chest, axilla or neck. The lesions are benign but may recur if inadequately excised. Diffuse lipoblastoma involving deeper soft tissue is called **lipoblastomatosis**.

Histologically, the central core of mature adipocytes and a peripheral envelope of cells containing variably sized fat vacuoles are noticed. Affected cells are smaller than normal, with 1–4 vacuoles, with a light, wispy cytoplasm between vacuoles. Some cells have nuclei centrally located, as seen in the moderately-sized cells of hibernoma, while others show the nucleus to be pushed toward the cytoplasmic membrane (signet-ring cell). Mitotic activity is extremely rare and fibrous septa separate fat lobules in this tumor. An abnormality of the long arm of chromosome **8q11-13** is a rather consistent finding in the lesional cells.

Treatment and Prognosis. Conservative surgical removal is the treatment of choice for oral lipoma, with occasional recurrences expected. An infiltrating lipoma often must be debulked.

Verruciform Xanthoma

(Verrucous xanthoma, inflammatory papillary hyperplasia with foam cell response)

Verruciform xanthoma is an uncommon lesion that usually occurs on the oral mucosa of unknown etiology and uncertain nature, first described as an entity by Shafer in 1971. Numerous cases have now been reported in the literature, including on the vulva, penis, on the skin of the thigh and perineum. Many authors consider it to be a reactive process rather than a true neoplasm.

The etiopathogenesis of verruciform xanthoma is unknown. It is thought that damage to the squamous cells with increased epithelial cell turnover, leading to the deposition of epithelial cell debris that is engulfed by macrophages in the corium may lead to the development of this lesion. An immunologic etiology has also been proposed.

Most commonly, the lesion has a verruciform appearance, but it may appear polypoid, papillomatous, or sessile. Rare lesions have been found to occur in cysts. The chief distinguishing feature of verruciform xanthoma is the presence of large numbers of lipid-laden foamy histiocytes in, and essentially limited to, the connective tissue papillae in the lesion.

Clinical Features. Verruciform xanthoma is uncommon, accounting for 0.025–0.05% of all pathology cases. The age of occurrence varies widely from 2 to 89 years. But most oral cases occur in middle-aged persons with mean age of 40–50 years, and no gender predilection is apparent. Most cases are reported in whites, but blacks are also affected. Verruciform xanthoma may occur at any site but its most preferred site is the alveolar ridge, or gingiva, followed by the buccal mucosa and then the palate, floor of the mouth, lip and lower mucobuccal fold with equal frequency.

Verruciform xanthoma occurs as a solitary lesion, either normal or reddish in color but sometimes pale or 'hyperkeratotic', with a rough, pebbly surface and either a sessile or pedunculated base. It may be as small as 2 mm or as large as 1.5 cm in diameter, and is invariably asymptomatic. In the oral cavity lesions can be found in association with lichen planus, pemphigus vulgaris, oral bullae, carcinoma *in situ,* or frank squamous cell carcinoma.

Depending on the nature of the individual lesion, it may clinically resemble any verrucous, papillary, or lichenoid oral lesion, particularly any such lesion that is also hyperkeratotic. It is frequently misdiagnosed at clinical examination as a papilloma.

Verruciform xanthoma outside oral mucosa is usually associated with other conditions like lymphoedema, epidermal nevi and congenital hemidysplasia with ichthyosiform erythroderma and limb defect (CHILD) syndrome.

Histologic Features. Verruciform xanthomas may appear verrucous, papillary, or cauliflower like, or they may show a lichenoid pattern histologically. A mixture of the above patterns may also be observed. A variable degree of parakeratosis is observed that is usually more marked in verrucous and papillary lesions, with hyperparakeratosis present in the crypts between papillae. The rete pegs are extremely elongated and uniform, although no increased mitoses or pseudoepitheliomatous hyperplasia are found. The connective tissue papillae are of variable length and thickness; they often extend close to the surface. Rarely, the entire process may occur in a cyst like structure.

The most striking and characteristic feature is the presence of large foam cells in the connective tissue papillae between the epithelial pegs. These are confined to the papillae and do not extend into the dermis beneath the pegs. Almost all of the papillae are involved with these cells, which occasionally may also be seen in the epithelium (i.e. epidermis, mucosa).

A slight inflammatory infiltrate may be present beneath the lesion. Occasional lesions have been associated with a massive or lichenoid infiltrate. No granulomatous change has been described other than the presence of the foamy macrophages. Microorganisms are not characteristically present. Although bacteria and fungal hyphae are occasionally described, they appear to play no role in the etiopathogenesis. Attempts to incriminate a viral role have been counterproductive.

Ultrastructurally, most studies have concluded that the foam cells in verruciform xanthoma are fat-laden macrophages, although other cell types, including Langerhans cells and even fibroblasts have been proposed.

Treatment. Local surgical excision is almost always curative. Recurrence is rare.

Immunohistochemical analysis revealed these cells to be positive for LCA and CD68 and negative for S100, a marker pattern also characteristic of macrophages. A few S100 negative dendritic or granular cells have been reported in these lesions as well and may represent Langerhans cells. The contents of the cells stain with lipid stains, and the vacuoles that contain this material are decorated with antihuman lysosome antibody. They are also periodic acid-Schiff (PAS) positive and diastase resistant, indicating that the PAS-positive material is not glycogen.

At electron microscopy, this material also demonstrates the appearance of lipid. Chemical studies by gas chromatography of extracted material show a preponderance of cholesterol esters. In addition to the lipid material, few researchers noted the presence of what they interpreted as degenerating epithelial cells in the foam cells. Cobb et al. described myelin figures, reduplication of the overlying basal lamina and fibroblasts, in addition to macrophage like cells, which contained lipid inclusions.

Oral Hemangiomas and Vascular Malformations
(Oral vasoformative tumor)

Hemangiomas are lesions that are not present at birth. They manifest within the first month of life, exhibit a rapid proliferative phase, and slowly involute to nonexistent. Hemangiomas are tumors identified by rapid endothelial cell proliferation in early infancy, followed by involution over time; vascular malformations result from anomalous development of vascular plexuses. The malformations have a normal endothelial cell growth cycle that affects the veins, the capillaries, or the lymphatics, and they do not involute. Vascular malformations are more stable and fail to regress.

Hemangiomas of the oral cavity are not common pathologic entities, but the head and neck are common sites. Most true hemangiomas involute with time, but 10–20% of true hemangiomas incompletely involute and require postadolescent ablative treatment.

Hemangiomas are associated with the following syndromes:

- Rendu-Osler-Weber syndrome (autosomal dominant inheritance, multiple telangiectasias, occasional GI tract involvement, occasional CNS involvement).
- Sturge-Weber-Dimitri syndrome (noninherited and nonfamilial, port-wine stain, leptomeningeal angiomas).
- Kasabach-Merritt syndrome (thrombocytopenic purpura associated with hemangioma, consumptive coagulopathy, microangiopathic hemolysis, intralesional fibrinolysis).
- Maffucci syndrome (hemangiomas of the mucous membranes, dyschondroplasia).
- von Hippel-Lindau syndrome (genetic transmission variable, hemangiomas of the cerebellum or the retina, cysts of the viscera).
- Klippel-Trenaunay-Weber syndrome (port-wine stain, angiomatosis of the extremities).

In 1982, Mulliken and Glowacki classified the vasoformative tumors into two broad groups: **hemangiomas and vascular malformations** (Table 2-13). Vascular malformations can be further subdivided into **venous, capillary, arteriovenous and lymphatic malformations.**

A simple classification is that proposed by Watson and McCarthy based upon a series of 1,308 blood vessel tumors, and is as follows: (1) capillary hemangioma, (2) cavernous hemangioma, (3) angioblastic or hypertrophic hemangioma, (4) racemose hemangioma, (5) diffuse systemic hemangioma, (6) metastasizing hemangioma, (7) nevus vinosus, or port-wine stain, and (8) hereditary hemorrhagic telangiectasia.

Clinical Features. By their definition, hemangiomas occur in infants and children. The incidence of hemangiomas increases to 23% in premature infants with a birthweight of less than 1,000 gm. The peak incidence of central hemangiomas of the jaws is in the second decade of life. But vascular malformations have a much broader range of incidence.

Hemangioma affects as many as 12% infants in whites, but it rarely occurs in darker-skinned individuals. Vascular malformations are also more common in whites. Hemangiomas are about three times more common in females than in males. But for venous malformations gender ratio is reported to be 1:1.

The most commonly affected facial bones are the mandible, the maxilla, and the nasal bones. Intraosseous lesions affect the mandible more often than the maxilla, with a ratio of 2:1. Involvement of the zygoma is rare. Intramuscular hemangiomas in the oral region are most commonly seen in the masseter, comprising 5% of all intramuscular hemangiomas.

Patients with multiple lesions have rates of resolution similar to those with single lesions; however, separate lesions in the same individual do not necessarily grow or involute simultaneously.

Vascular malformations are present at birth and continue to grow with the child. The growth may become accelerated when the patient undergoes puberty or pregnancy, with the attendant hormonal changes.

Oral Manifestations. The hemangioma of the oral soft tissue is similar to the hemangioma of the skin and appears as a flat or raised lesion of the mucosa, usually deep red or

Etiology. The causes of vasoformative tumors are unknown. One hypothesis postulates that placental cells, such as the trophoblast, may be the cell of origin for hemangiomas. Therefore, hemangiomas may arise secondary to some event *in utero.* However, conflicting evidence supports this hypothesis. The relationship between hemangiomas and placental tissues needs further investigation.

Pathophysiology. Vascular malformations need to be understood in terms of their embryology and development. The classic sequence of events usually falls into three stages:

- The undifferentiated capillary network stage
- The retiform developmental stage
- The final developmental stage.

In the undifferentiated capillary network stage, the primitive mesenchyme is nourished by an interlacing system of blood spaces without distinguishable arterial and venous channels. Separate venous and arterial stems appear on either side of the capillary network in the retiform developmental stage. The retiform developmental stage begins at about 48 days of embryonic development. The final developmental stage begins at two months of development and involves the gradual replacement of the immature plexiform network by the mature vascular channels.

The more common capillary hemangioma represents an arrest in the development of the mesenchyme primordia in the undifferentiated capillary network stage. As differentiation progresses, primitive vessels penetrate deeper into the subcutaneous layer, the muscle, or the bone tissue and give rise to capillary hemangiomas. Termination of development in the retiform developmental stage may produce venous, arterial, or capillary malformations because this stage is characterized by an established venous, arterial, and capillary system. In the final developmental stage, the maturation of the venous and lymphatic systems predominates. Aberrations in this mature stage of development result in venous malformations and lymphangiomas.

Proliferating hemangiomas have been shown to have estradiol-17 beta receptors in the cytoplasm, and corticosteroid treatment has been theorized to block these receptors. Thus steroid treatment is the first line of treatment for proliferating lesions. Estradiol receptors are absent in stable or involuting lesions.

Takahashi has outlined a number of cellular markers that distinguish the phases of hemangiomas; these markers include tissue metalloproteinase (TIMP-1), bFGF, proliferating cell nuclear antigen, type IV collagenase, VEGF, and urokinase.

Table 2-13: Classification of vasoformative tumors

Vasoformative tumor	New nomenclature	Old nomenclature
Hemangiomas	Capillary hemangioma Cavernous hemangioma Mixed hemangioma	Strawberry hemangioma Juvenile hemangioma Parotid hemangioma
Vascular malformations	Venous malformation	Cavernous hemangioma Hemangiomatosis
	Intramuscular venous malformation	Intramuscular hemangioma
	Capillary malformation	Capillary hemangioma Port-wine stain Arteriovenous hemangioma Arterial angioma
	Arteriovenous malformation	Arteriovenous aneurysm Cirsoid angioma Red angioma Serpentine aneurysm Capillary lymphangioma Cavernous lymphangioma
	Lymphatic malformation	Lymphangioma Cystic hygroma

bluish red and seldom well circumscribed. They are readily compressible and fill slowly when released. The most common sites of occurrence are the lips, tongue, buccal mucosa and palate (Fig. 2-50). The tumor often is traumatized and undergoes ulceration and secondary infection.

Certain tiny vascular formations of lip vessels called 'microcherry', 'glomerulus' and 'venous lake' have been described by Gius and his associates as lesions encountered with increasing frequency in the later decades of life and occurring with greater frequency in patients with gastric and duodenal ulcers.

The **intramuscular hemangioma** is one special form of hemangioma which is quite rare in the head and neck region. It arises within normal skeletal muscle, comprises less than 1% of all hemangiomas and is important chiefly because of the problem in differential diagnosis and of treatment of the lesion. Intramuscular hemangiomas represent a challenge on diagnosis because they exhibit few signs on clinical examination. Often times, the extent of the lesion is not clinically apparent on examination, and imaging studies frequently define more extensive lesions than suspected.

Central hemangiomas of the maxilla or mandible occasionally occur and frequently present difficulty in differential diagnosis. Lund and Dahlin reviewed 35 cases of hemangioma of the jaws and found that over 50% of the cases occurred in the first two decades of life and that two-thirds of the lesions were located in the mandible. Here the tumor is a bone-destructive lesion which may be of varying size and

A B

A B

Figure 2-51. Central hemangioma of bone.

appearance, but is often suggestive of a cyst (Fig. 2-51). Root resorption of the teeth has been reported in 30% of cases, but the vitality of the teeth is usually not affected. Some central hemangiomas present a honeycombed appearance on the radiograph, sometimes with radiating spicules at the expanded periphery forming a 'sunburst' appearance reminiscent of that effect seen in osteosarcoma. Radiographic appearance is also similar to that of a giant cell lesion or an ameloblastoma.

The attempt at radical surgical excision of such central lesions has often resulted in severe loss of blood, which has occasionally led to exsanguination of the patient to the point of death. In such bony lesions, it is always advisable to attempt to aspirate fluid contents through a needle before surgically opening the area. When the hemangioma is entirely central within bone, Gamez-Araujo and his associates have stated that the prognosis is excellent with adequate surgical intervention, in contrast to those lesions where soft tissue is also involved by capillary hemangioma. In these latter instances, the lesions become aggressive, invade locally and often recur if not totally eradicated.

The **arteriovenous aneurysm**, or arteriovenous fistula, is an uncommon lesion which often has been mistaken clinically for a hemangioma. It represents a direct communication between an artery and a vein through which the blood bypasses the capillary circulation. The arteriovenous aneurysm may be congenital or acquired, the latter usually being traumatic in origin. It may occur either in the soft tissues, such as in the case of the palate reported by Ingram and Coker, and on the alveolar ridge as reported by McComb and Trott, or central in the jaw as reported by Cook and Zbar. These aneurysms typically are classified as:

- A **cirsoid aneurysm** which is a tortuous mass of small arteries and veins linking a larger artery and vein.
- A **varicose aneurysm** which consists of an endothelium-lined sac connecting an artery and a vein.
- An **aneurysmal varix** representing a direct connection between an artery and a dilated vein.

The arteriovenous aneurysm has been reviewed in detail by Gomes and Bernatz, while Orbach has discussed the entire gamut of congenital arteriovenous malformations of the head and neck. He has emphasized the histogenesis and pathogenesis of these abnormalities, stressing the fact that they range from the most trivial angioma to the large-bore arteriovenous fistula.

Radiographic Features. Imaging should be considered to determine their extent and flow characteristics. Angiography is considered the most definitive of the studies, although the angiographic appearance of intraosseous lesions is less well defined than that of soft tissue lesions. Ultrasonography can be used to determine angiomatous in nature (i.e. hemangioma, lymphangioma), but it cannot differentiate a hemangioma from a lymphangioma. Contrast-enhanced MRI can be used to differentiate a hemangioma from a lymphangioma in the oral cavity. MRI appears to be highly reliable for lesions of either soft tissue or bone. Radiographically, intraosseous hemangioma shows honeycombed pattern that is well demarcated from normal bone. CT scans often show an expansile process with a high-density amorphous mass that may be suggestive of fibrous dysplasia.

Histologic Features. The usual hemangioma is composed of many small capillaries lined by a single layer of endothelial cells supported by a connective tissue stroma of varying density. It bears considerable resemblance to young granulation tissue and is nearly identical with some cases of pyogenic granuloma. Some cases show rather remarkable endothelial cell proliferation (Fig. 2-52). In fact, one common form is referred to as a juvenile hemangioendothelioma because it occurs in very early life and is characterized by an extremely cellular pattern. It is generally believed that this lesion is an immature stage of a capillary hemangioma and that, in time, it will either develop into a simple hemangioma or regress.

The cavernous form of hemangioma consists of large dilated blood sinuses with thin walls, each showing an endothelial lining. The sinusoidal spaces usually are filled with blood,

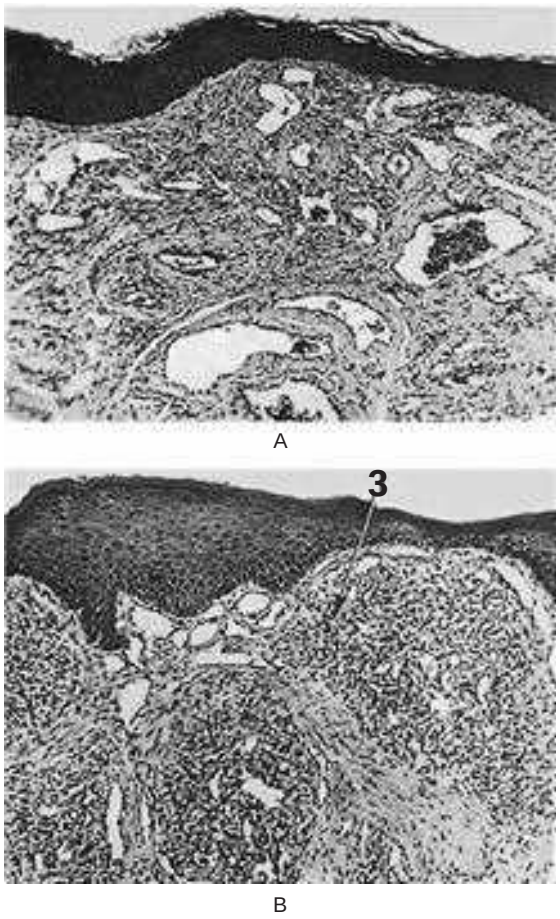

Figure 2-51. Hemangioma.
Some lesions **(A)** are characterized by the presence of many small dilated capillaries and a minimum of endothelial cells, while others **(B)** show large numbers of proliferating endothelial cells (1), but only moderate numbers of patent capillaries.

although an admixture with occasional lymphatic vessels occurs in some instances.

Intravascular angiomatosis, also referred to in the literature most commonly under the terms hemangioendotheliome vegetant intravasculaire of Masson, Masson's pseudoangiosarcoma, and intravascular papillary endothelial hyperplasia, is actually an unusual form of an organizing thrombus, although it is often mistaken for a vascular tumor, especially a malignant one such as angiosarcoma. This lesion has been discussed by McClatchey and his associates, who described perioral cases, including two on the lips which clinically resembled mucoceles, and emphasized that angiosarcoma could best be excluded as a diagnosis by the intravascular localization, the absent to rare mitoses and necrosis, and the rare solid cellular areas without vascular differentiation.

Treatment and Prognosis. Many congenital hemangiomas have been found to undergo spontaneous regression at a relatively early age. Cases which do not show such remission or those which arise in older persons have been treated in a variety of ways, including: (1) surgery, (2) radiation therapy (external radiation or radium), (3) sclerosing agents, such as sodium morrhuate or psylliate, injected into the lesion, (4) carbon dioxide snow, (5) cryotherap and (6) compression. Each form of treatment has its proponents and antagonists, but it appears that in skilled hands each has its proper place.

Salient histopathologic findings of vasoformative tumors (hemangioma and vascular malformations) are as follows:

- Hemangiomas (proliferative phase)
  - Endothelial cell hyperplasia forming syncytial masses
  - Thickened (multilaminated) endothelial basement membrane
  - Ready incorporation of tritiated thymidine in endothelial cells
  - Presence of large number of mast cells
- Hemangiomas (involuting phase)
  - Less mitotic activity
  - Little or no uptake of tritiated thymidine in endothelial cells
  - Foci of fibrofatty infiltration
  - Normal mast cell counts
- Vascular malformations
  - No endothelial cell proliferation
  - Contain large vascular channels lined by endothelium
  - Unilamellar basement membrane
  - Does not incorporate tritiated thymidine in endothelial cells
  - Normal mast cell counts

The prognosis of the hemangioma is excellent, since it does not become malignant or recur after adequate removal or destruction.

Hereditary Hemorrhagic Telangiectasia

(Osler-Weber-Rendu syndrome, Rendu-Osler-Weber syndrome, heredofamilial angiomatosis, familial hemorrhagic angiomatosis, Osler's disease)

Osler-Weber-Rendu syndrome, also known as hereditary hemorrhagic telangiectasia, is an autosomal dominant disorder identified typically by the triad of telangiectasia, recurrent epistaxis, and a positive family history for the disorder. The major cause of morbidity and mortality due to this disorder lies in the presence of multiorgan arteriovenous malformations (AVMs) and the associated hemorrhage that may accompany them.

Clinical Features. The disease most commonly occurs in white patients, but it has been described in patients of Asian, African and Arabic descent. The spider-like telangiectases are occasionally present at or shortly after birth, although in the majority of cases they do not become conspicuous until after puberty. They appear to increase in number and prominence as the patient ages. The skin lesions are most common on

Figure 2-53. Hereditary hemorrhagic telangiectasia.
(Courtesy of Dr Theodore Century).

the face, neck, and chest, although any area may be involved (Fig. 2-53). Involvement of the oral mucous membrane constitutes an important feature of the disease, the most commonly affected areas being the lips, gingiva, buccal mucosa and palate, as well as the floor of the mouth and the tongue.

One of the earliest signs of the disease, often occurring in childhood and preceding the appearance of telangiectasia, is epistaxis as well as bleeding from the oral cavity, both of which may be difficult to control. The diagnosis may be established if a history of epistaxis dating from childhood, the presence of the telangiectatic areas and the familial history are ascertained. The main areas of involvement are the nasal mucosa, skin, the GI tract, the pulmonary vasculature, and the brain.

Etiopathogenesis

The disease is caused by an inherited defect. Currently 2 loci have been identified associated with Osler-Weber-Rendu syndrome, one on chromosome arm 9q33–q34 and a second on chromosome arm 12q. Chromosome arm 9q34 harbors the endoglin gene, which encodes for a homodimeric integral membrane glycoprotein expressed at high levels on human vascular endothelial cells. Several mutations of the endoglin gene have been reported in family members affected with Osler-Weber-Rendu syndrome. Chromosome arm 12q harbors the activin receptor like kinase 1 (ALK1), which encodes for a surface receptor for the transforming growth factor beta superfamily of ligands. Several families with Osler-Weber-Rendu syndrome harbor mutations of ALK1.

Transforming growth factor beta has a role in tissue repair and angiogenesis. Thus, the development of abnormal vasculature, defects in the endothelial cell junctions, endothelial cell degeneration, and weakness of the perivascular connective tissue are thought to cause dilation of capillaries and postcapillary venules, which manifest as telangiectases, AVMs, and aneurysms.

Similar telangiectases of skin and oral mucous membranes may occur in a variety of other situations, however, and these include progressive systemic sclerosis (scleroderma) and the CREST syndrome (calcinosis cutis, Raynaud's phenomenon, esophageal dysfunction, sclerodactyly, and telangiectasia), lupus erythematosus, sarcoid and other rarer diseases. The differential diagnoses are important and have been discussed by Donaldson and Myall.

Histologic Features. The disease is due primarily to defects in the small blood vessels of the skin and mucosa. Hashimoto and Pritzker have shown, in an electron microscope investigation, that the actual cause of the hemorrhage is either a primary intrinsic defect of the endothelial cells permitting their detachment, or a defect in the perivascular supportive tissue bed which weakens the vessels, rather than a lack of elastic fibers as was thought at one time. Both clotting and bleeding times are normal, as are the blood elements, although with severe bleeding mild anemia and thrombocytopenia may result.

Treatment and Prognosis. The treatment of the disease is varied, depending upon its severity. The spontaneous hemorrhages may be controlled by pressure packs, particularly the nasal bleeding. The angiomatous or telangiectatic areas are sometimes cauterized, treated with X-ray radiation or surgically excised.

The disease is seldom so severe that life is endangered. Nevertheless a considerable number of deaths from severe hemorrhage have been reported.

Encephalotrigeminal Hemangiomatosis
(Sturge-Weber syndrome)

Sturge-Weber syndrome is a rather uncommon congenital condition. It consists of congenital hamartomatous malformations that may affect the eye, the skin, and the central nervous system at different times, characterized by the combination of a venous angioma of the leptomeninges over the cerebral cortex with ipsilateral angiomatous lesions of the face, and sometimes, of the skull, jaws and oral soft tissues. Sturge-Weber syndrome (SWS) belongs to a group of disorders collectively known as the phakomatoses (mother-spot diseases—Fig. 2-54).

Etiology. The clinical manifestations of SWS have a common embryological basis. The primary defect is a developmental insult affecting precursors of tissues that originate in the promesencephalic and mesencephalic neural crest. Then, these affected precursors give rise to vascular and other tissue malformations in the meninges, the eye, and the dermis.

Although the exact nature of the insult is unknown, it has been postulated that a somatic mutation in these precursors may lead to overproduction of an angiogenic factor. Others have suggested that SWS may be due to a lethal gene surviving by mosaicism. The influence of heredity in SWS has not been documented. To date, no gene defect has been associated with the syndrome. Several types of chromosomal abnormalities have been reported, but most patients with SWS have normal karyotypes. Most patients with SWS have a sporadic, nonfamilial disease.

Clinical Features. The facial cutaneous capillary venous angiomas (or port-wine nevi) are usually the first component of the syndrome to be observed, at birth, and are confined

A

B

Figure 2-54. Sturge-Weber syndrome.
(A) The unilateral distribution of angiomatous malformations which never cross the midline is pathognomonic of the syndrome. **(B)** Unilateral involvement of palate with angiomatous malformation.

almost exclusively to the skin area supplied by the trigeminal nerve. A second common feature is the presence of typical intracranial convolutional calcifications discernible in cranial radiographs. Ocular involvement occurs in some patients, consisting generally of glaucoma, exophthalmus, angioma of the choroid or other abnormalities.

Neurologic manifestations are among the most characteristic features of the disease and consist of convulsive disorders and spastic hemiplegia with or without mental retardation. These manifestations are directly related to the leptomeningeal angioma and calcifications, the latter being also related to the vascular disturbance.

Oral Manifestations. Occasionally, angiomatous lesions also involve the gingiva and buccal mucosa. There is generally no difficulty in diagnosis because of the presence of the facial lesions.

Treatment. The treatment of the disease is essentially a neurosurgical problem, although the convulsions can sometimes be controlled by anticonvulsant drugs.

Nasopharyngeal Angiofibroma
(Juvenile nasopharyngeal fibroma)

The nasopharyngeal angiofibroma is a relatively uncommon benign neoplasm occurring almost exclusively in the nasopharynx of adolescent males. Occasional cases have extended to involve the oral cavity, however, and for this reason the entity deserves consideration here.

Hippocrates described the tumor in the 5th century BC, but Friedberg first used the term angiofibroma in 1940. Other terms (e.g. nasopharyngeal fibroma, bleeding fibroma of adolescence, fibroangioma) also have been used.

Etiopathogenesis. A hormonal theory has been suggested due to the lesion's occurrence in adolescent males. Other theories include a desmoplastic response of the nasopharyngeal periosteum or the embryonic fibrocartilage.

Clinical Features. Nasopharyngeal angiofibroma accounts for 0.05% of all head and neck tumors. A frequency of 1: 5,000–1: 60,000 in otolaryngology patients have been reported. It occurs exclusively in males. Females diagnosed with nasopharyngeal angiofibroma should undergo genetic testing. Onset most commonly happens in the second decade; the range is 7–19 years, and it is rare in patients older than 25 years.

The lesion is generally manifested by nasal obstruction (80–90%), epistaxis (45–60%), sinusitis (25%), and facial swelling (10–18%). On examination, nasal mass (80%), orbital mass (15%), proptosis (10–15%) may be noticed. Other findings may include serous otitis due to eustachian tube blockage. Zygomatic swelling and trismus denote spread of the tumor to the infratemporal fossa. Decreasing vision due to optic nerve involvement has rarely been reported. Care must be taken to differentiate this lesion from ordinary nasal polyps, which it may resemble superficially. As the tumor mass enlarges, inferior depression of the palate and facial deformity may occur.

Oral Manifestations. The oral manifestations of the nasopharyngeal angiofibroma are generally those of a palatal or tonsillar mass, often with nasal obstruction. Occasionally, however, lesions of the posterior portion of the maxilla and even of the mandible have been seen which are microscopically identical with the nasopharyngeal lesions, and they may be considered similar in nature.

Radiographic Features. Radiograph of sinuses may demonstrate nasopharyngeal polyp, bowing of the posterior wall of the maxillary sinus and maxillary sinus opacification is very suggestive of JNA. CT scan can demonstrate extent of the tumor. Magnetic resonance imaging (MRI) is indicated

to delineate and define the extent of the tumor, especially in cases of intracranial involvement.

Histologic Features. On gross examination, the tumor is usually sessile, lobulated, rubbery, and red-pink to tan-gray in appearance. In rare cases, the tumor is polypoid or pedunculated.

The tumor is encapsulated and consists essentially of two basic and characteristic components: a vascular network and a connective tissue stroma. The vessels comprising the vascular network are of varying caliber, irregular in shape and generally consisting of a simple endothelial lining. The vascular element is generally most pronounced at the periphery of the lesion where active growth is occurring. Thrombosis and occlusion are frequently seen, usually in association with vasculitis.

The connective tissue stroma consists of both fine and coarse collagen fibrils, usually with an irregular, unoriented pattern, interspersed with plump, stellate cells arranged in a haphazard fashion (Fig. 2-55). An abundance of mast cells in the stroma and a lack of other inflammatory cells exist. Hyalinized foci are sometimes present, as well as areas resembling myxomatous degeneration. When the stromal cells are abundant, the resemblance to the sclerosing hemangioma may be pronounced. Multinucleated stromal cells are sometimes present, and with the occasional atypical nuclear and cellular changes that may be found, the lesion may be mistaken for a sarcoma.

When examined under electron microscope, stromal cells mostly are fibroblasts and show intensive immunostaining for vimentin. However, myofibroblasts may occur focally in connection with fibrotic areas and are characterized by the coexpression of vimentin and smooth muscle actin.

Treatment. Spontaneous regression is rare. Surgical resection with preoperative embolization is the preferred treatment. The testosterone receptor blocker flutamide was reported to reduce the size of the tumor in early stages. External beam irradiation is most often reserved for intracranial, unresectable, or recurrent disease. Complications are related to intracranial extension, uncontrolled hemorrhage and death, iatrogenic injury to vital structures. Postoperative radiographic surveillance is important due to high rates of recurrence (6–60%). Recurrences can occur as early as three or four months after surgery.

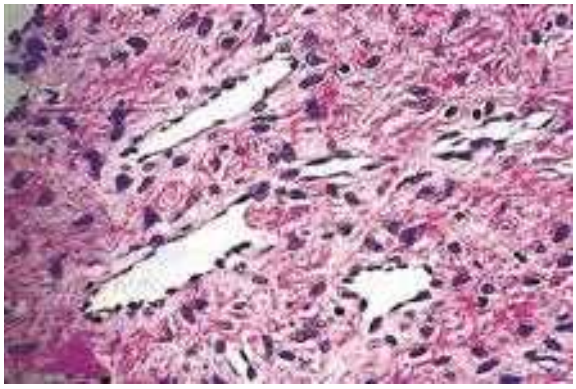

Figure 2-55. Nasopharyngeal angiofibroma.
The dense fibrous quality of the stroma and the numerous thin-walled vessels are characteristic of this entity *(Courtesy of Dr Juan Rosai)*.

Lymphangioma

The lymphangioma is a benign hamartomatous hyperplasia of lymphatic vessels, with three-fourths of all cases occurring in the head and neck region. While occasional adult-onset cases occur, this tumor is thought to be a developmental malformation of vessels which have poor communication with the normal lymph system. Diagnosed cases are typically superficial but may extend deeply into underlying connective tissues. Rarely, multiple lesions are seen in infancy and childhood in **lymphangiomatosis,** the lymphatic counterpart to angiomatosis of blood vessels and a potentially life-threatening disease when visceral involvement occurs.

A classification of the lymphangiomas has been suggested by Watson and McCarthy based upon their study of 41 cases. In this classification the following divisions are proposed: (1) simple lymphangioma, (2) cavernous lymphangioma, (3) cellular or hypertrophic lymphangioma, (4) diffuse systemic lymphangioma, and (5) cystic lymphangioma or hygroma. Very large cystic spaces may be seen in lesions proliferating in loose connective tissues and fascial spaces.

Clinical Features. The majority of cases of lymphangioma are present at birth, according to Watson and McCarthy, in whose series 95% of the tumors had arisen before the age of 10 years. In the series of 132 patients reported by Hill and Briggs, 88% of the lesions had developed by the end of the second year of life. In contrast to that of the hemangioma, the gender distribution of the lymphangioma is nearly evenly divided. The head and neck area in the series of Watson and McCarthy was the site of the tumor in 52% of the cases.

The most common head and neck location is the lateral neck, where this lesion typically contains large cystic spaces and is commonly called cystic lymphangioma or cystic hygroma.

Oral Manifestations. The intraoral lymphangioma most commonly occurs on the tongue, but is seen also on the palate, buccal mucosa, gingiva and lips (Fig. 2-56). The superficial lesions are manifested as papillary lesions which may be of the same color as the surrounding mucosa or of a slightly redder hue. The deeper lesions appear as diffuse nodules or masses without any significant change in surface texture or color. In some cases relatively large areas of tissue may be involved. If the tongue is affected, considerable enlargement may occur, and to this clinical feature the term 'macroglossia' may be applied. A series of 46 cases of lymphangioma of the tongue has been reviewed by Litzow and Lash. They pointed out that the anterior dorsal part of the tongue was most frequently affected. The irregular nodularity of the surface of the tongue with gray and pink projections is the commonest sign of the disease, and when associated with macroglossia, is pathognomonic of lymphangioma.

Lip involvement and its attendant deformity are referred to as macrocheilia. The cystic hygroma is a common and distinct

entity that is not manifested in the oral cavity but occurs in the neck as a large, deep, diffuse swelling. This has been discussed in particular by Bill and Sumner and by Paletta.

An unusual form of lymphangioma termed *lymphangioma of the alveolar ridge in neonates* has been reported by Levin and his associates. They found small blue domed fluid-filled lesions on the alveolar ridges in 55 (3.7%) of 1,470 normal black newborns; none were found in whites. Histologically, those biopsied were lymphangiomas. The natural history of this lesion is unknown, although spontaneous regression was noted in several cases.

Occasional cases of central lymphangioma of bone are also known to occur such as that in the tibia reported by Bullough and Goodfellow, as well as in the jaw.

Histologic Features. The lymphangioma consists of multiple, intertwining lymph vessels in a loose fibrovascular stroma. The lymphangioma, of which the cavernous type is the most common, consists of numerous dilated lymphatics, single layer of endothelial cells with flattened, occasionally plump, nuclei and containing lymph (Fig. 2-57). Those vessels just beneath the surface epithelium tend to fill or replace the connective tissue papillae, perhaps producing a papillary surface change. It is not unusual for a superficial lesion to have little or no fibrous stroma separating it from the overlying epithelium. Occasional channels may be filled with blood, a mixed **hemangiolymphangioma**. Occasional lesions demonstrate proliferation of lymphatic channels with another connective tissue component, primarily smooth muscle cells called **lymphangiomyoma**.

No encapsulation of even the tumors which appear well-circumscribed clinically. Deeper lesions show vessels interspersed between adipocytes and striated muscle bundles.

Lymphangioma can be subclassified into four categories:

1. **Lymphangioma simplex** (capillary lymphangioma, lymphangioma circumscriptum), composed of small, thin-walled lymphatics.
2. **Cavernous lymphangioma,** comprised of dilated lymphatic vessels with surrounding adventitia.
3. **Cystic lymphangioma** (cystic hygroma), consisting of huge, macroscopic lymphatic spaces with surrounding fibrovascular tissues and smooth muscle.
4. **Benign lymphangioendothelioma** (acquired progressive lymphangioma), lymphatic channels appear to be dissecting through dense collagenic bundles.

These categories are somewhat artificial and many lesions are combinations of categories.

Treatment and Prognosis. The treatment of the lymphangioma is considerably different from that of the hemangioma. Surgical excision is probably the treatment of choice, since the lymphangioma is more radioresistant and insensitive to sclerosing agents, such as sodium morrhuate, than the hemangioma. Spontaneous regression, according to most studies is rare. Because of the nonencapsulated and 'infiltrating' nature of the lymphangioma, complete removal is often impossible without excessive removal of surrounding normal structures. Surgical debulking of the tumor is, the typical treatment provided, and additional debulking procedures will most likely be required as the affected child grows.

Myxoma

Myxoma is a heterogeneous group of soft tissue tumors which have a common histologic appearance of abundant myxoid ground substance. This is composed of mucopolysaccharides, mainly hyaluronic acid. The myxoma of the soft tissues is a tumor which has been described by Stout as a true neoplasm made up of tissue resembling primitive mesenchyme. Thus it is composed of stellate cells arranged in a loose mucoid stroma which also contains delicate reticulin fibers. The lesion is benign and does not metastasize, although it frequently infiltrates adjacent tissues.

Clinical Features. Most soft-tissue myxomas are deeply situated lesions, occurring in the skin or the subcutaneous tissues, the genitourinary tract, the gastrointestinal tract or in organs such as the liver, the spleen, or even the parotid gland.

This tumor may make its appearance at any age, approximately equal numbers of cases having been reported in every decade of life. There is no definite gender predilection of this neoplasm. A detailed study of 58 patients with 64 tumors has been reported by Ireland and his associates.

Oral Manifestations. The intraoral soft-tissue myxoma is an extremely rare lesion. The majority of oral cases undoubtedly represent only myxomatous degeneration in a fibrous tumor, and these cannot be considered true myxomas, although Elzay has presented 15 intraoral cases which he accepted as bona fide examples.

Other cases occurring centrally within the bone of the jaws have been classified, particularly in the dental literature, as odontogenic myxomas, i.e. as tumors derived from odontogenic tissue. Even though such tumors are sometimes associated with missing or displaced teeth, their dental origin is difficult, is not impossible, to establish. Nevertheless, for the sake of convenience, the central myxoma of bone is discussed under the odontogenic myxoma in the odontogenic tumor section (q.v.).

The **nerve sheath myxoma** is a benign tumor thought to arise from perineural cells of peripheral nerves and is characterized by the occurrence of stellate cells in a prominent mucoid matrix. A few cases have been reported in the oral cavity on the tongue, buccal mucosa and retromolar area and these have been reviewed by Sist and Greene. Their ultrastructural studies, along with those of Webb, supported the perineural origin of these lesions. They are treated by local excision and do not recur.

Oral focal mucinosis, the oral counterpart of a dermal lesion known as cutaneous focal mucinosis and/or cutaneous myxoid cyst, is the lesion most commonly misdiagnosed as an intraoral soft tissue myxoma, according to the study of Tomich. In fact, he has stated that most, if not all, cases diagnosed as oral soft-tissue myxomas are in reality lesions of this entity. He reported eight cases of oral focal mucinosis, including the histologic and histochemical findings, postulating that the lesion develops because of a fibroblastic overproduction of hyaluronic acid due to an unknown stimulus.

Histologic Features. The soft-tissue myxoma is characteristically a loose-textured tissue containing moderate numbers of delicate reticulin fibers and mucoid material, probably hyaluronic acid. Oral focal mucinosis lacks this reticulin network. Interspersed throughout are varying numbers of stellate cells which occasionally assume a spindle shape. The tumor is not encapsulated and may invade surrounding tissue. This invasiveness is not characteristic of oral focal mucinosis.

Tomich has listed the 'myxoid' appearing lesions to be considered in the differential diagnosis as including: soft- tissue myxoma, odontogenic myxoma, myxomatous degeneration in a fibrous lesion, oral focal mucinosis, nerve sheath myxoma, myxoid neurofibroma, mucous retention phenomenon, and localized myxedema.

Treatment and Prognosis. The treatment of the myxoma is essentially surgical, since X-ray radiation is of little benefit. Recurrence is common, but this is not of grave concern, since the tumor does not metastasize. The attempt to avoid recurrence may necessitate the sacrifice of an appreciable amount of apparently uninvolved surrounding tissue, although this is generally not true of the intraoral lesion. In contrast, oral focal mucinosis has no tendency to recur.

Chondroma

The chondroma, a benign central tumor composed of mature cartilage, is a well-recognized entity in certain areas of the bony skeleton, but is uncommon in the bones of the maxilla or mandible. Reported cases were reviewed by MacGregor in 1952. A later review by Chaudhry and his coworkers contained only 18 cases from English scientific literature between 1912 and 1959. The lesion is of considerable clinical importance because of the propensity of the tumor to undergo malignant degeneration in some instances, even after remaining quiescent for long periods of time.

The chondroma seldom develops in membrane bones, particularly if no vestigial cartilaginous rests are present, but since both the maxilla and mandible may contain such remnants, the tumor certainly may occur in these bones. Miles pointed out that areas of 'secondary cartilage', cartilage not related to recognized parts of the chondrocranium, occur in the mandible in the mental region, coronoid process and condyle. At least in the embryo, cartilage is found in the maxilla on the lateral aspects near the malar process close to the molar teeth, as well as in the premaxillary area.

Clinical Features. This neoplasm may develop at any age and shows no apparent gender predilection. The chondroma usually arises as a painless, slowly progressive swelling of the jaw which, like many other neoplasms, may cause loosening of the teeth. The overlying mucosa is seldom ulcerated. The anterior portion of the maxilla is the most frequent site of involvement by this tumor because it is here that vestigial cartilage rests are found, particularly in the midline lingual to or between the central incisors. In the mandible the most common site of occurrence is posterior to the cuspid tooth, involving the body of the mandible, or the coronoid or condylar processes. It is also documented in the nasal septum and nasal spine and has been discussed here by Tomich and Hutton.

Occasional peripheral cases, outside bone, have been reported, such as that on the soft palate described by Gardner and Paterson or the relatively common chondroma or osteochondroma of the tongue. However, these may represent only islands of chondroid metaplasia or even a choristoma rather than a true neoplasm. Thus, they would be analogous to **osteoma mucosae** (q.v.). The relationship of these intraoral peripheral chondromas, especially those of the tongue, to the well-recognized **chondroma of soft parts**, reviewed by Chung and Enzinger, is not clearly established.

Radiographic Features. The radiograph shows an irregular radiolucent or mottled area in the bone. The chondroma is a

destructive lesion and, in addition, has been shown to cause root resorption of teeth adjacent to it.

Histologic Features. The distinction between chondroma and chondrosarcoma is a narrow one and may offer a serious problem to the pathologist confronted with only a small biopsy specimen. The chondroma is made up of a mass of hyaline cartilage which may exhibit areas of calcification or of necrosis. The cartilage cells appear small, contain only single nuclei and do not exhibit great variation in size, shape or staining reaction. Cartilaginous tumors vary considerably in appearance from area to area, so that some malignant lesions present regions of apparent benignity. For this reason, care must be exercised in the unequivocal diagnosis of such a tumor from a small biopsy specimen.

Treatment and Prognosis. The treatment of the chondroma is surgical, since the tumor is resistant to X-ray radiation. The fact that sarcomatous change is not an unlikely occurrence suggests that somewhat more than a conservative enucleation should be carried out, although radical resection cannot be justified unless the tumor is of unusual size. Because of the dearth of reported cases, the prognosis of this disease in the jaws is not known, but to judge from cases in other parts of the body, it is probably good.

Benign Chondroblastoma

(Epiphyseal chondromatous giant cell tumor, Codman's tumor)

The benign chondroblastoma of bone, named by Jaffe and Lichtenstein in 1942 but described earlier by Ewing in 1928 and Codman in 1931, is a distinct entity usually involving long bones but sometimes occurring in the cranial bones. Of 13 such cranial tumors reviewed by Al-Dewachi and his coworkers, nine occurred in the temporal bone, one in the parietal, two in the mandible and one in the maxilla.

Clinical Features. This benign, primary central bone tumor occurs predominantly in young persons, nearly 90% of a series of 69 cases reported by Schajowicz and Gallardo ranging between the ages of five and 25 years. Identical findings were reported in a series of 125 cases by Dahlin and Ivins. Males are involved more than females, usually in a ratio of about 2 to 1. The vast majority of cases involve the long bone of the upper and lower limbs. However, cases involving the mandibular condyle have been reported by Goodsell and Hubinger and by Dahlin and Ivins, while a case involving the anterior maxilla of a 13-year-old girl has been reported by Al-Dewachi and his associates. In addition, an extraskeletal chondroblastoma of the ear has been reported by Kingsley and Markel.

Histologic Features. The tumor is composed of relatively uniform, closely packed, polyhedral cells with occasional foci of chondroid matrix. A scattering of multinucleated giant cells may be found, usually associated with areas of hemorrhage, necrosis or calcification of the chondroid material. Formation of bone and osteoid also occurs, and as pointed out by Gravanis and Giansanti, is probably more common than is generally accepted. In addition, occasional cases have histologic features overlapping those of the chondromyxoid fibroma of bone.

Treatment. Conservative surgical excision is the usually accepted treatment, although recurrence is not uncommon. In a series of 25 cases reported by Huvos and his associates, an aneurysmal bone cyst was found engrafted on the primary bone lesion in 6–24% of the cases, and recurrence rate was higher in this group than in the group without the associated aneurysmal cysts.

Chondromyxoid Fibroma

The chondromyxoid fibroma is an uncommon benign tumor of cartilage derivation first described as an entity in 1946 by Jaffe and Lichtenstein.

Clinical Features. This central bone tumor has a predilection for occurrence in young persons, approximately 75% of patients being under the age of 25 years. There is no definite gender predilection. The majority of cases occur in long bones but it is also found in the small bones of the hands and feet, in the pelvic girdle and elsewhere sporadically. A case in the anterior mandible extending on either side of the symphysis of a 10-year-old girl has been reported by Schutt and Frost. It is extremely rare here, however, considering the relatively large series of cases of chondromyxoid fibroma in other bones reported, such as the 189 cases by Feldman and his associates, the 32 cases by Schajowicz and Gallardo, and the 76 cases by Rahimi and his associates. The possible cases in the jaws have been reviewed by Grotepass and his associates, adding an additional case, as have Davis and Tideman as well as Browne and Rivas.

Pain is the outstanding clinical characteristics of the lesion. Evident swelling is uncommon but does occur.

Histologic Features. This tumor characteristically exhibits lobulated myxomatous areas, fibrous areas and areas having a chondroid appearance, i.e. cells resembling chondroblasts and chondrocytes in lacunae in a chondroid matrix. In addition, foci of calcification are sometimes found. Care must be taken not to make a mistaken diagnosis of chondrosarcoma or mesenchymal chondrosarcoma.

Treatment. Conservative surgical excision is the preferred treatment for this benign tumor. However, recurrence of this tumor in other bones is not uncommon, particularly in young patients in whom the lesions appear to act somewhat more aggressively. Too few cases in the jaws have been reported to draw valid conclusions regarding biologic behavior here.

Osteoma

The osteoma is a benign neoplasm characterized by a proliferation of either compact or cancellous bone, usually in an endosteal or periosteal location. In many parts of the body it is not difficult to establish an incontrovertible diagnosis of osteoma. In the jaws, however, where infection is common it is not always possible to differentiate a bony mass induced by irritation or inflammation from one of a true neoplastic nature. In addition, the so-called exostoses and enostoses further complicate the picture, since they may produce a similar

clinical, radiographic and histologic picture. Although their nature is unknown, they might more properly be considered developmental lesions.

Clinical Features. The osteoma is not a common oral lesion. Although it may arise at any age, it seems to be somewhat more common in the young adult. The lesion of periosteal origin manifests itself as a circumscribed swelling on the jaw producing obvious asymmetry, but it must not be confused with Garre's nonsuppurative sclerosing osteomyelitis or proliferative periostitis. The osteoma is a slow-growing tumor, and so the patient does not usually become alarmed. The osteoma of endosteal origin is slower to present clinical manifestations, since considerable growth must occur before there is expansion of the cortical plates (Fig. 2-58A and B). There is seldom any pain associated with this tumor. Multiple osteomas of the jaws, as well as of long bones and skull, are a characteristic manifestation of Gardner syndrome (q.v.).

The **soft-tissue osteoma** of the oral cavity is a relatively uncommon lesion, a total of 25 cases from the literature being reviewed and reported by Krolls and his coworkers. The lesion is also known as 'osteoma mucosae,' analogous to the well-recognized dermal lesion 'osteoma cutis' and as 'osseous choristoma' after Krolls. These lesions occur almost exclusively in the tongue, although occasional cases are found in the buccal mucosa. They occur at any age and present as a firm nodule ranging up to 2 cm in diameter. Of the 25 reported cases, 18 occurred in females and only seven in males but the significance of this is not known. The bone itself is normal, well-circumscribed lamellar bone, usually compact but sometimes showing fatty marrow (Fig. 2-59B).

Radiographic Features. The central lesion usually appears within the jaw as a well-circumscribed radiopaque mass which is indistinguishable from scar bone (Fig. 2-58B). Sometimes this osteoma is diffuse, but it must be differentiated from chronic sclerosing osteomyelitis. The periosteal form of the disease also is manifested as a sclerotic mass.

Histologic Features. The osteoma is composed either of extremely dense, compact bone or of coarse cancellous bone. In any given area the bone formed appears normal (Fig. 2-58C). The lesion is most often well circumscribed, but not encapsulated. In some tumors foci of cartilage may be found, in which case the term 'osteochondroma' is often used. Myxomatous tissue also may be intermingled on rare occasions.

Treatment and Prognosis. Treatment consists of surgical removal if the lesion is causing difficulty or if a prosthetic appliance is to be constructed, particularly when the tumor lies close to the surface of the alveolar bone. The osteoma does not recur after surgical removal.

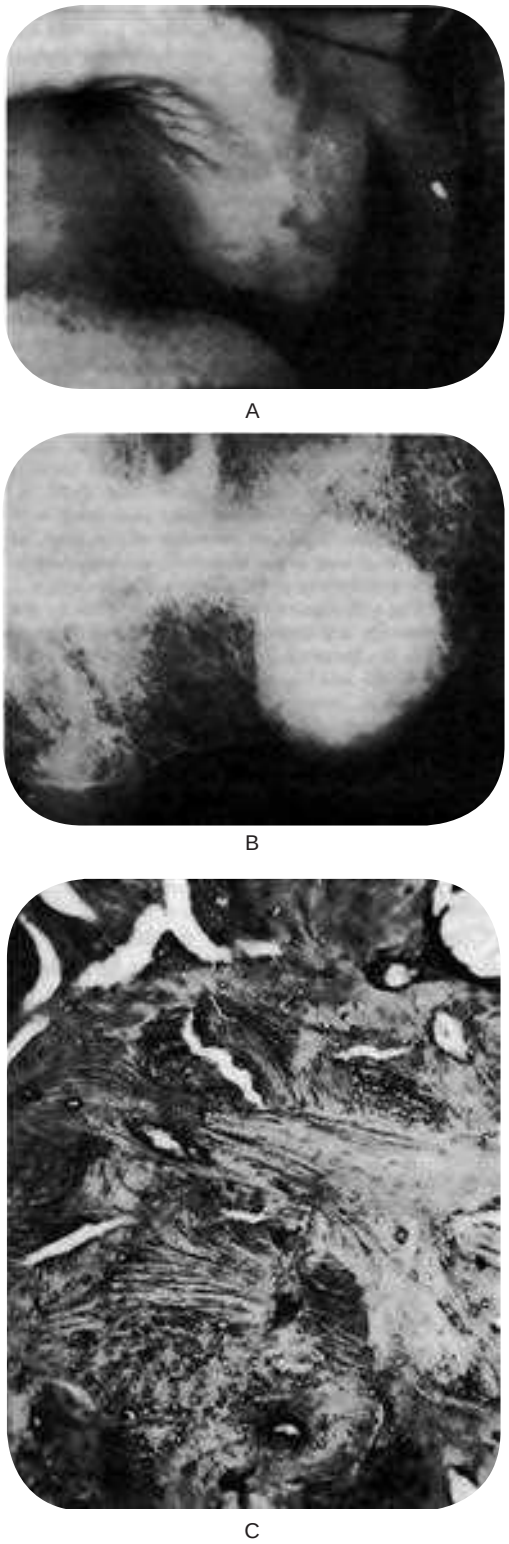

Figure 2-58. Osteoma.
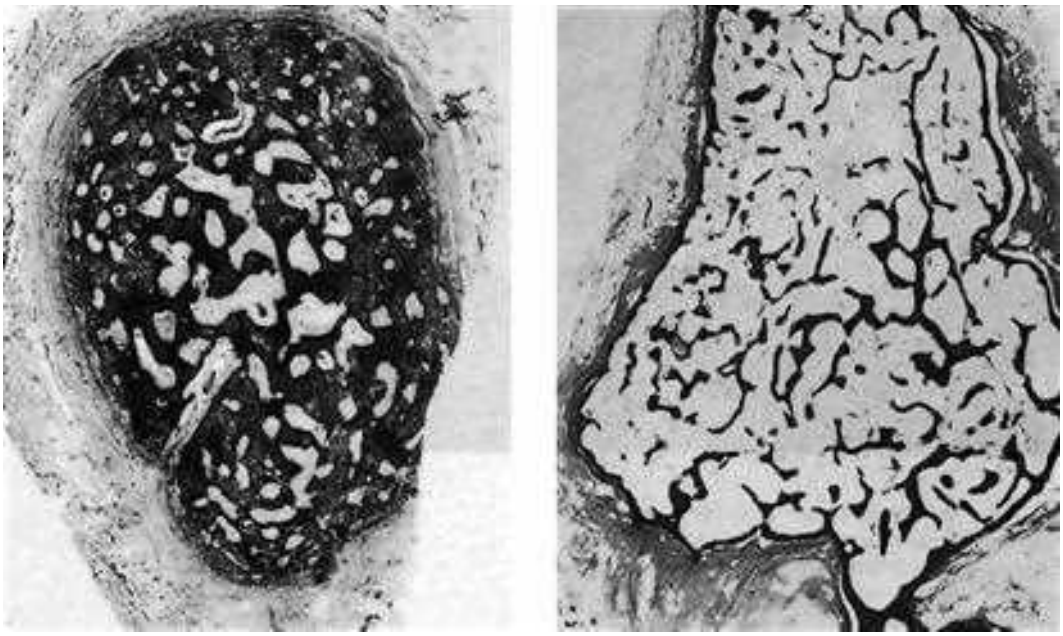
The clinical expansion of the alveolar ridge, **(A)** is seen on the radiograph, **(B)** to be due to a well-circumscribed radiopaque mass. Microscopically, this was composed entirely of dense, compact bone **(C)**.

Osteoid Osteoma

The osteoid osteoma is a benign tumor of bone which has seldom been described in the jaws. The true nature of this lesion is unknown. Jaffe and Lichtenstein have suggested that the lesion is a true neoplasm of osteoblastic derivation, but other workers have reported that the lesion occurs as a result



A B

Figure 2-59. Soft-tissue osteoma.
The osteoma mucosae may be composed of quite dense bone **(A)**, or very loose trabecular bone **(B)**.

of trauma or inflammation. In some instances it has been confused with chronic sclerosing osteomyelitis, and the osteoid osteoma may actually represent a form of this osteomyelitis. A review of the literature with an additional report of 80 cases by Freiberger and his associates has supported the neoplastic theory.

Clinical Features. The osteoid osteoma usually occurs in young persons, seldom developing after the age of 30 years. Young children under the age of 10 years or even five years are frequently affected. In most series, males predominate over females by a ratio of at least 2 to 1. It has been reported most frequently in the femur or in the tibia, although other bones throughout the body have occasionally been involved. One of the chief symptoms of the condition is severe pain out of all proportion to the small size of the lesion. The pain of osteoid osteoma is described as unrelenting and sharp, worse at night. Classically, the pain is relieved by aspirin. Localized swelling of the soft tissue over the involved area of bone may occur and may be tender.

Oral Manifestations. Greene and his associates have reviewed the literature and added one more case, bringing the total number of cases of osteoid osteoma of the jaws to seven. Of these, four have occurred in the mandible and three in the maxilla. Of the mandibular lesions, three were in the body and one in the condyle, while one maxillary lesion involved the antrum.

Radiographic Features. Radiographically, the osteoid osteoma presents a pathognomonic picture characterized by a small ovoid or round radiolucent area surrounded by a rim of sclerotic bone. The central radiolucency may exhibit some calcification. The lesion seldom is larger than 1 cm in diameter, but the overlying cortex does become thickened by subperiosteal new bone formation.

Histologic Features. The microscopic appearance of the osteoid osteoma is characteristic and consists of a central nidus composed of compact osteoid tissue, varying in degree of calcification, interspersed by a vascular connective tissue. Formation of definite trabeculae occurs, particularly in older lesions, outlined by active osteoblasts. Osteoclasts and foci of bone resorption are also usually evident. The overlying periosteum exhibits new bone formation, and in this interstitial tissue collections of lymphocytes may be noted (Fig. 2-60).

Ultrastructural investigation of five cases of osteoid osteoma by Steiner has revealed the morphology of the osteoblasts to be similar to that of normal osteoblasts although atypical

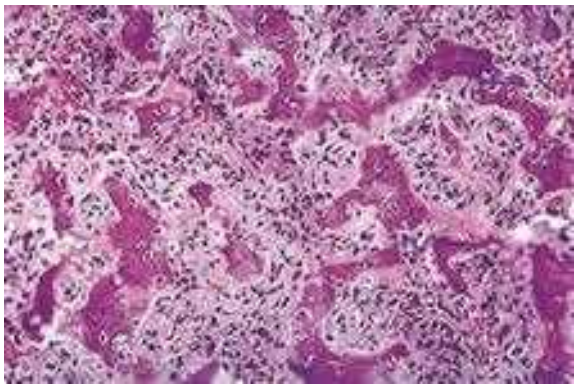


Figure 2-60. Osteoid osteoma.
This is the central nidus of an osteoid osteoma composed of irregular reactive new bone.

mitochondria could be seen. For comparison, the osteoblasts of a benign osteoblastoma were studied and were found to be essentially identical, including the atypical mitochondria. The author concluded that his observations supported the idea that the osteoid osteoma and the osteoblastoma are closely related lesions. Unlike in osteoblastoma, neural staining techniques reveal many axons throughout an osteoid osteoma, which probably accounts for the pain (the nidus). Levels of prostaglandin E_2 are markedly elevated in the nidus; this is presumably the cause of pain and vasodilatation.

Treatment. The treatment of the osteoid osteoma consists of surgical removal of the lesion. If the lesion is completely excised, recurrence is not to be expected. There is fairly good circumstantial evidence that spontaneous regression may occur in at least some untreated cases.

Benign Osteoblastoma
(Giant osteoid osteoma)

The osteoblastic nature of the tumor often results in zones similar to those of an osteoid osteoma producing a histologic resemblance that cannot be ignored. Benign osteoblastoma differs, however, in that it does not share the markedly limited growth potential of the average osteoid osteoma. Furthermore, the benign osteoblastoma frequently lacks the characteristic pain and the halo of sclerotic bone associated with osteoid osteoma. McLeod and coworkers resolved this problem by arbitrarily regarding an equivocal lesion as an osteoblastoma when the lesion was more than 1.5 cm in its greatest dimension.

The term **giant osteoid osteoma,** introduced several years ago, was an attempt to recognize the pathologic similarity of this lesion to osteoid osteoma, at the same time indicating a difference, especially in the size of the average tumor. **Benign osteoblastoma,** nevertheless, has become the most widely accepted designation for this tumor (Unni KK, 1996).

One can logically question whether benign osteoblastoma is correctly classed with true neoplasms because some osteoblastomas regress or become arrested after incomplete surgical removal. Fields within some of these tumors resemble portions of an aneurysmal bone cyst. This resemblance, coupled with the pronounced clinical similarity, suggests that both tumors may be different manifestations of a reaction to some as yet unknown agent.

There are rare well documented examples of osteoblastoma undergoing malignant change to osteosarcoma (Unni KK, 1996). The lesion called **cementoblastoma,** at or around the root of a tooth, is similar, and has been included with osteoblastoma.

The benign osteoblastoma was first described under the name 'giant osteoid osteoma' by Dahlin and Johnson in 1954 and under the presently more accepted name by Jaffe and by Lichtenstein in 1956 in separate reports. The lesion is not common but is nevertheless very important in as much as it is frequently mistaken for a malignant bone tumor even though it is actually entirely benign.

Clinical Features. This central bone tumor occurs most frequently in young persons, approximately 75% of the patients being under 20 years of age and 90% under 30 years of age. However, it does occur even in elderly adults. In most reported series, there is a definite predilection for occurrence in males. The lesion is characterized clinically by pain and swelling at the tumor site, the duration being just a few weeks to a year or more. Unlike osteoid osteoma, the pain of osteoblastoma is more generalized and less likely to be relieved by salicylates.

The most common site of occurrence is the vertebral column. Other frequently affected sites include the sacrum, long tubular bones and calvarium. The first case in the jaws was reported by Borello and Sedano in 1967, but it is now recognized that the benign osteoblastoma occurs in both the maxilla and mandible with some frequency, and a number of cases have been reported. These have been reviewed by Greer and Berman, and more recently, by Miller and his coworkers, who tabulated 26 cases: 14 mandible, 11 maxilla, and one unstated.

Radiographic Features. The lesion is not distinctive but, on the radiograph, appears rather well circumscribed. In some instances, there is purely bone destruction, while in other cases there is sufficient bone formation to produce a mottled, mixed radiolucent-radiopaque appearance (Fig. 2-61). A periosteal counterpart has been described by Goldman and such a case in the mandible is reported by Farman and his associates. The spectrum of the osteoblastoma is discussed by McLeod and his associates.

Histologic Features. There may be considerable variation in the microscopic appearance of the benign osteoblastoma. Nevertheless, the hallmark of the benign osteoblastoma consists of:

- The vascularity of the lesion with many dilated capillaries scattered throughout the tissue
- The moderate numbers of multinucleated giant cells scattered throughout the tissue, and
- The actively proliferating osteoblasts which pave the irregular trabeculae of new bone (Fig. 2-62).

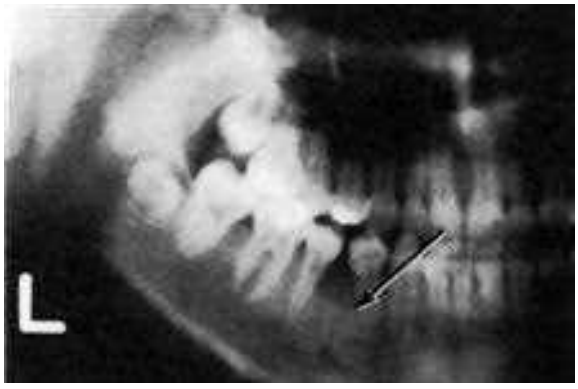

Figure 2-61. Benign osteoblastoma.
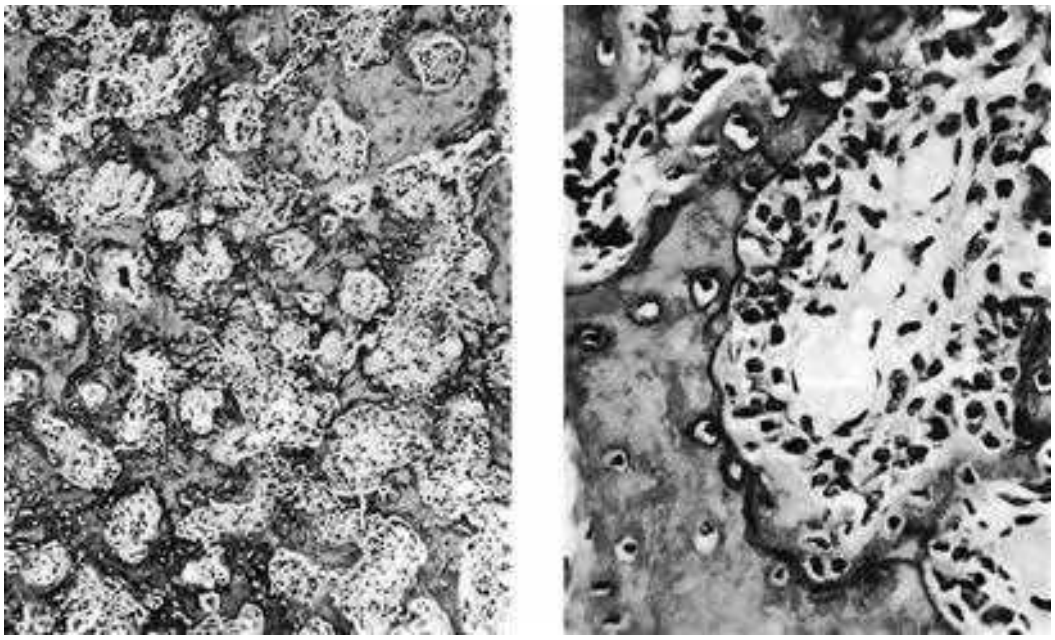
(Courtesy of Dr Ronald Vincent).



A B

Figure 2-62. Benign osteoblastoma.

These osteoblasts often appear so active and are present in such numbers that, in the past, mistaken diagnosis of osteosarcoma have often been rendered. In addition, some cases bear remarkable resemblance to an aneurysmal bone cyst.

The osteoblastoma has been studied ultrastructurally by Steiner who noted that, with a few exceptions, the tumor osteoblasts resembled normal osteoblasts. Comparative differences of osteosarcoma cells from osteoblastoma cells also did not appear pathognomonic, so he concluded that the final diagnosis of osteoblastic tumors rested at the light microscope level.

A **malignant osteoblastoma** has been described by Schajowicz and Lemos on the basis of a histologically more bizarre pattern of cells: more abundant and often plump hyperchromatic nuclei, greater nuclear atypia, and numerous giant cells. While locally more aggressive than the benign osteoblastoma, it has a better prognosis than a conventional osteosarcoma.

Finally, malignant transformation of a previously benign osteoblastoma into an osteosarcoma has also been reported, such as the case discussed by Merryweather and his coworkers.

Treatment. Conservative surgical excision is the preferred treatment for this tumor. Recurrence is rare.

Torus Palatinus

The torus palatinus is a slowly growing, flat-based bony protuberance or excrescence which occurs in the midline of the hard palate. Numerous theories have been suggested, but a plausible and thoroughly convincing explanation for this common oral lesion is still lacking. A study by Suzuki and Sakai offered evidence that both the torus palatinus and torus mandibularis are hereditary conditions, thought to follow a mendelian dominant pattern.

Clinical Features. The incidence of torus palatinus reported in the United States varies between 20 and 25%. Women are affected more frequently than men, the approximate ratio found by Kolas and his associates being 2 to 1. Although the palatine torus may occur at any age, including the first decade, it appears to reach its peak incidence shortly before the age of 30 years. Certain races, such as the American Indian and the Eskimo, are reported to exhibit a much higher incidence of torus palatinus than the general population in this country, including blacks.

The torus palatinus presents itself as an outgrowth in the midline of the palate and may assume a variety of shapes (Fig. 2-63). It has been classified clinically on this basis as flat, spindle-shaped, nodular or lobular. The mucosa overlying the torus is intact, but occasionally appears blanched. It may become ulcerated if traumatized. The torus itself may be composed either of dense compact bone or of a shell of compact bone with a center of cancellous bone, and thus it is often visible on an intraoral palatal radiograph.

Treatment and Prognosis. There is little clinical significance attached to this lesion, since it is benign and never becomes malignant. The torus is usually not treated, although occasionally it may be of such size and shape that it is impossible or impractical to construct a full or partial denture over the structure because of undercuts, the probability of trauma

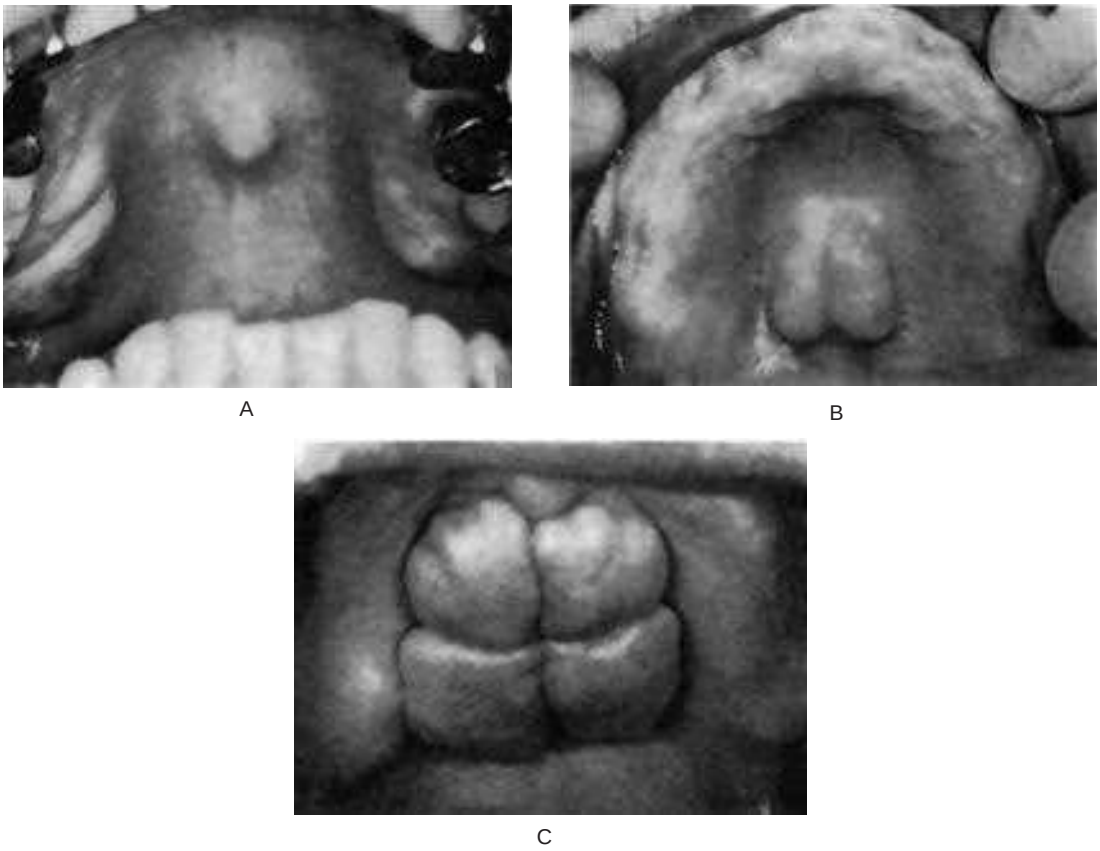


Figure 2-63. Torus palatinus.
This lesion may be a small outgrowth in the midline of the palate **(A)**, a larger lobed mass **(B)**, or may nearly completely fill the palatal vault **(C)**.

to the overlying mucosa or inability to seat the denture, owing to rocking. In such cases the situation must be appraised and the torus removed surgically before the construction of the prosthetic appliance.

Torus Mandibularis

The torus mandibularis is an exostosis or outgrowth of bone found on the lingual surface of the mandible. Just as in the case of the palatine torus, numerous causes have been suggested, but the etiology of the torus mandibularis is actually still unknown.

A genetic or ethnic background is suggested, for example, by the high frequency of occurrence in Mongoloid groups and a low frequency in Caucasoid groups, as pointed out by Sellevold. Supporting this idea through familial investigations, Suzuki and Sakai have commented on its apparent hereditary nature. Essentially, their studies showed that when one or both parents had either type of torus, the frequency of occurrence of a torus in the children ranged between 40 and 64%. When neither parents had a torus, the incidence of a torus in the children was only 5–8%. In contrast, some studies seem to favor an environmental background as the more important factor. For example, it has been found that groups of the same population living in different environments have different frequencies of occurrence of this torus, while different racial groups living in approximately the same environment have similar frequencies of occurrence. It has been an idea held for many years that a torus mandibularis will develop as a reinforcement of bone in this bicuspid area in response to the torsional stress created by heavy mastication.

Clinical Features. This growth on the lingual surface of the mandible occurs above the mylohyoid line, usually opposite the bicuspid teeth (Fig. 2-64). Like the palatine torus, it may

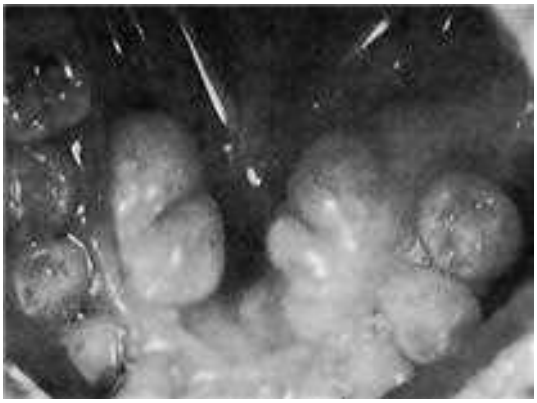

Figure 2-64. Torus mandibularis.

vary considerably in size and shape. Although the mandibular tori are usually bilateral, they are seen as a unilateral condition in about 20% of the cases. Both unilateral and bilateral protuberances may be single or multiple, and they are frequently visible on dental periapical radiographs. There is no correlation in the frequency of simultaneous occurrence of torus palatinus and torus mandibularis, according to the studies of Kolas and coworkers, suggesting that the two conditions are not related. Suzuki and Sakai reported a highly significant correlation in the frequency of simultaneous occurrence of the two tori, however.

The bilateral bony growths on the lingual of the mandible may be lobed or multiple.

The reported incidence in the United States varies between 6 and 8%, with no differences between the genders noted. Some races, such as the Alaskan Eskimos and Aleuts, are reported to have a much higher incidence of mandibular tori. Among the general population in this country the torus mandibularis is infrequently seen in the first decade of life, but it usually has its onset by the age of 30 years.

Treatment and Prognosis. Surgical removal of the torus mandibularis may be necessary because of difficulties encountered in attempting to construct a denture over the outgrowth. The lesion is comparable to the torus palatinus in its benignity.

Multiple Exostoses

Multiple exostoses of the jaws are somewhat less common than the maxillary and mandibular tori and are usually found on the buccal surface of the maxilla below the mucobuccal fold in the molar region. Clinically, these exostoses appear as small nodular protuberances over which the mucosa may appear blanched (Fig. 2-65).

There are numerous small excrescences part of bone on the buccal surface of the maxilla above the teeth and below the mucobuccal fold.

Their etiology is unknown, and no figures are available as to their incidence or disposition. They are of no clinical significance except that, if large, they may interfere with the preparation or insertion of a prosthetic appliance.

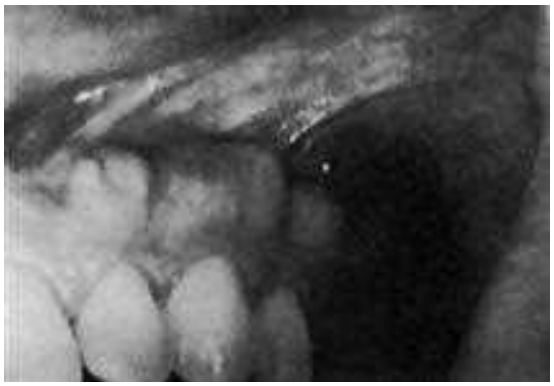

Figure 2-65. Multiple exostoses.

MALIGNANT TUMORS OF CONNECTIVE TISSUE ORIGIN

Fibrosarcoma

Fibrosarcoma is a tumor of mesenchymal cell origin that is composed of malignant fibroblasts in a collagenous background. It can occur as a soft tissue mass or as a primary or secondary bone tumor. The fibrosarcoma was once considered to be one of the most common of the malignant soft-tissue neoplasms. However, the gradual separation of other tumors from this group as our knowledge of fibrous lesions increased has in effect reduced the apparent frequency of the disease, so that nowadays fibrosarcoma, particularly of the head and neck area, is a quite uncommon neoplasm.

The sarcomas as a group differ from malignant epithelial neoplasms by their typical occurrence in relatively younger persons and their greater tendency to metastasize through the blood stream rather than the lymphatics, thereby producing more widespread foci of secondary tumor growth.

Two main types of fibrosarcoma of bone exist, **primary** and **secondary**. Primary fibrosarcoma is a fibroblastic malignancy that produces variable amounts of collagen. It is central, arising within the medullary canal, or peripheral, arising from the periosteum. Secondary fibrosarcoma of bone arises from a preexisting lesion or after radiotherapy to an area of bone or soft tissue. This is a more aggressive tumor with poorer prognosis.

Etiopathogenesis. Fibrosarcoma, like other soft tissue sarcomas, has no definite cause.

Several inherited syndromes like multiple neurofibromas may have a 10% risk over a lifetime of developing a neurosarcoma or fibrosarcoma.

Current research indicates that many sarcomas are associated with genetic mutations. Recently, a unique fusion transcript has been detected in 10 out of 11 cases (Jacqueline M et al., 2000). This fusion results from the translocation **t(12;15)(p13;q25)** giving rise to ETV6-NTRK3 (ETS variant gene 6; neurotrophic tyrosine kinase receptor type 3) gene fusion. It is absent in other spindle cell tumors of childhood as well as adult fibrosarcoma.

Fibrosarcoma also has been noted to arise from preexisting lesions, such as fibrous dysplasia, chronic osteomyelitis, bone infarcts, Paget's disease, and in previously irradiated areas of bone. These lesions are very aggressive and are associated with much poorer outcome than the primary fibrosarcoma of bone.

Clinical Features. Fibrosarcoma represents only about 10% of musculoskeletal sarcomas and less than 5% of all primary tumors of bone. No known racial predilection exists. Fibrosarcoma of bone occurs slightly more commonly in men than in women. Fibrosarcoma of bone is seen more commonly in patients of fourth decade of life and is usually in the lower extremities, especially the femur and the tibia. Fibrosarcoma of the soft tissues usually affects a wider age

spectrum of patients than fibrosarcoma of the bone, with an age range of 35–55 years. It often arises in the soft tissues of the thigh and the posterior knee. It is generally a large painless mass deep to fascia and has an ill-defined margin.

An infantile form (in children <10 years) of fibrosarcoma exists. Unlike fibrosarcoma in adults, it has an excellent prognosis, even in the face of metastatic disease at presentation, when treated with a combination of neoadjuvant and adjuvant chemotherapy and resection.

Sarcomas involving bone often present with pain and swelling after a long duration of symptoms. They may even grow large enough to threaten the structural integrity of the bone and cause pathologic fracture as the initial presentation. A prior history of bone infarct, irradiation, or other such risk factors should alert the physician to the possibility of a secondary fibrosarcoma.

Soft tissue sarcomas most often present as painless masses. The duration, however, is often shorter than with lesions involving bone. Because these lesions often arise deep in the muscular fascia, they may become extremely large tumors prior to diagnosis.

Differential diagnoses include fibrous dysplasia, fibrous histiocytoma, osteosarcoma, Paget's sarcoma, malignant fibrous histiocytoma, malignant neurosarcoma.

Histologic Features. Fibrosarcomas are tumors of malignant fibroblasts. They vary in histologic grade.

Well-differentiated forms have multiple plump fibroblasts with pale eosinophilic cytoplasm and deeply staining spindled nuclei with tapered ends. The malignant cells are dispersed in a rich collagen background. The lesion is typically scattered, histologically normal mitotic figures are seen in small numbers, but cells and nuclei are not pleomorphic (Fig. 2-66).

Intermediate grade tumors are cellular and have the typical **herringbone** pattern showing the diagnostic parallel sheets of cells arranged in intertwining whorls. Quite cellular with slight degree of cellular pleomorphism but moderate amounts of mature collagen may be produced, perhaps with areas of hyalinization (Fig. 2-67).

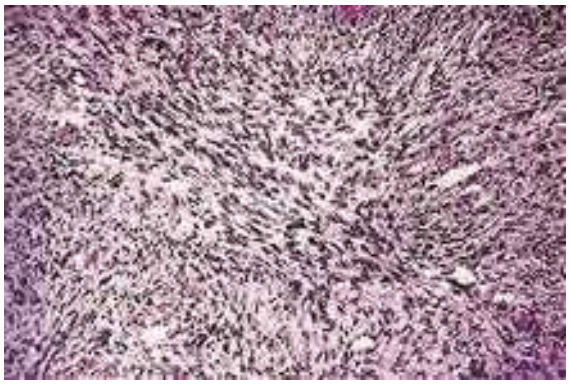

Figure 2-66. Low power appearance of well-differentiated fibrosarcoma. The tumor has a monotonous hypercellular look with regimentation of nuclei. Mitotic figures are common.

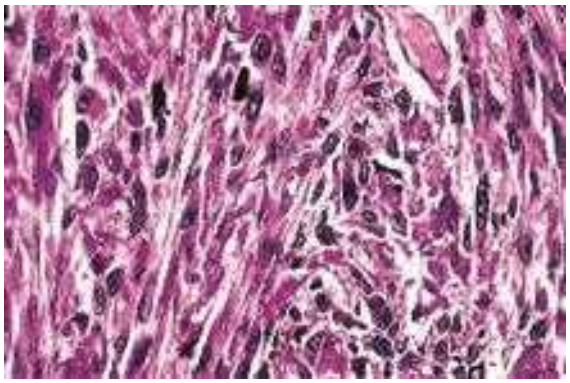

Figure 2-67. Fibrosarcoma showing moderate degree of nuclear pleomorphism.

High-grade lesions are very cellular with marked cellular atypia and mitotic activity. The matrix is sparse. Multinucleated giant cells are rarely seen. No malignant osteoid formation should be present. Higher grades are extremely anaplastic and pleomorphic with bizarre nuclei that bring to mind the histologic features of malignant fibrous histiocytoma. In fact, some pathologists believe that the division between malignant fibrous histiocytoma, high-grade osteosarcoma, and fibrosarcoma may be artificial. Immunohistochemical studies reveal positivity for smooth muscle actin, desmin, S100 protein, and CD34.

Sclerosing epithelioid fibrosarcoma is an uncommon tumor of deep soft tissues. Histologically, sclerosing epithelioid fibrosarcoma composed predominantly of small to moderate size, round to ovoid, relatively uniform cells, often with clear cytoplasm, embedded in a hyalinized fibrous stroma. The only consistent immunohistochemical finding was a strong, diffuse reactivity of tumor cells for vimentin.

Treatment and Prognosis. Tumors require radical surgery, including removal of potentially invaded muscle and bone. The use of chemotherapy is controversial, but is generally used in bone lesions. Radiation therapy is used in conjunction with surgery for soft tissue fibrosarcomas, with or without additional chemotherapy. Fibrosarcoma seldom metastasizes except late in its clinical course, but when this does occur the metastatic deposits are usually blood-born and carried to distant sites, especially the lungs, liver and bones. Radiotherapy may be used as salvage for recurrences.

If all grades are included, primary fibrosarcoma of the bone has a worse prognosis than osteosarcoma, with a five-year survival rate of 65%. Specifically, in high-grade primary fibrosarcoma, the 10-year survival rate is less than 30%. Secondary fibrosarcoma is associated with a very poor outcome, with a less than 10% survival rate at 10 years.

Miscellaneous Locally Aggressive Fibrous Lesions

There is a sizable of locally aggressive but nonmetastasizing fibrous lesions which must always be differentiated type. In the past, many of these benign but locally aggressive lesions

have been confused with sarcoma, and it is only in recent years that the pathologist has been able to separate these lesions with any assurance.

All of these lesions are quite uncommon in the oral cavity, and for this reason, no detailed description of them will be made here. This group consists chiefly of the following:

1. Nodular fasciitis (pseudosarcomatous fibromatosis)
2. Aggressive fibromatosis (extra abdominal desmoid)
3. Proliferative myositis
4. Fibrous histiocytoma (fibroxanthoma)
5. Atypical fibroxanthoma (and malignant variant)
6. Desmoplastic fibroma of bone.

Each of these lesions has been described in detail in the Atlas of Tumor Pathology Fascicle on Tumors of the Soft Tissues (AFIP) by Stout and Lattes and in the World Health Typing of Soft Tissue Tumors by Enzinger, Lattes and Torloni.

Definitions of each of the above lesions have been proposed in this WHO monograph and are reproduced as follows:

1. Nodular fasciitis. "A benign and probably reactive fibroblastic growth extending as a solitary nodule from the superficial fascia into the subcutaneous fat, or less frequently, into the subjacent muscle. Confusion with a sarcoma is possible because of its cellularity, its mitotic activity, its richly mucoid stroma, and its rapid growth. Other fibroblastic proliferations, such as proliferative myositis, are probably akin to this lesion. Nodular fasciitis is most common in the upper extremity, the trunk and the neck region of young adults."

Nodular fasciitis of the head and neck has been described in detail by Werning, who reported 41 cases in this area and reviewed the pertinent literature. In his series, lesions occurred in every age group but were most common in the third through the fifth decade of life. These lesions developed most often within subcutaneous tissues overlying the mandible and zygoma, although intraoral lesions of buccal mucosa, tongue and alveolar mucosa also occurred. Since so many of the cases occurred in areas which serve as sites of origin or insertion of muscles of mastication and which are particularly vulnerable to trauma, Werning has emphasized that this lends support to the theory that nodular fasciitis is a pseudoneoplastic exuberant fibroblastic or myofibroblastic reactive process. These were usually firm, painless masses but, on occasion, there was pain, tenderness and a history of rapid growth. The treatment for this lesion is surgical excision and recurrence is rare.

2. Aggressive fibromatosis. "A nonmetastasizing tumor like fibroblastic growth of unknown pathogenesis involving voluntary muscle as well as aponeurotic and fascial structures. Histologically, it is indistinguishable from an abdominal fibromatosis. The lesion has a strong tendency to local recurrence and aggressive, infiltrating growth. It is most common in the shoulder girdle, the thigh, and the buttock of young adults."

Aggressive fibromatosis of the oral or paraoral structures has been reported on occasion but it is quite uncommon in this location. Melrose and Abrams, reporting three cases involving the jaws of children, have discussed the protean nature of this group. For example, some are rapidly enlarging while others are of quite slow growth. Pain may or may not be present. When in apposition to bone, destruction of the bone occurs. The microscopic appearance of their lesions was quite uniform, however, consisting of cellular interlacing bundles of elongated fibroblasts showing no pleomorphism, little or no mitotic activity and no giant cells but typically with numerous slit-like vascular spaces not associated with inflammation. Treatment consists of complete surgical excision with generous margins of normal tissue. Recurrence is always a strong possibility and some workers recommend prolonged indefinite follow-up.

3. Proliferative myositis. "A rapidly growing, poorly circumscribed, probably reactive proliferation of fibroblasts and ganglion cell-like giant cells involving chiefly the connective tissue framework of striated muscle tissue. In contrast to myositis ossificans, a history of preceding trauma is infrequent and the lesion occurs chiefly in patients older than 45 years. The lesion is benign and should not be mistaken for a rhabdomyosarcoma or some other malignant neoplasm. Proliferative myositis has been discussed in Chapter 20 on Diseases of the Nerves and Muscles (q.v.).

4. Fibrous histiocytoma. "A benign, unencapsulated and often richly vascular growth made up of histiocytes and collagen-producing fibroblast-like cells, which are arranged in a whorled or cartwheel pattern. Frequently, the growth contains lipid-carrying macrophages. It may occur anywhere but is most common in the dermis."

5. Atypical fibroxanthoma. "A probably benign growth, which is closely related to fibroxanthoma but shows a much greater degree of cellular pleomorphism with multinucleated giant cells and occasional giant cells of the Touton type as well as numerous mitotic figures, including atypical forms. The relatively small size of the lesion (generally less than 3 cm), its prevalence in the sun-damaged or irradiated skin of elderly individuals, and the fact that it is usually well-circumscribed, help in the difficult differential diagnosis from malignant fibroxanthoma. It probably does not occur in the oral cavity.

6. Desmoplastic fibroma of bone. This is a lesion of bone, including the jaws, which is histologically indistinguishable from aggressive fibromatosis or the extra abdominal desmoid. Although there is a wide spread in the age of occurrence, the vast majority of cases have occurred in the second decade. The lesion does not metastasize but often shows local recurrence. Wide local excision is, therefore, the treatment of choice.

The desmoplastic fibroma of the jaws has been reviewed by Freedman and his associates, who have analyzed and discussed 26 cases described in the literature. They found also that nearly all cases in this location occurred in the first three decades of life with the vast majority involving the mandible, particularly the molar-ramus-angle area. Swelling of the jaw was the common presenting complaint, pain or tenderness rarely being present. In a high percentage of cases, the lesions appeared as well-delineated radiolucencies, either unilocular or multilocular. The broadening of the microscopic

parameters of this lesion was also emphasized by Freedman, who summarized the concept of the desmoplastic fibroma of bone as being composed of cells that may be either small and uniform, plump and uniform, or both in the same lesion, set in a variably collagenized stroma. The cells lack anaplastic forms or significant numbers of mitotic figures. Treatment of this lesion appears to be surgical excision or thorough curettage. Recurrence of jaw lesions has been uncommon.

Fibrous Histiocytoma

Fibrous histiocytoma represents a benign but diverse group of neoplasms which exhibit both fibroblastic and histiocytic differentiation. The cell of origin is believed to be the histiocyte, but the varied microscopic appearance of the lesion has led to the use of numerous alternative diagnostic terms, including dermatofibroma, sclerosing hemangioma, xanthogranuloma, fibroxanthoma, and nodular subepidermal fibrosis. A malignant variant of this neoplasm is discussed in the following section.

Clinical Features. The most common site of occurrence is the skin of the extremities, where it usually presents as a small, firm nodule. Oral and perioral lesions are uncommon, but when seen they occur predominantly on the buccal mucosa and vestibule (Fig. 2-68). The oral lesion is typically found in middle-aged and older adults, where it presents as a painless submucosal nodule which can vary in size from a few millimeters to several centimeters. Deeper tumors tend to be larger and most lesions cannot be easily moved about beneath the epithelium.

Histological Features. Fibrous histiocytoma is characterized by a submucosal, cellular aggregation of spindle-shaped, fibroblast like cells with relatively pale, oval nuclei; scattered rounded histiocytic cells are also present. Foamy histiocytes and **Touton-type** multinucleated giant cells, with nuclei pushed to the periphery, may be seen to contain phagocytosed lipid or hemosiderin; these cells sometimes are so numerous that they form xanthomatous aggregates. A background stroma of variably dense collagenous tissue and vascularity is seen. The spindled cells may be arranged randomly but usually there are large areas with tumor cells streaming in interlacing fascicles from a central nidus and intersecting with cells from adjacent aggregates, imparting a **storiform** or crisscross pattern on low power magnification.

Figure 2-68. Benign fibrous histiocytoma of cheek (intraoperative view).

The fibrous histiocytoma is poorly demarcated from surrounding tissues and is separated from the overlying mucosa by a zone of fibrovascular connective tissue (grenz zone). The overlying epithelium often demonstrates considerable acanthosis, with regular elongation of rete processes. Chronic inflammatory cells, especially lymphocytes, are usually scattered throughout the tumor in small numbers. The lesional stroma is occasionally very densely fibrotic or hyalinized, leading some in the past to use the diagnostic misnomer **sclerosing hemangioma**. Deeper lesions may contain focal areas of dystrophic calcification or metaplastic osteoid.

Benign fibrous histiocytoma is often confused with other benign fibrous lesions and must be differentiated from nodular fasciitis, myofibroma, palisading encapsulated neuroma, neurofibroma, leiomyoma and the spindle cell type of myoepithelioma. It is important, moreover, to separate this tumor from aggressive forms of fibrous and fibrohistiocytic neoplasms such as dermatofibrosarcoma protuberans, malignant fibrous histiocytoma and fibrosarcoma.

Treatment and Prognosis. Benign fibrous histiocytoma is treated by wide surgical excision, with 5–10% of cases recurring locally. Deeper and larger lesions have a higher rate of recurrence. More aggressive examples usually show the microscopic features of dysplasia, such as marked cellularity, mitotic activity, focal necrosis, even atypical giant cells. It is sometimes, however, very difficult to predict biological behavior on the basis of cellular features alone. This warrants the need for extensive follow-up of cases.

Malignant Fibrous Histiocytoma

Malignant fibrous histiocytoma (MFH) was first described in 1964 under the name malignant fibrous xanthoma. Since then several major variants have been identified and it has become the most commonly diagnosed of all the sarcomas of adults. Oral and maxillofacial sites are seldom involved, however, and the tumor occurs primarily in the soft tissues of the extremities and retroperitoneum.

Clinical Features. The MFH occurs primarily in adults, especially those 50–70 years of age, but rare cases have been described in children. Regardless of the histopathologic subtype, men are affected almost twice as frequently as women.

Within the maxillofacial region the most common complaint is a moderately firm submucosal mass expanding slowly or moderately fast, with or without pain and surface ulceration. The irregular nodular lesion is typically unencapsulated and attached to surrounding tissues and adjacent structures. It is usually less than 4 cm in greatest diameter at the time of biopsy. The myxoid variant often has a soft consistency and the angiomatoid variant is often found in a location more superficial than that of the other variants.

Histologic Features. MFH has a wide spectrum of cellular and tissue alterations. The cellular differentiation and density vary markedly, even within the same tumor. The classic histopathologic features, however, include at least mild cellular and nuclear pleomorphism, an admixture of fibroblastic and histiocytic elements, and focal areas with a storiform or cartwheel pattern of streaming spindle cells. This classic pattern is the one most frequently encountered in head and neck sites and is often referred to as the **storiform-pleomorphic MFH**.

Most lesional cells are spindled fibroblast like cells which tend to be arranged in short woven fascicles or bundles. The spindle cells may be long and thin with minimal atypia, but there are usually areas with plump cells containing enlarged, hyperchromatic and irregular nuclei. Varying numbers of rounded, polygonal and irregularly shaped histiocyte like cells may dominate some areas of the lesion, often with very pleomorphic, multinucleated giant cells interspersed. The histiocytic cells have either abundant eosinophilic cytoplasm or pale foamy cytoplasm, and cell membranes are not easily visualized. Areas with histiocytic predominance usually have a haphazard structural appearance.

Chronic inflammatory cells are often scattered sparsely throughout the tumor, including foamy histiocytes, lymphocytes and plasma cells. Mitotic activity varies widely and is directly related to the degree of cellular pleomorphism.

The fibrous stroma of MFH varies in density, being less pronounced in areas of lesser cellular differentiation. Myxoid stroma may be found, and rarely, foci of osteoid or cartilage metaplasia are present. While blood vessels are usually inconspicuous, some lesions present with numerous dilated, branching vessels. Depending on the dominant morphology, MFH is currently subclassified as one of several major variants: **pleomorphic-storiform, myxoid, angiomatoid (aneurysmal), and giant cell MFH**.

Treatment and Prognosis. MFH of the oral region is usually treated by radical surgical resection, but at least 40% of lesions recur locally and a similar proportion metastasize within two years. Five-year survival is no more than 30%, although it is somewhat better for the myxoid variant.

Synovial Sarcoma

Synovial sarcoma comprises 8–10% of all sarcomas and most commonly affects adults in the third-to-fifth decades of life. The malignancy most commonly involves the extremities, especially the lower extremities around the knees. Synovial sarcoma frequently is misdiagnosed as benign often because of its small size, slow growth, and well-defined appearance.

Etiopathogenesis. Synovial sarcoma is so named because of its resemblance to developing synovial tissue under light microscope. It arises from pluripotential mesenchymal cells near joint surfaces, tendons, tendon sheaths, juxta-articular membranes, and fascial aponeuroses.

Clinical Features. Synovial sarcoma can occur in patients with a wide age range, but it is most common in patients in the third-to-fifth decades of life. In one series of 121 cases, 83.6% of tumors occurred in patients aged 10–50 years, with a median age of 31.3 years (Lewis JJ et al, 2000). A slight male predilection is seen with the male-to-female ratio of 3 : 2. The region around the knee is the most common site of involvement. In head and neck area this tumor is very rare. Other head and neck locations include the cervical or parapharyngeal regions, masticator space, soft palate, tongue, suboccipital and infratemporal fossa regions, and sinonasal space. Most synovial sarcomas are found within 5 cm of a joint; only 10% of cases are intraarticular.

The clinical features of synovial sarcoma are nonspecific. No features to distinguish synovial sarcoma from other sarcomas. Most commonly, patients notice a slowly enlarging, deep-seated mass, which is painful in slightly more than one half of patients. In head and neck involvement, patients complain of symptoms such as dyspnea, dysphagia, hoarseness, and headache.

Specific cytogenetic abnormalities have been identified. More than 90% of patients have a **t(X;18)** translocation mutation, which is not associated with other sarcomas. The **t(X;18)(p11;q11)** translocation fuses the SYT gene from chromosome 18 to either of two homologous genes at Xp11, either SSX1 or SSX2. The fusion proteins SYT-SSX1 and SYT-SSX2 are believed to function as aberrant transcriptional regulators, resulting in either activation of protooncogenes or inhibition of tumor suppressor genes. The downstream targets of these fusion proteins that lead to transformation have not been identified.

Radiographic Features. Plain radiograph may aid in the diagnosis as synovial sarcoma typically produces spotty calcification (**snowstorm**) within the matrix of the soft-tissue tumor. CT scan or MRI is used to confirm the presence of a mass, its size, and its location.

Histologic Features. Gross specimens are usually well-demarcated, pink, fleshy masses with a heterogeneous appearance, and specimens may display solid, hemorrhagic, or cystic components on sectioning. Calcification foci are occasionally noted. Heavy calcification tends to indicate less aggressive lesions and offers a more favorable prognosis.

Typical morphology is that of two strikingly distinct well-differentiated cell populations. Depending on which cell type predominates, overall histologic appearances can be described as **biphasic** (epithelioid and spindle cell), **monophasic** spindle cell, or monophasic epithelioid. Marked cellular pleomorphism and atypia are uncommon, and when present, the appearance overlaps with that of high-grade malignant fibrous histiocytoma and fibrosarcoma.

The histologic appearance is that of large polygonal cells (epithelioid) which show an organization suggestive of microscopic joint spaces (cleft like or slit like spaces lined by cuboidal epithelial-like cells). The spaces may contain a PAS-positive mucoid material. These cells are surrounded

by spindle cells that simulate subsynovial mesenchymal cells. Punctate areas of calcification may be observed. The second pattern is comprised of a fibrosarcoma like proliferation of cells with associated collagen and reticulin. A monophasic pattern without the slit like spaces exists but is very uncommon.

Treatment. The treatment is wide resection with negative margins, which often include surrounding muscle groups or total amputation. Resection is commonly followed by localized irradiation. Synovial sarcomas have been shown to be markedly chemosensitive, multidrug adjuvant chemotherapy is currently recommended for systemic control of the tumor. The prognosis of head and neck synovial sarcoma is better than that of sarcoma involving the extremities, with five-year survival rates of 47–82%.

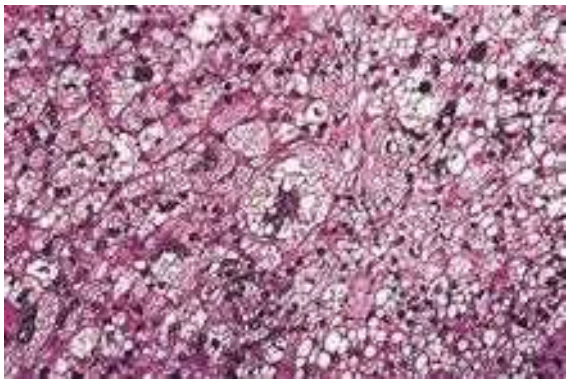

Figure 2-69. Liposarcoma.
Numerous tumor giant cells and malignant cells showing features of lipoblasts *(Courtesy of Dr Juan Rosai).*

Liposarcoma

Liposarcoma is a malignancy of fat cells. Virchow first described liposarcoma in the 1860s.

The most recent World Health Organization classification of soft-tissue tumors recognizes five categories of liposarcomas:

- Well differentiated, which includes the adipocytic, sclerosing, and inflammatory subtypes
- Dedifferentiated
- Myxoid
- Round cell
- Pleomorphic.

In rare circumstances, lesions can have a combination of morphologic types; these are classified as **combined or mixed-type** liposarcomas.

Chromosomal reciprocal translocation **t(12;16) (q13;p11.2)** is seen to be associated with the development of liposarcomas. The 12q13–15 region encodes for important protooncogenes including MDM2, CDK4, HMGI-C, SAS, GLI, CHOP, OS1, and OS9 which play varying roles in oncogenesis.The most common chromosomal translocation is the CHOP-FUS, TLS or EWS fusion gene, which encodes a transcription factor necessary for adipocyte differentiation.

Etiopathogenesis. No well-established causative factor has been identified, although trauma has been implicated. The development of a liposarcoma from a preexisting benign lipoma is rare. Most cases arise de novo. Liposarcomas most frequently arise from the deep-seated connective tissue stroma rather than the submucosal or subcutaneous fat.

Clinical Features. Liposarcoma is the most common soft-tissue sarcoma, accounting for approximately 17% of all soft-tissue sarcomas with an annual incidence of 2.5 cases per million population, and 3% of all liposarcomas occur in the head and neck region.

Although there is a wide range, from children to the very elderly, the liposarcoma of the head and neck region occurs most frequently in adults. Liposarcomas are slightly more common in males than in females. No association with race or geography is known. Oral involvement is rare; a fewer than 50 oral cases has been reported.The most commonly affected site was the tongue; other sites are the submandibular area, cheek, tongue, floor of mouth and soft palate. Most cases present as a slowly growing, painless, nonulcerated submucosal mass. But some lesions grow rapidly and become ulcerated early. The clinical impression seems to be lipoma or fibroma in the majority of cases. Tumor size ranged from 0.6–8.0 cm.

Histologic Features. The recognition of lipoblasts is the key finding in the diagnosis of liposarcoma. A lipoblast has the ability to produce and accumulate nonmembrane-bound lipid within its cytoplasm (Fig. 2-69).

Well-differentiated liposarcomas usually contain a predominance of mature fat cells with relatively few, widely scattered lipoblasts. A misdiagnosis of lipoma can result from inadequate sampling. In the **sclerosing subtype** of a well-differentiated liposarcoma, collagen fibrils that encircle fat cells and lipoblasts make up a prominent part of the matrix.

Myxoid liposarcoma, the most common type, is diagnosed by the observation of a delicate plexiform (chicken wire) pattern of capillary network that is associated with both primitive mesenchyme-like cells (spindle cells) and a variable number of lipoblasts. The stroma contains a large proportion of myxoid ground substance (i.e. hyaluronic acid), in which numerous microcysts may form.

In the **round-cell** type, lipoblasts with very little lipid are interspersed among sheets of poorly differentiated round cells. The round cells have a small to moderate amount of finely vacuolated or granular cytoplasm and may appear epithelioid or pericytoid.

Poorly differentiated **pleomorphic liposarcoma** is recognized by an extreme cellularity, mixture of bizarre, often multivacuolated lipoblasts and atypical stromal cells, many of which contain highly abnormal mitotic figures including bizarre giant cells. Lesional cells may be polygonal or stellate

with pale eosinophilic cytoplasm and poorly-demarcated cell boundaries. Hemorrhagic and necrotic areas are common. The characteristic lipoblast distinguishes pleomorphic liposarcoma from malignant fibrous histiocytosis (MFH). The round-cell and pleomorphic types are the high-grade liposarcomas.

However, it has been noted by Baden and Newman that the majority of liposarcomas of the head and neck area were myxoid liposarcomas and that the majority of these were well-differentiated neoplasms.

Stains for lipids are often useful in the diagnosis of liposarcoma, but this material may be scarce and is sometimes produced by unrelated mesenchymal and epithelial neoplasms. The mucinous matrix, when present, will stain with alcian blue and is metachromatic with toluidine blue and cresyl violet stains; it is weakly positive with Meyer's mucicarmine stain. Intracellular glycogen (diastase-sensitive, PAS positive) may be seen in some lesional cells. Adipocytes and lipoblasts react positively for vimentin and S100 protein immunostains, but these vary in intensity and may not be expressed in poorly differentiated lesions.

Treatment and Prognosis. Liposarcoma of the oral region is typically treated by wide local excision. Radiotherapy may be used to control local recurrence and lessen the risk of metastasis.

Hemangioendothelioma

Hemangioendothelioma is a varied group of proliferative and neoplastic vascular lesions, which have a biological behavior that falls somewhere between the benign hemangioma and malignant angiosarcoma. Approximately 10% of cases are associated with other developmental anomalies or syndromes, including early onset varicose veins, lymphedema, Klippel-Trenaunay-Weber syndrome, and Maffucci's syndrome.

Chromosomal translocation involving chromosomes 1 and 3 **[t(1;3)(p36.3;q25)]** was detected in few cases of epithelioid hemangioendothelioma.

Clinical Features. The tumor is usually seen during the second and third decades of life and there is no gender predilection. This neoplasm may occur anywhere in the body, but is most commonly found in the skin and subcutaneous tissues. Primary lesions of the oral cavity, though not common, have been reported in a variety of locations, including the lips, palate, gingiva, tongue and centrally within the maxilla and mandible. The literature pertaining to malignant hemangioendotheliomas of the oral cavity was reviewed by Wesley and his associates and Zachariades and his coworkers, who tabulated 46 reported oral cases.

The hemangioendothelioma arises at any age and has been found present even at birth. Females appear to be affected almost twice as often as males. Localized swelling may be the primary manifestation of the lesion, although pain is occasionally present as well.

The malignant hemangioendothelioma is similar to the hemangioma in appearance and is usually manifested clinically as a flat or slightly raised lesion of varying size, dark red or bluish red, sometimes ulcerated and showing a tendency to bleed after even slight trauma. Bone may be involved by the tumor, producing a destructive process.

Histologic Features. The hemangioendothelioma is a poorly circumscribed, usually biphasic proliferation of venous or capillary vessels. There are dilated and congested veins with inactive endothelial cell nuclei and with occasional thrombi or phleboliths. These vessels are intermixed with solid sheets of epithelioid (**epithelioid hemangioendothelioma**) or spindle-shaped (**spindle cell hemangioendothelioma**) mesenchymal cells with minimal dysplasia, few mitotic figures, and minimal differentiation toward a vascular lumen or channel.

The epithelioid cells have abundant eosinophilic cytoplasm, may contain vacuoles (primitive lumina), and may be admixed with smooth muscle bundles. These cells stain positively with *Ulex europaeus* and many will show cytoplasmic factor VIII-associated antigen reactivity with immunohistochemistry. Tumor cells also stain for endothelial markers such as CD31 and CD34 in approximately one-fifth of cases.

The lesional cells of the spindle cell hemangioendothelioma are rather bland, bipolar mesenchymal fibroblast like cells which may contain vacuoles, presumed to be abortive or primitive vascular lumina. Epithelioid cells are usually seen in small numbers in scattered areas and the associated dilated venous channels are more prone to contain thrombi and phleboliths than are those of the epithelioid hemangioendothelioma. **Kaposiform hemangioendothelioma,** histopathologically an admixture of tissues similar to both capillary hemangioma and Kaposi's sarcoma, has been reported from an oral or pharyngeal location (Zukerberg LR et al, 1993). Uniform spindle cells with pale eosinophilic cytoplasm and elongated nuclei associated with slit like vascular channels, similar to those of Kaposi's sarcoma, with mild extravasation of erythrocytes and hemosiderin deposition within or outside of macrophages. Mitotic figures and atypia are rare.

Polymorphous hemangioendothelioma consists of mixture of solid and primitive vascular and angiomatous endothelial areas.

The pathologist must be careful to rule out metastatic carcinoma or melanoma, which typically display much more dysplasia than hemangioendothelioma. The various epithelioid sarcomas must also be ruled out, especially the epithelioid angiosarcoma.

Treatment and Prognosis. Hemangioendothelioma is treated with wide surgical excision, with more than half of all cases recurring at the operative site or near by. Almost one third of epithelioid hemangioendotheliomas develop metastases to regional lymph nodes, the lungs, liver or bones.

Hemangiopericytoma

Stout and Murray in 1942 were the first to suggest hemangiopericytoma as a distinctly different vascular neoplasm. Stout also was the first to report an oral hemangiopericytoma, just a few years after its initial reporting. It is a neoplasm which is usually benign but has a definite malignant counterpart.

Head and neck lesions represent 16–25% of all reported hemangiopericytomas, and the tumor represents 2–3% of all soft tissue sarcomas in humans. Chromosomal translocations **t(12;19) and t(13;22)** have been observed in lesional cells.

Clinical Features. The oral hemangiopericytoma is typically a rapidly enlarging red or bluish mass which arises in all age groups but is rare prior to the second decade or after the seventh decade. There is no gender predilection. It is soft or rubbery, is usually painless and is relatively well demarcated from the surrounding mucosa. The lesion may be sessile or somewhat pedunculated, and may demonstrate a surface lobularity or telangiectasia. Intraosseous examples have been reported.

The oral/pharyngeal mucosa is, additionally, one of the most common locations for the rarely reported **infantile hemangiopericytoma.** This lesion is usually multiple and congenital, and often demonstrates an alarmingly rapid rate of enlargement after birth. Although this entity tends to recur after surgical excision, there is no potential for metastasis.

Histologic Features. On gross examination, hemangiopericytomas may be well circumscribed and appear grayish white. The appearance is much less hemorrhagic than endothelial tumors. The consistency is variable and may be solid or spongy, friable or granular (Fig. 2-70).

Hemangiopericytoma is a tumor thought to be derived from pericytes. Hemangiopericytoma consists of numerous vascular channels with plump endothelial nuclei and a surrounding, tightly packed proliferation of oval and spindled cells, hyerchromatic nuclei and a moderate amount of cytoplasm. The cells have indistinct cytoplasmic borders. The tumor cells do not arise from endothelial cells even though they surround irregular vascular spaces. The branching vascular channels

Figure 2-70. Hemangiopericytoma of floor of mouth.
(Courtesy of Dr Irwin A Small).

Figure 2-71. Dilated, thin-walled vessels as shown here are common. These vessels simulate 'staghorns' that are often associated with hemangiopericytoma.

of varying sizes is often described as a **'staghorn'** pattern (Fig. 2-71). Older, less aggressive lesions tend to have less cellularity and may have a largely mucoid interstitial appearance, which can be mistaken for myxoid lipoma or myxoid liposarcoma. Focal cartilage production may rarely be seen and such lesions must be differentiated from mesenchymal chondrosarcoma.

Reticulin staining will demonstrate lesional vessels lined by a single layer of endothelial cells, with the pericytes lying outside the basal lamina. Lesional cells are immunoreactive for vimentin (variable intensity), factor XIIIa antigen, HLA-DR antigen and QBEND10 (CD34). They do not stain for or react with factor VIII-related antigen, *Ulex europaeus* I lectin, alpha-smooth muscle actin, desmin, myoglobin, low-molecular weight cytokeratin, high-molecular weight cytokeratin, or epithelial membrane antigen.

The differential diagnosis of this lesion includes, in addition to the tumors named above, fibrous histiocytoma, MFH, synovial sarcoma, other stromal sarcomas, vascular leiomyoma, and juvenile hemangioma.

Treatment and Prognosis. The treatment of hemangiopericytoma is dependent on the amount of cellular dysplasia and mitotic activity. The more bland lesions with minimal mitotic activity are treated by wide local excision, but the more active and dysplastic lesions are treated by radical surgical excision, with or without adjunctive radiotherapy.

Multiple Idiopathic Hemorrhagic Sarcoma of Kaposi
(Kaposi's sarcoma, angioreticuloendothelioma)

Kaposi's sarcoma is a multicentric proliferation of vascular and spindle cell components, which was first described in 1872 by Moritz Kaposi, a Hungarian dermatologist, who described skin tumors in five men in their sixth and seventh decades of life as **'idiopathic multiple pigmented sarcoma of the skin'**. Now considered to be a viral-induced or viral-associated tumor, it is unclear whether the lesion is a true neoplasm or a simple hyperplasia. This tumour is currently incriminated with HIV/AIDS and its clinical stage depends greatly on the

immune status of the patient. Although found predominantly in HIV-infected persons, HIV does not seem to be the direct cause of the tumorous proliferation and HIV amino acid sequences have not been identified within lesional cells.

Clinical Features. Kaposi's sarcoma has four major clinical presentations: **classic (chronic), endemic (lymphadenopathic; African), immunosuppression-associated (transplant), and AIDS-related.**

The classic variant is often associated with altered immune states as well as lymphoreticular and other malignancies. Cutaneous multifocal blue-red nodules develop on the lower extremities and slowly increase in size and numbers, with some lesions regressing while new ones are forming on adjacent or distant skin. Oral involvement in this form of the disease is quite unusual but when it occurs it does so as soft, bluish nodules of the palatal mucosa or gingiva.

Lymphadenopathic Kaposi's sarcoma is endemic to young African children and presents as a localized or generalized enlargement of lymph node chains, including the cervical nodes. The disease follows a fulminant course with visceral involvement and minimal skin or mucous membrane involvement. In the head and neck region, salivary glands may be affected. This variant does not appear to be HIV related.

Transplantation-associated Kaposi's sarcoma is seen in 1–4% of renal transplant patients, usually becoming manifested one or two years after transplantation. The extent and progression of the disease correlates directly with the loss of cellular immunity of the host. Sarcomatous involvement occurs on the skin as well as internal organs, but oral mucosal lesions are decidedly rare.

AIDS-related Kaposi's sarcoma. Approximately 40% of homosexual AIDS patients will develop Kaposi's sarcoma, often as an early sign of the disease. Affected patients are usually young adults or early middle-aged males, with the average age at diagnosis being 39 years in the US. Individual lesions occur in many cutaneous locations, especially along lines of cleavage and on the tip of the nose. Oral lesions can also occur on any mucosal surface but have a strong predilection for palatal and gingival mucosa.

Figure 2-72. Kaposi's sarcoma.

Early oral mucosal sarcomas are flat and slightly blue, red or purple plaques, either focal or diffuse, may be completely asymptomatic and easily overlooked. With time, lesions become more deeply discolored and surface papules and soft nodules develop, or may become exophytic and ulcerated, and may bleed, usually remaining less than 2 cm *in size* (Fig. 2-72). Individual lesions may coalesce and occasional patients never develop the nodular variant. Cervical lymph nodes and salivary gland enlargement may also be seen. The patient may have oral candidiasis and AIDS-related gingivitis as well. Other oral sites of KS involvement include the gingiva, tongue, uvula, tonsils, pharynx, and trachea. These lesions

Etiology. The etiology of Kaposi's sarcoma remains unknown. While immunosuppression is highly associated with Kaposi's sarcoma, it cannot be considered an etiology. Immunosuppression is believed to create an environment that allows an opportunistic factor to cause Kaposi's sarcoma. A causal model to explain the occurrence of Kaposi's sarcoma has been developed by Wahman et al., 1991. Their cofactor model suggests that "the combined effects of numerous infectious agents, host factors, and environmental factors encourage Kaposi's sarcoma proliferation".

The evidence also suggests that the disease is promoted by the effects of immunosuppression and immune activation, possibly combined with a sexually transmissible infectious agent.

In two recently published studies (Chang et al., 1994, Moore et al., 1995), herpes virus like DNA sequences, dubbed **human herpes virus 8 (HHV8 or KSHV),** have been isolated from lesions and in Kaposi's sarcoma-derived cell cultures.

There is increasing evidence that circulating growth factors appear to play a key role in the pathogenesis of HIV-related Kaposi's sarcoma. A number of cytokines and viral products produced by retrovirally infected cells (or by the Kaposi's sarcoma cells themselves) are potent growth factors for lesional cells *in vitro.* These include the HIV-1 tat protein, basic fibroblast growth factor (bFGF), the cytokines IL-1, TNF and IL-6, and others. HIV-infected lymphocytes are also capable of producing their own set of similar cytokines.

Friedman-Kien et al., 1990 have suggested a genetic predisposition to the disease as a result of studies implicating increased incidence of the histocompatibility marker HLA-DR5 in 62% of classic Kaposi's sarcoma cases. Windle-Taylor and Shah 1983 suggested an environmental etiology due to the overall geographical distribution of the disease.

Some evidence suggests that Kaposi's sarcoma may not, in fact, be a true malignancy but rather an angiogenic disorder with widespread cellular proliferation occurring in response to circulating growth factors (reactionary).

may interfere with mastication × phonation and cause tooth loss and airway obstruction (eating and speaking, cause tooth loss, or compromise the airways).

Histologic Features. Kaposi's sarcoma has a similar histopathologic appearance in all of its clinical subtypes. The early lesion **(patch stage)** is characterized by proliferation of small veins and capillaries around one or more preexisting dilated vessels. The slit like vessels are present around preexisting blood vessel, skin adnexa and between collagen fibers. Vessels are lined by plump, mildly atypical endothelial cells. The features resemble granulation tissue. A pronounced mononuclear inflammatory cell infiltrate, including mast cells, scattered erythrocytes and hemosiderin deposits may be present. There may be an inconspicuous perivascular proliferation of spindle cells, but cellular atypia is minimal.

More advanced lesions **(plaque stage)** are nodular and show increased numbers of small capillaries or dilated vascular channels interspersed with proliferating sheets of sarcomatous or atypical spindle cells, often with large numbers of extravasated erythrocytes and abundant hemosiderin deposition. Slit like vascular channels without a visible endothelial lining are typically interspersed with the spindle cells. Lesional cells have somewhat enlarged, hyperchromatic nuclei with mild to moderate pleomorphism. Mitotic activity is quite variable but is usually minimal. Infiltration by chronic inflammatory cells is also variable. In the **nodular stage,** all the histologic features are more prominent than plaque stage.

Treatment and Prognosis. Various treatments have been used in oral Kaposi's sarcoma with variable success. Small or localized lesions can be surgically excised with a small surrounding margin of clinically normal tissue, but more recent therapies have concentrated on low-dose irradiation and intralesional chemotherapy and sclerosing solutions. For larger and multifocal lesions, systemic chemotherapy is often effective.

Immunoreactivity is somewhat variable, but the spindle cells are consistently reactive for CD34 and the delicate, flattened endothelial cells lining the vascular clefts are reactive for both CD31 and CD34. The vascular channels are often reactive for *Ulex europaeus* agglutinin, but nonreactive for factor XIIIa (Fig. 2-73).

Ewing's Sarcoma
(Endothelial myeloma, 'round cell' sarcoma)

Ewing's sarcoma is a sarcoma of the bone, classically described under small round cell tumors. There is considerable clinical and histologic overlap between this tumor and the primitive neuroectodermal tumor (PNET). Now with sophisticated molecular biological analysis, it turns out that both tumors share a common and unique chromosomal translocation. Most investigators now believe that Ewing's sarcoma and PNET are different morphological expressions of one tumor type. In general, Ewing's sarcoma arises within the bone while PNET arises within soft tissues. However, there are overlap cases of Ewing's sarcoma arising within soft tissue (extraosseous Ewing's sarcoma) and PNET arising within the bone. Under the microscope, the tumors share a considerable homology though there are usually more **neuroendocrine** features with PNET. Ewing's sarcoma is thought to be a more undifferentiated tumor. Though data is conflicting, some investigators believe Ewing's sarcoma to have a slightly better prognosis.

A practical working definition is to consider all highly malignant, small round-to-oval cell sarcomas with the clinical and radiographic characteristics of a primary osseous lesion to be Ewing's tumor (Unni KK, 1996). Inherent in this concept is the exclusion of cytologically incompatible lesions such as myeloma, malignant lymphoma, and histiocytosis X. Production of a chondroid or osteoid matrix by the neoplastic cells likewise excludes Ewing's sarcoma. Similarly, true spindling of the nuclei is incompatible with the diagnosis of Ewing's sarcoma. It is sometimes impossible to differentiate a biopsy specimen of a metastatic malignant tumor such as neuroblastoma, small cell carcinoma of the lung, or even a leukemic infiltrate from a specimen of Ewing's tumor, even after critical histologic study according to modern concept. Immunoperoxidase stains, however, can effectively rule out metastatic carcinomas and lymphomas and leukemias.

Clinical Features. This neoplastic disease occurs predominantly in children and young adults between the ages of five and 25 years, the median age of occurrence is 13 years, 80% occur within first two decades of life, but is seen on occasion in older patients also. In the series of 107 cases reported by Bhansali and Desai, six patients were over the age of 40 years, the oldest being an 83-year-old woman. Thus it arises in the same general age group in which osteogenic sarcoma is most prevalent. It is approximately twice as common in males as in females, and uncommon in blacks.

It is noteworthy that an episode of trauma often precedes the development of the tumor, although it must not be inferred that this is in any manner important in the etiology of the neoplasm.

Pain, usually of an intermittent nature, and swelling of the involved bone are often the earliest clinical signs and symptoms of Ewing's sarcoma. The bones most commonly affected are the long bones of the extremities, although the skull, clavicle, ribs and shoulder and pelvic girdles may be involved, as well as the maxilla and mandible. The jaws were involved in 13% of a series of 126 cases reported by Geschickter and Copeland. Nine additional cases, eight in the mandible and one in the maxilla, have been reported by Potdar.

Facial neuralgia and lip paresthesia have been reported in cases of jaw involvement. The appearance of the jaw swelling is often a relatively rapid one, and the intraoral mass may become ulcerated. The patient may have a low-grade fever and an elevated white blood cell count, and these findings have often given rise to an erroneous tentative diagnosis of an infection.

An extraskeletal form of this tumor has been described by Angervall and Enzinger and termed **Ewing's sarcoma of soft tissues**. The ultrastructural characteristics of the cells constituting this tumor, studied by Gillespie and his associates, among others, are identical to those of the typical Ewing's cells.

Radiographic Features. The radiographic appearance of Ewing's sarcoma has been described as being suggestive but not pathognomonic of the disease. The lesion is a destructive one and produces an irregular, diffuse radiolucency, although lesions of the jaw resembling sclerosing osteomyelitis have been described.

A common characteristic radiographic feature is the formation of layers of new subperiosteal bone producing the so-called 'onion skin' appearance on the film. This thickened cortex is usually infiltrated by tumor. Osteophyte formation may also be visible on the radiograph and, in such cases, may be similar to the 'sun-ray' appearance of osteosarcoma.

Histologic Features. Ewing's sarcoma is an extremely cellular neoplasm composed of solid sheets or masses of small round cells with very little stroma, although a few connective tissue septa may be present (Fig. 2-74). The cells themselves are small and round, with scanty cytoplasm and relatively large round or ovoid nuclei with dispersed chromatin and hyperchromasia. The cell borders are indistinct. The sarcoma cells are arranged in Filigree pattern. Mitotic figures are common. The cells are positive for glycogen and are diastase resistant. The importance of intracytoplasmic glycogen in the diagnosis of Ewing's sarcoma has been reaffirmed by Telles and his coworkers 1978, who also emphasized that therapy did not alter the presence of this glycogen. Rosettes present in 10% of cases. Many tiny vascular channels may also be present. Hemorrhage with vascular lakes or sinuses may be seen. Geographic necrosis with perivascular sparing is a common feature. However, as Telles and his associates pointed out in an autopsy study of 26 cases of Ewing's sarcoma, increased cellular pleomorphism and increased numbers of bizarre giant cells may be found in the lesions in patients treated with radiation and adjuvant chemotherapy.

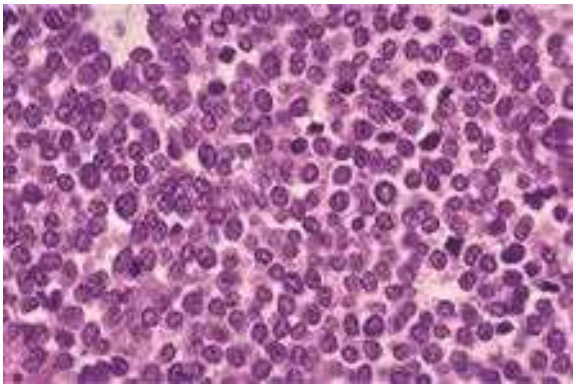

Figure 2-74. Ewing's sarcoma.
Ewing's sarcoma is one of the 'small round blue cell' tumors histologically. Note the many mitotic figures in the field.

Encroachment of tumor cells on a bone trabecula causing its ragged resorption is apparent. Necrosis is also present on the opposite side of the fragment of bone (Fig. 2-75).

The cells of Ewing's sarcoma can generally be differentiated from reticulum cell sarcoma with little difficulty. In some cases of Ewing's sarcoma, however, the cells are larger and may simulate the malignant lymphoma. Schajowicz has reported that tumor cells of Ewing's sarcoma contain histochemically demonstrable glycogen, which is absent in cells of the reticulum cell sarcoma, thus providing an easy method of differentiation. Other tumors which have to be differentiated from Ewing's sarcoma are small cell osteosarcoma, PNET (peripheral neuroectodermal tumor of infancy), metastatic neuroblastoma, mesenchymal chondrosarcoma.

Cytogenetic studies of the Ewing's sarcoma have identified a consistent alteration of the Ewing's sarcoma locus on chromosome 22 band q12 that may involve other chromosomes, including 11 or 21. Characteristically, the amino terminus of the Ewing's sarcoma gene is juxtaposed with the carboxy terminus of another gene. In most cases (90%), the carboxy terminus is provided by *FL1,* a transcription factors gene located on chromosome 11 band q24. Other genes which may combine with the Ewing's sarcoma gene in order of frequency are *ERG* (located on chromosome 21), *ETV 1* (located on chromosome 7), and *E1AF* (located on chromosome 17), which result in the following translocations: t(21;22), t(7;22), and t(17;22) respectively. Besides these consistent aberrations involving the Ewing's sarcoma gene at 22q12, additional numerical and structural aberrations have been observed in Ewing's family of tumors, including gains of chromosomes 2, 5, 7, 8, 9, and 12, the nonreciprocal translocation t(1;16)(q12;q11.2), and deletions at the short arm of chromosome 1.

Characteristic translocation is seen with Ewing's sarcoma of the bone. The fusion gene is designated as **EWS/FLI-1(t(11;22)(q24q12)).** Monoclonal antibodies to the fusion gene protein product are termed CD99.

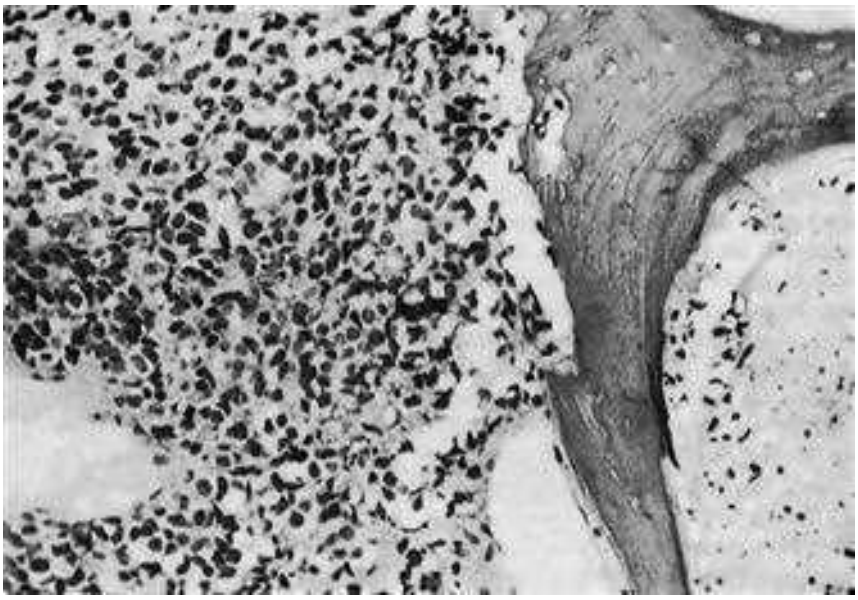

Figure 2-75. Ewing's sarcoma.

Treatment and Prognosis. This neoplasm is radiosensitive, but unfortunately, in the past, has seldom been cured by X-ray radiation. Radical surgical excision has been done, alone and coupled with X-ray radiation, but it has been common for metastatic foci to appear in other bones and organs, such as lungs and lymph nodes, within a matter of a few weeks or months. Five-year survival with a combination of surgery and chemotherapy is 74%.

Chondrosarcoma

The chondrosarcoma is the malignant counterpart of the chondroma, and like the benign lesion, may occur in either the maxilla or the mandible, as well as in many other bones in the body.

The exact origin of chondrosarcoma is obscure, but the salient pathologic fact is that its basic proliferating tissue is cartilage throughout. Large portions of these tumors may become myxomatous, calcified or even ossified. Sometimes at the periphery of the lobules of a high-grade chondrosacroma, a few fibrosarcoma like spindled tumor cells occur. Osseous trabeculae, when present, are seen at the periphery of the lobules and appeared to be rimmed with osteobalsts, however, when the malignant cells produce an osteoid lacework or osteoid trabeculae directly, even in small foci, the neoplasm has clinical characteristics of osteosarcoma and belongs in that category (Unni KK, 1996).

Chondrosarcoma usually has a slow clinical evolution. Metastasis is relatively rare and often occurs late. Chondrosarcomas can arise de novo (primary chondrosarcoma) in extraskeletal tissues or in teratomas and other mixed tumors. Chondrosarcomas composed of hyaline cartilage are extremely rare in the somatic soft tissues; most of the lesions are **myxoid chondrosarcomas**. Their general characteristics are similar to those of the skeletal examples.

Secondary chondrosarcomas arise most commonly in osteochondromas (osteocartilaginous exostoses), especially in the mutiple familial type. The primary and secondary chondrosarcomas may, on occasion, give rise to more highly malignant tumors—osteosarcomas, fibrosarcomas, or malignant fibrous histiocytomas—and these are called **dedifferentiated chondrosarcomas.**

Clinical Features. There are no pathognomonic signs or symptoms presented by the chondrosarcoma, nor may it be differentiated from the chondroma purely on the basis of the clinical findings. The tumor can occur at any age between 10 and 80 years. However, in the series of 288 cases reported by Henderson and Dahlin, the peak incidence was between 30 and 60 years, while in the series of 151 cases of McKenna and his associates, it was between 30 and 50 years. The secondary chondrosarcoma occurs at an earlier age than the primary chondrosarcoma, by an average of about 10 years. In general, chondrosarcomas occur more often in males, in a ratio of about 2 to 1. The presentation of chondrosarcoma depends on the grade of the tumor. A high-grade, fast growing tumor can present with excruciating pain. A low grade, more indolent tumor is likely to be present in an older patient complaining of pain and swelling. Chondrosarcoma usually has a slow clinical evolution. Metastasis is relatively rare and often occurs late.

Rare variants with distinctive microscopic and clinical features are discerned: clear cell chondrosarcoma (1%), mesenchymal chondrosarcoma (2%), juxtacortical chondrosarcoma (2%), extraskeletal myxoid chondrosarcoma (5%) and dedifferentiated chondrosarcoma (Table 2-14).

Mesenchymal chondrosarcoma is a characteristic and distinctive type of chondrosarcoma in which the majority of cases occur between the ages of 10 and 30 years, and in which there is an approximately equal gender distribution. In

Table 2-14: Chondrosarcoma of bone and variants

Conventional chondrosarcoma

Dedifferentiated chondrosarcoma
Mesenchymal chondrosarcoma
Chondrosarcoma of small bones

addition, the most common sites of origin are the jaws and ribs, according to Salvador and his associates.

Clear cell chondrosarcoma is a recognized variant of the usual chondrosarcoma from which it should be separated because of its slow growth pattern and its favorable clinical course with low metastatic potential and high probability of cure. Without radical excision, however, death can result. It may occur in the jaws, and such a case has been reported by Slootweg.

Dedifferentiated chondrosarcoma is the most malignant form of chondrosarcoma. This tumor is a mix of low grade chondrosarcoma and high grade spindle cell sarcoma where the spindle cells are no longer identifiable as having a cartilage origin. The dedifferentiated portion of the lesion may have histological features of malignant fibrous histiocytoma, osteosarcoma, or undifferentiated sarcoma. Dedifferentiated chondrosarcoma has a five-year survival of 10%.

Oral Manifestations. Chaudhry and his associates have reviewed all cartilaginous tumors of the jaws reported in the English literature between 1912 and 1959. Both primary and secondary jaw chondrosarcomas appear as an expanding lesion which is frequently painless (Fig. 2-76A). The mucosa is often intact. The tumor may occur in the mandible or the maxilla with primary involvement of the alveolar ridge, or sometimes in the maxilla near the antrum. Resorption and exfoliation of teeth sometimes occur. In general, these lesions are invasive and destructive and metastasize readily.

Radiographic Features. Radiographic findings do not differ remarkably from those seen in the benign chondroma unless the lesion is of relatively long standing and has produced considerable destruction of bone. Occasional tumors will appear as radiopaque lesions because of calcification of the neoplastic cartilage (Fig. 2-76B, C).

Histologic Features. Chondrosarcoma is one of the most difficult of the malignant tumors of the bone for the pathologist to diagnose. The criteria that differentiate a low-grade chondrosarcoma from a chondroma are very subtle. However, some lesions may appear to be malignant by conventional criteria but are benign. The features proposed by Lichtenstein and Jaffe are very helpful when viable fields are studied. These include many cells with plump nuclei, more than an occasional cell with two such nuclei, and especially, giant cartilage cells with large single or multiple nuclei or with clumps of chromatin. The correct diagnosis depends on correct interpretation of the subtle qualitative characteristics. Furthermore, malignant foci may be obscured by necrotic regions or by zones with insufficient cytologic evidence for the diagnosis of sarcoma.

Most chondrosarcomas have sheets of chondrocytes, which may have a lobulated growth pattern under low power. Some chondrosarcomas, however, have pronounced cluttering of the chondrocytes similar to the classic appearance in synovial chondromatosis. Chondrosarcoma is not a spindle cell neoplasm, because chondrocytes lie within lacunae. Occasionally, however, the nuclei appear spindle shaped (Fig. 2-77).

Most of the **secondary chondrosarcomas** are extremely undifferentiated, so that a clear histologic diagnosis of chondrosarcoma is usually not possible. In osteochondroma, there is a columnar arrangement of the chondrocytes towards the base. This orderly arrangement is lost when chondrosarcoma supervenes. Nodules of cartilage apparently permeating soft tissues and separated from the main mass of the tumor also are evidence of chondrosarcoma. Mitotic figures are uncommon in chondrosarcoma.

The **mesenchymal chondrosarcoma** consists of sheets of small, round or ovoid, undifferentiated cells interspersed by small islands of well-differentiated cartilage which often show calcification and metaplastic bone formation. Ultrastructural studies by Steiner and his associates have confirmed the presence of two cell types: a poorly differentiated mesenchymal cell and a cell with cartilaginous differentiation in an early stage of maturation.

The **clear cell chondrosarcoma** consists of single or clustered benign giant cells and tumor cells with clear cytoplasm. Conventional low-grade chondrosarcoma may sometimes be found in areas.

Dedifferentiated chondrosarcoma consists of a mix of low grade chondrosarcoma and high grade spindle cell sarcoma where the spindle cells are no longer identifiable as having a cartilage origin. The dedifferentiated portion of the lesion may have histological features of malignant fibrous histiocytoma, osteosarcoma, or undifferentiated sarcoma.

Grading. Chondrosarcomas are graded mainly based on the cellularity of the neoplasm and the cytologic atypia. Because mitotic activity is uncommon in chondrosarcomas, it is not used in grading these tumors. Grade 1-chondrosarcomas are relatively hypercellular compared with enchondromas and have moderate cytologic atypia. Grade 2-chondrosarcomas are more cellular than grade 1, and similarly, cytologic atypia is more pronounced. Grade 3-chondrosarcomas are extremely uncommon. They are characterized by extreme cellularity, large

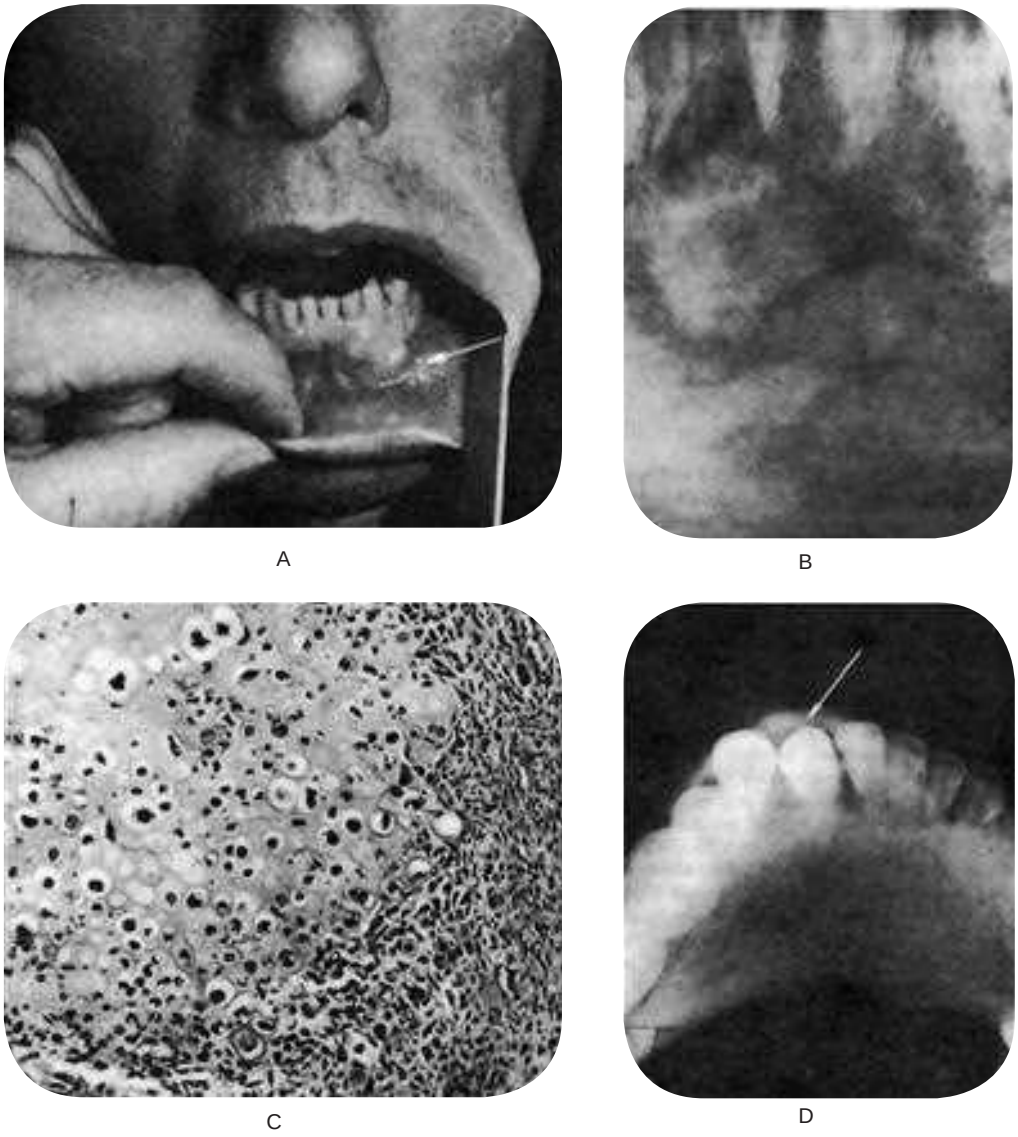

Figure 2-76.Chondrosarcoma.
The clinical expansion of the mandible **(A)** manifests obvious changes in the dental radiographs **(B, C)**. The photomicrograph **(D)** illustrates malignant cartilage cells comprising the neoplasm *(Courtesy of Dr Charles A Waldron)*.

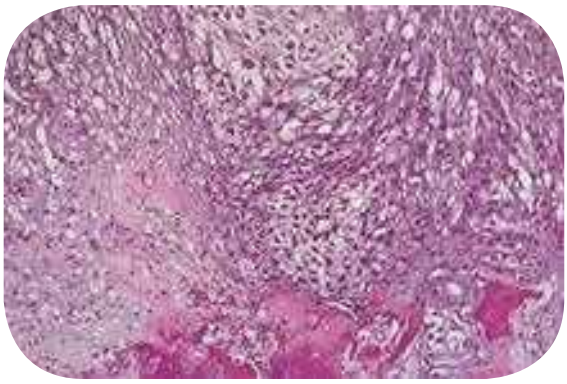

Figure 2-77. Low power chondrosarcoma.
This is the low power microscopic appearance of a chondrosarcoma. The tissue is recognizable as cartilage, and there are chondrocytes in clear spaces, but there is no orderly pattern. At the bottom, this neoplasm can be seen invading and destroying bone.

bizarre nuclei, and small foci of spindling at the periphery of the lobule. Sheets of spindle cells are not seen in chondrosarcoma.

Approximately 10% of the tumors that recur have an increase in the degree of malignancy.

Treatment and Prognosis. The only beneficial treatment of the chondrosarcoma is surgery. The malignant nature of this tumor demands wide excision to ensure the greatest possibility for cure. X-ray radiation is of little value, since this type of neoplasm is resistant to such therapy. Neither does chemotherapy appear to be of significant benefit.

Data gathered from known cases of chondrosarcoma of the jaws indicate that the tumor in this location is exceedingly dangerous and often results in death, either from local invasion or from metastasis to distant sites. Although the lesion tends to grow slowly, surgical intervention often stimulates the growth rate and increases the tendency for metastasis.

The **mesenchymal chondrosarcoma** is even more variable in its clinical course, since metastasis may occur many years after the original surgical procedure and death is markedly delayed. Expression of 'five-year survival' is of little significance in the case of this tumor.

Osteosarcoma
(Osteogenic sarcoma)

Osteosarcoma is the third most common cancer in adolescence, occurring less frequently than only lymphomas and brain tumors. It is thought to arise from a primitive mesenchymal bone-forming cell and is characterized by production of osteoid.

Clinical Features. Osteosarcoma is a bone tumor that can occur in any bone. It most commonly occurs in the long bones of the extremities near metaphyseal growth plates. The most common sites are femur (42%, with 75% of tumors in the distal femur), tibia (19%, with 80% of tumors in the proximal tibia), and humerus (10%, with 90% of tumors in the proximal humerus). Other significant locations are the skull or jaw (8%) and pelvis (8%).

Incidence is slightly higher in males than in females (1.25: 1). Osteosarcoma occurs chiefly in young persons, the majority between 10–25 years with decreasing incidence as the age advances. It is very rare in young children and the incidence increases steadily with age; a more dramatic increase in adolescence corresponds with the growth spurt.

The exact cause of osteosarcoma is unknown. However, a number of risk factors exist. Rapid bone growth appears to predispose patients to osteosarcoma, as suggested by the increased incidence during the adolescent growth spurt, and osteosarcoma's typical location near the metaphyseal growth plate of long bones. Exposure to radiation is the only known environmental risk factor. A genetic predisposition may exist, for example:

- Familial cases where the deletion of chromosome **13q14** thus inactivating the retinoblastoma gene (RB gene) leading to development of retinoblastoma and is associated with a particularly high risk of osteosarcoma to develop.
- Bone dysplasias, including Paget's disease, fibrous dysplasia, enchondromatosis, and hereditary multiple exostoses, increase the risk of osteosarcoma.
- Li–Fraumeni syndrome (germline TP53 mutation) is a predisposing factor for osteosarcoma development.
- Rothmund–Thomson syndrome (i.e. autosomal recessive association of congenital bone defects, hair and skin dysplasias, hypogonadism, cataracts) is associated with increased risk of osteosarcoma.

A number of variants of osteosarcoma are: **conventional types (i.e. osteoblastic, chondroblastic, fibroblastic); multifocal; telangiectatic; small cell; intraosseous well-differentiated; intracortical; periosteal; paraosteal; high-grade surface; and extraosseous** (Table 2-15).

Swelling and pain, particularly with activity of the involved bone, are the early features of the neoplasm. Patients may complain of a sprain, arthritis, or so-called grawing pain. Systemic symptoms, such as fever and night sweats, are rare. Sometimes the presenting signs and symptoms are indistinguishable from those of osteomyelitis. Often, the patient has a history of trauma, though pathologic fractures are not particularly common. (The exception is the telangiectatic type of osteosarcoma, which is commonly associated with pathologic fractures). If in an extremity, the pain may result in a limp. Regional lymphadenopathy is unusual.

Oral Manifestations. Several large series of cases of osteosarcoma of the jaws have been published in recent years, contributing greatly to our knowledge of this tumor. The largest series was that of Garrington and his associates who analyzed 56 cases and found that the most common presenting symptoms of the patients were swelling of the involved area, often producing facial deformity and pain, followed by loose teeth, paresthesia, toothache, bleeding, nasal obstruction and a variety of other manifestations (Fig. 2-78).

The median age of the patients at the time of appearance of the first related symptoms was about 27 years, nearly a decade older than patients with osteosarcoma of other bones of the skeleton. Of 44 cases of osteosarcoma of the jaws and facial bones reported by Kragh and his associates, the mean age of occurrence was 33 years. In all series, mandibular tumors are more common than those in the maxilla, and there is usually a predilection for occurrence in males.

As indicated previously, it has been reported on numerous occasions that trauma to other sites in the skeleton has preceded the development of osteosarcoma at that site. Furthermore, it is recognized that osteosarcoma develops with considerable frequency in bone affected by osteitis deformans, or Paget's disease, as in the 80 cases studied by Price and Goldie. Finally, bone that has been subjected to therapeutic X-ray radiation may undergo malignant transformation, as in the 50 cases studied by Arlen and his associates. Surprisingly, in nearly all cases of osteosarcoma of the jaws, there is no preceding history of trauma or of Paget's disease. However, cases of osteosarcoma developing after X-ray radiation for benign jaw lesions such as fibrous dysplasia and giant cell granuloma are adequately documented; 43 such cases were discussed by De Lathouwer and Brocheriou in their review of the literature.

Table 2-15: Variants of osteosarcoma

1.	Multifocal synchronous	Divided into synchronous and asynchronous – Pulmonary metastasis is absent usually – Childhood form is most common in 10 years of age with tumors confined to the medullary cavity with minimal extraosseous extension – Adult form less common with mean 37 years Histology – Usually osteoblastic with high grade histology – Adult forms usually better differentiated – Lesions discovered within 6 months of each other – Often symmetric appearance with similar size and not a dominant lesion: osseous metastasis is rare
	Asynchronous	– Develop less than 24 months after the initial lesion
2.	Telangiectatic	– 0.4–12% of all the osteosarcomas is seen commonly in adolescence and early adulthood – Pathologic fractures seen in 25% of cases – May be confused radiographically with an aneurysmal bone cyst or giant cell tumor – Hemorrhagic and necrotic areas seen in tumor Histology – Contains large, blood filled spaces
3.	Small cell	– 1–4% of all the osteosarcomas – Presentation is simillar to conventional osteosarcomas – 70% in first or second decades of life – 90% have at least focal osteoblastic features Histology – Small round cells with at least focal osteoid – Focal hemangiopericytoma-like pattern may be common – May have a Ewing's sarcoma-like pattern in 2/3rd of cases and lymphoma-like pattern in 1/3rd of cases
4.	Intraosseous well-differentiated	– 1–2% of osteosarcomas – Peak incidence in third decade, may affect older adults also – Metaphyseal regions of long bones are commonly affected site – In radiograph 85% cases appear as central medullary lesions Histology – Well differentiated mature appearing bone with small central osteocytes within fibroblastic stroma with mild atypia – Mitotic figures 1–2/10 hpf
5.	Intracortical	– Very rare – Diaphyses of lower extremity long bone – Radiographically presents as intracortical radiolucency surrounded by sclerosis Histology – Osteoblastic sclerotic tumors
6.	Periosteal	– < 2% of osteosarcomas – Subtype of surface osteoscaroma – Which most often occurs in older patients who have a long history of symptoms, reflecting its indolent nature – Predilection for diaphyseal region of long bones – Arises from the cortex but usually encircles the bone – Located on the external surface of the cortex and extends into the surrounding soft tissue – May not invade the medullary cavity Histology – Chondromatous foci predominate with focal malignant osteoid
7.	Paraosteal	– 5% of all osteosarcomas – Can be seen in childhood or adulthood – Arises from the juxtacortical region of the long bones – Striking predilection for the distal femur, especially the posterior aspect – Dense mushroom shaped mass attached to the outer metaphyseal cortex by broad base, as it grows it may encircle the involved bone-separated from the cortex by a narrow lucent zone Histology – Long narrow trabeculae or ill-defined islands of osteoid and woven bone separated by a fibrous stroma – Trabeculae may undergo a maturation resulting in the formation of lamellar bone – Spaces between bony trabeculae filled with spindled cells with minimal cytologic atypia – May contain foci of dedifferentiation and these tumors have a very poor prognosis; may occur in 16% of cases
8.	High-grade surface	– Arises from the outer cortex of the bone with minimal or absent intramedullary expansion – Very rare – Median age 20 years – Involves the diaphyseal or less commonly the diaphyseal-metaphyseal regions, distal femur being most common site of occurrence – Partially mineralized mass attached to the outer cortical surface with some cortical erosion – High grade neoplasms with microscopic foci of intramedullary extension in 60% of cases

Parosteal (juxtacortical) osteosarcoma is a very uncommon form of osteosarcoma which occurs in many bones throughout the skeleton and is characterized by its slow growth and good prognosis because of its lower tendency for metastasis. It is exceedingly rare in the jaws, although two cases have been reported in a series of 20 osteosarcomas of the maxilla and mandible by Roca and his coworkers. A total of seven cases in the jaws have now been reported, according to a recent review by Bras and his coworkers (Fig. 2-79).

Figure 2-79. Osteosarcoma of the maxilla.
(Courtesy of Dr Twinkle S Prasad).

Periosteal osteosarcoma appears to be an aggressive variant of the parosteal osteosarcoma and has been separated out as an entity by Unni and his associates because of its more active biologic behavior. Nevertheless, it still has a much better prognosis than the conventional intramedullary osteosarcoma.

Extraosseous osteosarcoma involving extraskeletal osteosarcoma of soft tissue in the absence of a primary skeletal tumor occasionally occurs but is rare. Osteosarcoma occurring in certain organs, such as the breast, liver and kidney, may only represent malignant teratoma but, excluding these, a true soft-tissue osteosarcoma does exist. It is a highly malignant tumor and has been discussed by Miller and his associates.

Radiographic Features. As with many bone tumors, both benign and malignant, the radiographic appearance is variable and depends on the amount of tumor bone synthesized by the malignant osteoblasts. In those tumors with little tumor bone, the radiographic appearance will be radiolucent; whereas those tumors with much tumor bone will be radiodense. Mixed lucent-dense lesions indicate an intermediate degree of tumor bone formation. *Cumulus cloud* densities form within the intramedullary and soft tissue components caused by mineralizing tumor osteoid.

There are three features of osteosarcoma that are classics:

- Small streaks of bone radiate outward from approximately 25% of these tumors. This produces a **sunray (sunburst)** pattern.
- This tumor may grow within the periodontal membrane space causing resorption of the adjacent bone resulting in uniform widening of the space. Widening of the periodontal membrane space may also be seen in other conditions such as chondrosarcoma and scleroderma, and so it is not pathognomonic.
- In the long bones affected with osteosarcoma, the periosteum is elevated over the expanding tumor mass in a tent-like fashion. At the point on the bone where the periosteum begins to merge (edge of the tent), an acute angle between the bone surface and the periosteum is created. This is called **Codman's triangle** and is highly suspicious for osteosarcoma.

Histologic Features. Gross tissue of osteoblastic osteosarcoma show white-tan, yellow in color and firm in consistency. The chondroblastic elements appear as translucent lobules and fibroblastic elements appear as tan colored, with soft, or firm consistency. Hemorrhage and necrosis are common.

Osteosarcoma is characterized by the proliferation of both atypical osteoblasts and their less differentiated precursors. In general, the characteristic feature of osteosarcoma is the presence of osteoid formed by malignant osteoblasts in the lesion, even at sites distant from bone (e.g. the lung). Stromal cells may be spindle shaped and atypical with irregularly shaped nuclei.

A number of distinct histologic types of osteosarcoma exist. The conventional type is the most common in childhood and adolescence, and has been subdivided on the basis of the predominant features of the cells (i.e. osteoblastic, chondroblastic, fibroblastic), though the subtypes are clinically indistinguishable.

In the osteoblastic type of osteosarcoma atypical, neoplastic osteoblasts exhibit considerable variation in size and shape, show large, deeply staining nuclei and are arranged in a disorderly

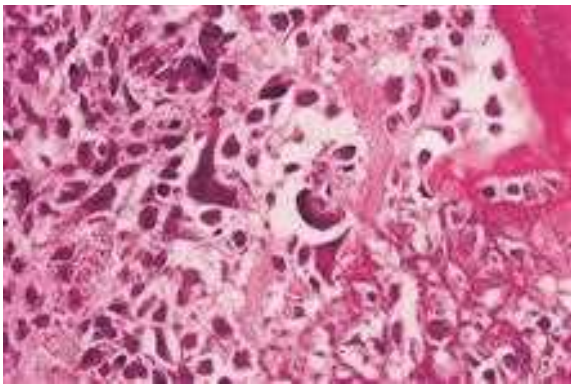

Figure 2-81. The neoplastic spindle cells of osteosarcoma are seen to be embedded in a matrix of osteoid (tumor osteoid) produced by these cells.

fashion about trabeculae of bone. In addition, there is a great deal of new tumor osteoid and bone formation, mostly in an irregular pattern and sometimes in solid sheets rather than in trabeculae. This comprised nearly 60% of the jaw lesions of Garrington's group. Varying degrees of proliferation of anaplastic fibroblasts are also found, and in the absence of significant amounts of tumor osteoid or bone, when these cells predominate, the lesion is designated as a fibroblastic type of osteosarcoma. This type comprised about 34% of the above group of jaw tumors. Some tumors show occasional areas of neoplastic myxomatous tissue and cartilage. Most authorities currently believe that even though a lesion is composed chiefly of malignant cartilage, it should be diagnosed as osteosarcoma if significant malignant osteoblasts and tumor osteoid or bone can be identified since the course of the lesion will probably be that of an osteosarcoma rather than of a chondrosarcoma (Fig. 2-81). However, when only limited chondroid is present, it is termed chondroblastic type and this form accounts for less than 10% of jaw osteosarcomas.

Staging. The purpose of staging tumors is to stratify risk groups. The conventional staging system used for other solid tumors is not appropriate for skeletal tumors because these tumors rarely involve lymph nodes or spread regionally.

The osteosarcoma staging system can be summarized as follows:

- Stages
  - Stage I – Low-grade lesions
  - Stage II – High-grade lesions
  - Stage III – Metastatic disease
- Substages
  - A – Intramedullary lesion
  - B – Local extramedullary spread
- Site of primary
  - Distal extremity – Best prognosis
  - Distal femur – Intermediate prognosis
  - Axial skeleton – Worst prognosis

Treatment. In the case of long bone involvement, amputation is a prime requisite. Neoplasms in other sites must be treated by radical resection, but, especially in the jaws, it is difficult to perform adequate and complete excision. Primary X-ray radiation is of no avail. Neoadjuvant (preoperative) chemotherapy has been found to facilitate subsequent surgical removal by shrinking the tumor. More recently, adjuvant chemotherapy in combination with surgery, including resection of pulmonary metastases, has appeared to offer promise of increased survival from this disease.

Patients who have a good histopathologic response to neoadjuvant chemotherapy (>95% tumor cell killed or necrosed) have a better prognosis than those whose tumors do not respond as favorably. The prognosis depends considerably upon the condition of the patient and the duration of the lesion when treatment is instituted. Under favorable conditions, when skeletal osteosarcoma was treated by proper radical means, the five-year cure rate of a series of 183 cases of sclerosing osteosarcoma reported by Geschickter and Copeland was 21%, while the five-year cure rate for their series of 149 cases of osteolytic osteosarcoma was 16%.

Of 45 cases of osteosarcoma of the jaws available for follow-up in the Garrington series, 50% developed clinical evidence of metastasis, most commonly to the lung. The overall five-year survival rate for maxillary osteosarcoma was 25% and for mandibular osteosarcoma, 41%. There was no correlation between histologic characteristics of the tumor and prognosis.

The overall five-year survival rate for patients diagnosed between 1974 and 1994 was 63% (59% for males, 70% for females).

Malignant Lymphoma

The malignant lymphomas constitute a group of neoplasms of varying degrees of malignancy which are derived from the basic cells of lymphoid tissue, the lymphocytes and histiocytes in any of their developmental stages. For this reason these diseases are intimately related to each other, and a concise distinction cannot always be drawn even on histologic grounds. Lukes has rendered the following excellent definition of this disease process, "Malignant lymphoma is a neoplastic proliferative process of the lymphopoietic portion of the reticuloendothelial system that involves cells of either the lymphocytic or histiocytic series in varying degrees of differentiation and occurs in an essentially homogeneous population of a single cell type. The character of histologic involvement is either diffuse (uniform) or nodular and the distribution of involvement may be regional or systemic (generalized); however, the process is basically multicentric in character. Lymphomas and leukemias of lymphocytes and histiocytes are identical, and the variation in the frequency of cells appearing in the peripheral blood appears to be related to differences in distribution and is dependent usually upon the occurrence of bone marrow involvement."

The malignant lymphomas, with the exception of Hodgkin's disease which is well established nosologically, are currently in

a state of change relative to a universally accepted classification. The non-Hodgkin's lymphomas as they are known nowadays, were called lymphosarcomas for many years. In the late 1930s and early 1940s, Gall and Mallory and Jackson and Parker developed classifications for the malignant lymphomas including Hodgkin's disease. These classifications were generally accepted, but in 1956, Rappaport and his colleagues presented a new classification of the malignant lymphomas. Rappaport revised this classification in 1966 and currently it is used by many pathologists because of its clinicopathologic relevance. However, many authorities claim that the modified Rappaport classification is scientifically inaccurate. In 1974, Lukes and Collins developed an immunologic classification of the non-Hodgkin's lymphomas which was scientifically accurate but difficult to use in a clinical situation. During the ensuing years, a number of classifications of non-Hodgkin's lymphomas have evolved. These too have not been based upon extensive clinicopathologic correlation and in addition have required modifications as new entities or variants of lymphomas were recognized.

At the present time, there are six well-described classifications of the non-Hodgkin's lymphomas. Each has its proponents, advantages and disadvantages. As a result, the US-based National Cancer Institute sponsored an international study of nearly 1,200 cases of non-Hodgkin's lymphoma. The panel consisted of six 'expert' proponents of the respective classifications as well as six other pathologists with experience and expertize in lymph node pathology. The study was designed "to assess the clinical applicability and reproducibility of six major histopathologic systems of classification for the non-Hodgkin's lymphomas and to evaluate whether any classification was superior to others in these regards." Based upon morphologic criteria only, without the use of immunologic methods, a working classification of 10 major types of non-Hodgkin's lymphoma was devised. This working classification has provided a means for translating a lymphoma into the various classifications but most importantly has reaffirmed the prognostic significance of a follicular architecture in the non-Hodgkin's lymphomas. Unfortunately, there is no unanimity of opinion as to whether this system is superior to the others or to the revised Rappaport classification as far as clinical significance, scientific accuracy and reproducibility is concerned. Because these current classifications of the non-Hodgkin's lymphomas are as yet not finalized and universally accepted, only a division of the non-Hodgkin's lymphomas and Hodgkin's disease will be used here until there is unification of the lymphoma concept.

Over the years, classifications have evolved from purely morphologic systems combined with prognostic categories (working classification) to one which integrate immunohistochemical data (Revised European American Lymphoma and WHO Classifications).

Non-Hodgkin's Lymphoma

The American Cancer Society predicted that approximately 23,000 cases of non-Hodgkin's lymphomas would occur in the United States in 1982. This accounts for approximately 70% of all new cases of malignant lymphoma. The non-Hodgkin's lymphomas are a heterogeneous group of lymphoproliferative malignancies which can involve both lymph nodes and lymphoid organs as well as extranodal organs and tissues. The lymph nodes of the head and neck are commonly involved as well as the extranodal tissues of this area.

Classification. The treatment of patients with non-Hodgkin's lymphoma (NHL) has been hampered by lack of a uniform classification system. In 1982, results of a consensus study were published as the Working Formulation. **The Working Formulation** combined results from six major classification systems into one classification. This allowed comparison of studies from different institutions and countries. The **Rappaport classification,** which also follows, is no longer in common use (Table 2-16).

The WHO modification of the Revised European American Lymphoma (REAL) classification recognizes three major categories of lymphoid malignancies based on morphology and cell lineage (Table 2-17). The categories include **B-cell neoplasms, T-cell/natural killer (NK)-cell neoplasms, and Hodgkin lymphoma**. Both lymphomas and lymphoid

Table 2-16: Comparison of working formulation and Rappaport classification

Working Formulation	Rappaport classification
Low-grade	
A. Small lymphocytic, consistent with chronic lymphocytic leukemia (SL)	Diffuse lymphocytic, well-differentiated (DLWD)
B. Follicular, predominantly small cleaved cell (FSC)	Nodular lymphocytic, poorly differentiated (NLPD)
C. Follicular, mixed small cleaved and large cell (FM)	Nodular mixed, lymphocytic and histiocytic (NM)
Intermediate-grade	
D. Follicular, predominantly large cell (FL)	Nodular histiocytic (NH)
E. Diffuse, small cleaved cell (DSC)	Diffuse lymphocytic, poorly differentiated (DLDP)
F. Diffuse mixed, small and large cell (DM)	Diffuse mixed, lymphocytic and histiocytic (DM)
G. Diffuse, large cell cleaved or noncleaved cell (DL)	Diffuse histiocytic (DH)
High-grade	
H. Immunoblastic, large cell (IBL)	Diffuse histiocytic (DH)
I. Lymphoblastic, convoluted or nonconvoluted cell (LL)	Diffuse lymphoblastic (DL)
J. Small noncleaved cell, Burkitt's or non-Burkitt's (SNC)	Diffuse undifferentiated Burkitt's or non-Burkitt's (DU)

Table 2-17: Updated Revised European American Lymphoma (REAL)/ WHO Classification (2001)

	B-cell neoplasms
1.	Precursor B-cell neoplasm: precursor B-acute lymphoblastic leukemia/lymphoblastic lymphoma (B-ALL, LBL)
2.	Peripheral B-cell neoplasms (a) B-cell chronic lymphocytic leukemia/small lymphocytic lymphoma (b) B-cell prolymphocytic leukemia (c) Lymphoplasmacytic lymphoma/immunocytoma (d) Mantle cell lymphoma (e) Follicular lymphoma (f) Extranodal marginal zone B-cell lymphoma of MALT type (g) Nodal marginal zone B-cell lymphoma (± monocytoid B-cells) (h) Splenic marginal zone lymphoma (± villous lymphocytes) (i) Hairy cell leukemia (j) Plasmacytoma/plasma cell myeloma (k) Diffuse large B-cell lymphoma (l) Burkitt's lymphoma
	T-cell and putative NK-cell neoplasms
1.	Precursor T-cell neoplasm: precursor T-cell lymphoblastic leukemia/lymphoblastic lymphoma (T-ALL, LBL)
2.	Peripheral T-cell and NK-cell neoplasms (a) T-cell chronic lymphocytic leukemia/prolymphocytic leukemia (b) T-cell granular lymphocytic leukemia (c) Mycosis fungoides/Sézary syndrome (d) Peripheral T-cell lymphoma, not otherwise characterized (e) Hepatosplenic gamma/delta T-cell lymphoma (f) Subcutaneous panniculitis-like T-cell lymphoma (g) Angioimmunoblastic T-cell lymphoma (h) Extranodal T-/NK-cell lymphoma, nasal type (i) Enteropathy-type intestinal T-cell lymphoma (j) Adult T-cell lymphoma/leukemia (HTLV 1+) (k) Anaplastic large cell lymphoma, primary systemic type (l) Anaplastic large cell lymphoma, primary cutaneous type (m) Aggressive NK-cell leukemia
	Hodgkin's lymphoma (Hodgkin's disease)
1.	Nodular lymphocyte-predominant Hodgkin's lymphoma
2.	Classical Hodgkin's lymphoma (a) Nodular sclerosis Hodgkin's lymphoma (b) Lymphocyte-rich classical Hodgkin's lymphoma (c) Mixed-cellularity Hodgkin's lymphoma (d) Lymphocyte-depleted Hodgkin's lymphoma

Source: Adapted from Med News, National Cancer Institute, 2004.

leukemias are included in this classification because both solid and circulating phases are present in many lymphoid neoplasms and distinction between them is artificial. Within B-and T-cell categories, two subdivisions are recognized: precursor neoplasms, which correspond to the earliest stages of differentiation, and more mature differentiated neoplasms.

Etiology. Genetic abnormalities like nonrandom chromosomal and molecular rearrangements play an important role in the pathogenesis of many lymphomas and correlate with histology and immunophenotype (Table 2-18). Most lymphomas do not have a familial pattern; however, coexistence of multiple breast cancers, ovarian cancer, sarcomas, and lymphomas in a family may suggest an inherited abnormality in tumor suppressor genes.

The most common chromosomal abnormality associated with NHL is the **t(14;18)(q32;q21)** translocation that is found in 85% of follicular lymphomas and 25–30% of intermediate-grade NHLs. This translocation results in the juxtaposition of the bcl-2 apoptotic inhibitor oncogene at chromosome band 18q21 to the heavy-chain region of the immunoglobulin (Ig) locus within chromosome band 14q32, resulting in its overexpression. The **t(11;14)(q13;q32)** translocation results in overexpression of bcl-1 (cyclin-D1/PRAD1), a cell cycle control gene on chromosome band 11q13, and is diagnostic of mantle cell lymphoma.

Environmental factors also seem to play a role in the development of NHL. Certain chemicals have been linked to the development of NHL include a variety of pesticides and herbicides (e.g. organophosphates, chlorophenols), solvents and organic chemicals (e.g. benzene, carbon tetrachloride), and wood preservatives. Thus certain workers like pesticide applicators, workers in the petroleum, rubber, plastics, and synthetic industries have a slightly increased risk of NHL. Patients who receive cancer chemotherapy and/or radiation therapy are at increased risk of developing NHL.

Several **viruses** have been implicated in the pathogenesis of NHL, including the Epstein-Barr virus in Burkitt's lymphoma (especially in endemic areas of Africa), sinonasal lymphoma in Asia and South America, and lymphomas in immunocompromised patients; HTLV-1 in adult T-cell lymphoma/leukemia; and human herpesvirus 8 (HHV 8) in body cavity-based lymphomas in patients with HIV infection.

Immunodeficiency states that seem to predispose to NHL include congenital immunodeficiency states (e.g. ataxia telangiectasia, Wiskott–Aldrich syndrome, common variable hypogammaglobulinemia, severe combined immunodeficiency (SCID) as well as acquired immunodeficiency states (e.g. HIV infection, iatrogenic immunosuppression for solid organ or bone marrow transplant recipients).

Connective-tissue disorders, including Sjögren syndrome, rheumatoid arthritis, chronic lymphocytic thyroiditis, and systemic lupus erythematosus (SLE) are also associated with increased risk of NHL.

Clinical Features. The median age at presentation for all subtypes of NHL is older than 50 years. High-grade lymphoblastic and small noncleaved cell lymphomas are the only subtypes of B-cell NHL that are observed more commonly in children and young adults. NHL is more common in male subjects, with a reported incidence of 19.2 cases per 100,000 population as compared with 12.2 cases per 100,000 population in women. Certain endemic geographical factors appear to influence the development of NHL in specific areas, e.g. follicular lymphomas are more common in North America and Europe but are rare in the Caribbean, Africa, China, Japan, and the Middle East. HTLV-1-associated adult T-cell lymphoma/ leukemia occurs commonly in Japan and in the Caribbean.

Table 2-18: Chromosomal abnormalities in B-cell NHL

Cytogenetic abnormality	Histology	Antigen rearrangement	Oncogene expression
t(14;18)(q32;q21)	Follicular, diffuse large cell	IgH*	bcl-2
t(11;14)(q13;q32)	Mantle cell	IgH	bcl-1
t(1;14)(p22;q32)	Extranodal marginal zone B-cell lymphoma of MALT type	IgH	bcl-10
t(11;18)(q21;q21)	Extranodal marginal zone B-cell lymphoma of MALT type	IgH	API2, MLT
t(9;14)(p13;q32)	Lymphoplasmacytic lymphoma	IgH	PAX-5

Source: Modified from Ajeet Gajra, eMedicine Specialities. Haematology, 2005.

Lymphadenopathy is the most common manifestation of lymphoma. Systemic symptoms like fevers, night sweats, weight loss, and fatigue, pruritus are noticed. Sometimes waxing and waning lymphadenopathy may be seen. Spontaneous remissions have been documented in some patients with low-grade lymphomas.

Organ-specific symptoms such as shortness of breath, chest pain, cough, abdominal pain and distention, or bone pain, may lead to identification of specific sites of involvement. Neurological symptoms are important because CNS involvement may occur with aggressive lymphomas.

Oral Manifestations. Numerous cases of non-Hodgkin's lymphoma of the oral cavity have been reported. In many instances, the oral involvement is simply a manifestation of disseminated disease. On the other hand, many lesions are the sole expression of the disease or the initial manifestation of generalized disease.

The oral lesions are characterized by swellings which may grow rapidly and then ulcerate. In some cases, these become large, fungating, necrotic, foul-smelling masses (Fig. 2-82). Pain is a variable feature. When underlying bone is involved, tooth mobility and pain may develop. A number of cases have been reported in which paresthesia of the mental nerve developed.

Tomich and Shafer reported 21 cases of malignant lymphomas in the hard palate. Reported as *lymphoproliferative disease of the hard palate,* all proved to be non-Hodgkin's lymphomas. These lesions occurred primarily in elderly men and women with an average age of 70 years. They presented as soft, fluctuant swellings which were occasionally bilateral. The swellings were ulcerated or discolored in some cases (Fig. 2-83). Although lymphoid lesions in the hard palate are very likely to be lymphomas, follicular lymphoid hyperplasia can present in this anatomic location and therefore careful histologic examination is of paramount importance. Harsany and his associates described such a condition and discussed the histologic differentiation between lymphoid hyperplasia, non-Hodgkin's lymphoma and benign lymphoepithelial lesion (q.v.).

Histologic Features. The non-Hodgkin's lymphomas present a histologic pattern which is described as either nodular or diffuse. In the nodular pattern, the neoplastic cells tend to aggregate in such a way that large clusters of cells are seen (Fig. 2-84A). In contrast, the diffuse pattern is characterized by a monotonous distribution of cells with no evidence of nodularity or germinal center formation. The diffuse lymphomas produce an entire effacement of normal lymph node architecture (Fig. 2-84B). The histologic pattern of involvement is very important, since there is clinicopathologic and prognostic correlation between the two types. The nodular pattern is seen in lymphomas in adults more often than in children and is associated with a more favorable prognosis than the diffuse type. The histologic pattern of involvement, therefore, has been a basis for the classification of non-Hodgkin's lymphoma. A diagnosis of nodular or diffuse lymphoma is highly reproducible among pathologists, and it has definite clinical significance.

The actual cell type involved in the non-Hodgkin's lymphoma has proven to be an enigma for histopathologists. Immunologic cell surface marking studies have shown that the nodular lymphomas are of B-cell origin. Many of the diffuse lymphomas are likewise of B-cell origin but some diffuse lymphomas prove to be of T-cell origin. From a purely morphologic observation, without the use of immunologic markers, the determination of the cell of origin is difficult. This has resulted in cells being interpreted as lymphocytes, reticulum cells and histiocytes in various degrees of differentiation. Currently, cells formerly interpreted as 'reticulum cells' or 'histiocytes' are known to represent large lymphocytes.

Figure 2-82. Non-Hodgkin's lymphoma.
(A) The child has a fungating tissue mass after extraction of the second deciduous molar because of sudden looseness. **(B)** The intraoral radiograph demonstrates loss of supporting bone around the first permanent molar, an unusual and serious finding in a child. **(C)** The photomicrograph shows dense diffuse infiltration of the tissues by abnormal lymphocytes.

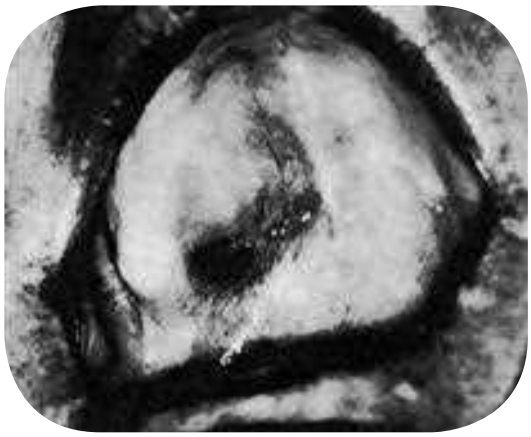

Figure 2-83. Lymphoproliferative disease of the hard palate.

A

B

Figure 2-84. Non-Hodgkin's lymphoma.
The nodular pattern is characterized by large clusters of cells **(A)** while the diffuse pattern shows no such clustering but rather a monotonous population of cells **(B)**.

However, it is thought that a histiocytic lymphoma does exist, albeit uncommon. The problem of cell identification on a morphologic, nonimmunologic basis is one of the major obstacles in arriving at a universally acceptable classification of the non-Hodgkin's lymphomas.

The **Ann Arbor staging system** is commonly used for patients with NHL. In this system, stages I, II, III, and IV, adult NHL can be subclassified into A and B categories: B for those with well-defined generalized symptoms and A for those without such symptoms. The B designation is given to patients with any of the following symptoms:

- Unexplained loss of more than 10% of body weight in the six months before diagnosis
- Unexplained fever with temperatures above 38° C
- Drenching night sweats.

Stage I
Involvement of a single lymph node region (I) or localized involvement of a single extralymphatic organ or site (IE).

Stage II
Involvement of two or more lymph node regions on the same side of the diaphragm (II) or localized involvement of a single associated extralymphatic organ or site and its regional lymph nodes with or without other lymph node regions on the same side of the diaphragm (IIE). The number of lymph node regions involved may be indicated by a subscript (e.g. II3).

Stage III
Involvement of lymph node regions on both sides of the diaphragm (III) that may also be accompanied by localized involvement of an extralymphatic organ or site (IIIE), by involvement of the spleen (IIIS), or both (IIIS+E).

Stage IV

Disseminated (multifocal) involvement of one or more extralymphatic sites with or without associated lymph node involvement or isolated extralymphatic organ involvement with distant (nonregional) nodal involvement.

The histologic findings in B-cell NHL are varied. The salient features of the most common subtypes are:

Follicular lymphoma (nodular). Represents 22% of all non-Hodgkins lymphomas. At low magnification, a predominantly nodular growth pattern is observed in lymph nodes. Two principal cell types are observed in varying proportions: small cells with irregular or cleaved nuclear contours and scant cytoplasm that are referred to as **centrocytes** (small cleaved cells) and larger cells with open nuclear chromatin, several nucleoli, and modest amounts of cytoplasm that are referred to as **centroblasts**. In most follicular lymphomas, small cleaved cells comprise the majority of the cellularity. Peripheral blood involvement sufficient to produce lymphocytosis (usually <20,000/dl) is observed in about 10% of patients. Bone marrow involvement occurs in 65% of patients and characteristically takes the form of paratrabecular lymphoid aggregates. Splenic white pulp and hepatic portal triads are also frequently involved (Fig. 2-85).

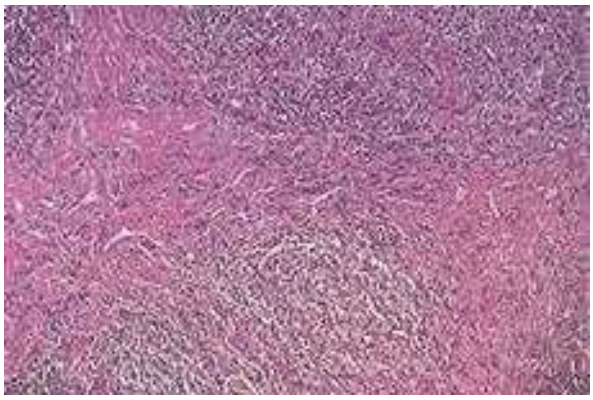

Figure 2-85. Follicular non-Hodgkin's lymphoma.

Diffuse large B-cell lymphoma. Represents 31% of all non-Hodgkin's lymphomas. The common morphologic features that unite this group are the relatively large cell size (usually four or five times that of a small lymphocyte) and a diffuse pattern of growth. In other respects, a fair degree of morphologic variation exists. In most cases, the tumor cells have a round or oval nucleus that appears vesicular because of margination of chromatin at the nuclear membrane, but large multilobed or cleaved nuclei predominate in some cases. Nucleoli may be two or three in number and located adjacent to the nuclear membrane, or they may be single and centrally placed. Cytoplasm is usually present in moderate abundance and may be pale or basophilic. Other more anaplastic tumors may contain multinucleated cells with large inclusion like nucleoli that closely resemble Reed–Sternberg cells, and phenotyping is often necessary to distinguish these two entities.

Treatment and Prognosis. NHL can be treated with radiotherapy, chemotherapy (forms the cornerstone of therapy in lymphoma and has a curative, as well as a palliative role) or biologic therapy (comprised of interferon therapy and monoclonal antibodies). The NHLs can be divided into two prognostic groups: the **indolent** lymphomas and the **aggressive** lymphomas. Indolent NHL types have a relatively good prognosis, with median survival as long as 10 years, but they usually are not curable in advanced clinical stages. Early-stage (I and II) indolent NHL can be effectively treated with radiation therapy alone. Most of the indolent types are nodular (or follicular) in morphology. The aggressive type of NHL has a shorter natural history, but a significant number of these patients can be cured with intensive combination chemotherapy regimens. In general, with modern treatment of patients with NHL, overall survival at five years is approximately 50–60%. 30–60% of patients with aggressive NHL can be cured. The vast majority of relapses occur in the first two years after therapy. The risk of late relapse is higher in patients with a divergent histology of both indolent and aggressive disease.

Although significant advances in lymphoma treatment have been made, the disease is still a serious one, and the prognosis for any particular patient should be considered individualistic.

Primary Lymphoma of Bone

(Primary lymphocytic lymphoma, reticulum cell sarcoma of bone)

Primary lymphoma of bone (PLB) is a rare malignant neoplastic disorder of the skeleton. In 1939, it was described as a distinct clinical condition by Parker and Jackson. In 1963, the term primary lymphoma of bone was introduced by Ivins and Dahlin.

Most (94%) primary lymphoma of bone cases result from non-Hodgkin's lymphoma and 6% resulted from Hodgkin's disease. Primary lymphoma of bone tumors produce osteoclast-stimulating factors that cause lytic bone destruction.

The etiology of bone lymphoma is unknown. Viral agents and immunosuppression are implicated in some cases. Primary lymphoma of bone has been documented as a post-transplant lymphoproliferative disorder in patients who were immunosuppressed. Bone has also been documented as a site for primary lymphoma in patients with AIDS. Rarely, patients with Paget's disease of bone may develop malignant lymphoma in the involved bone. However, these associations are not commonly documented and are the subject of a few case reports in the literature.

Clinical Features. The incidence of disease is distributed fairly evenly in the second through eighth decades. This disease is rare in children younger than 10 years, as are most primary bone malignancies. Male-to-female ratio ranges from 1.5–2 : 1. Patients of all races are affected.

The most common presenting feature of bone lymphoma is pain, which occurs in 60–100% of patients. Other presenting features are palpable swelling or mass and pathologic fracture. Pediatric patients may present with functional deficits in involved bone. Systemic symptoms such as weight loss, fever, and night sweats are seen in fewer than 10% of patients. Regional lymph node involvement is more common in cases of bone involvement in patients with systemic lymphoma.

The diagnostic criteria (Coley et al, 1950) by WHO are:

- A primary focus in a single bone
- Histologic confirmation
- At the time of diagnosis, no evidence of distant soft tissue or distant lymph node involvement.

Regional lymph node involvement at diagnosis is not considered exclusionary using these criteria. Currently, it is recognized that PLB may involve multiple bones, as long as the other two criteria are met.

Oral Manifestations. Primary lymphoma of bone is not a common disease of the jaws, but it appears to be somewhat more frequent in the mandible than in the maxilla. Of the 150 primary cases of Dahlin, 22 or 15% occurred in the mandible. There were no cases in the maxilla. It occurs in the jaws with a predilection for the male gender.

Gerry and Williams collected all the reported cases of primary lymphoma of the mandible and noted that the principal presenting symptom of the disease was pain, usually present for a period of several months to a year or more before the patient sought advice and treatment. Demonstrable swelling or enlargement of the bone was often noted.

The oral mucosa in this disease seldom is ulcerated over the involved bone, although there may be minor change in the texture or hue, sometimes, appearing diffusely inflamed (Fig. 2-86A, B). The teeth often become exceedingly loose, owing to destruction of bone. When the neoplasm involves the maxilla, there may be evidence of expansion of the bone as well as symptoms of nasal obstruction due to superior growth of the tumor into the floor of the nasal cavity. Aside from this local discomfort, the patient seldom exhibits systemic signs or symptoms of the disease.

Radiographic Features. The most common radiographic features, reported in a review of 237 cases by Mulligan et al, included the following: permeative lytic pattern of bone destruction (74%), metadiaphyseal location (69%), periosteal reaction (58%), soft tissue mass (80–100%).

Sometimes variable findings such as no detectable abnormal findings on initial conventional radiographs (<5%), focal geographic lesions that may have a mixed or blastic appearance (11%), pathologic fracture (22%), varied periosteal reactions, ranging from a single continuous layer to interrupted multiple layers are found. Interrupted single or multiple layers were the most common type of periosteal reaction (52%).

Laboratory Findings. Most patients have elevated lactate dehydrogenase (LDH) levels, this is directly proportionate to the disease load. Erythrocyte sedimentation rate (ESR) also is frequently elevated in systemic disease involvement. Hypercalcemia is seen in some patients and has been associated with a poorer prognosis.

Histologic Features. The primary cell of this osseous lesion is identical with that of the soft-tissue tumor, and diagnosis depends upon adequate biopsy with microscopic examination of the tissue by a competent and qualified pathologist (Fig. 2-86C, D). Since the oral tissues frequently exhibit considerable inflammatory cell infiltration, confusion of this tumor with an inflammatory lesion sometimes occurs.

The most common subtype seen as primary lymphoma of bone is diffuse large B-cell lymphoma, which accounts for 60–90% of cases. These cases show a diffuse population of large lymphoid cells, sometimes with convoluted nuclear contours. Admixed fibrosis is present with a background population of reactive small lymphocytes.

Other types of lymphoma seen in primary bone lesions include follicular lymphoma, Burkitt's lymphoma, precursor B-lymphoblastic lymphoma, and B-cell small lymphocytic lymphoma. T-cell lymphomas are distinctly uncommon. Cases of anaplastic large cell lymphoma, peripheral T-cell lymphoma, and adult T-cell lymphoma have been reported, the latter associated with human T-cell lymphotrophic virus type I (HTLV-I) infection.

Histologic differential diagnoses include Ewing's sarcoma, osteolytic osteosarcoma, neuroblastoma and other small round cell tumors, bone metastasis, granulocytic sarcoma, and Langerhans cell histiocytosis.

Treatment and Prognosis. The consensus now favors radiation for control of the primary lesion. Sometimes surgical

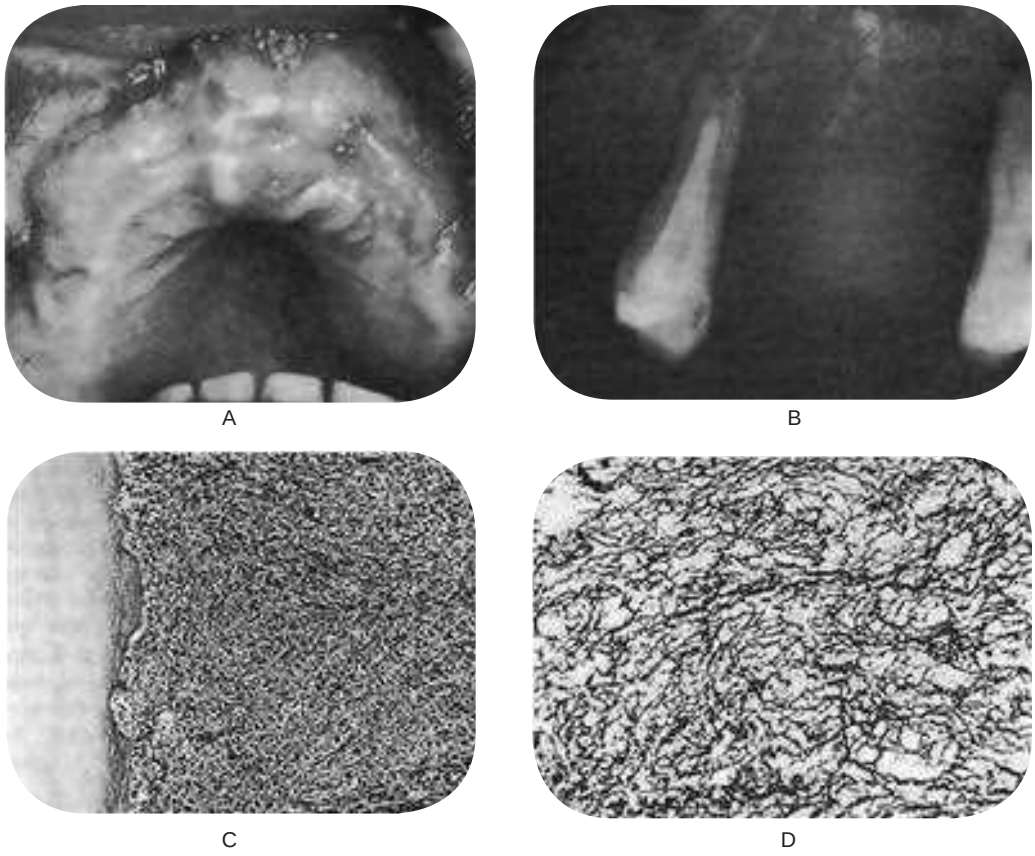

Figure 2-86. Primary lymphoma of bone.
(A) The maxilla is diffusely involved by the neoplasm, but presents no remarkable changes in the oral mucosa. **(B)** The intraoral radiograph, taken just before extraction of the few remaining teeth, shows bone destruction causing loosening of the teeth. **(C)** The photomicrograph illustrates the cellular nature of the neoplasm in an area of tissue attached to one tooth. **(D)** A special silver stain shows the profusion of reticulin fibers produced by the lesion.

ablation becomes necessary because radiation either results in local necrosis that is disabling or fails to halt the growth of the primary tumor. Regional lymph nodes require attention, and radiation therapy is likely to be the most efficacious for these. Chemotherapy is indicated for disseminated disease.

Many reports indicate that malignant lymphoma has the best prognosis of all the primary malignant tumors of bone. Five-year survival rates of 40–50% and even higher have been reported. Patients with involvement of multiple bones but without involvement of nonskeletal sites had a surprisingly good survival rate of 42% at five years (Unni KK, 1996).

Most of the small group of patients with mandibular tumors in the series of KK Unni (1996) reported long-term survival. A gratifying percentage of patients with locally invasive and basically inoperable lymphomas of the maxillary region, can be cured by appropriate radiation therapy.

African Jaw Lymphoma
(Burkitt's lymphoma)

A tumor peculiar to the children of tropical central Africa was reported by Denis Parsons Burkitt (1958–59), which later became named after him. Burkitt's lymphoma (BL) occurs endemically in parts of Africa and Papua, New Guinea and is restricted to areas with endemic malaria. BL also occurs sporadically throughout the world.

It is a high-grade B-cell neoplasm and has two major forms: the endemic (African) form and the nonendemic (sporadic) form. Burkitt's lymphoma is a childhood tumor but it is observed in adult patients too. Burkitt's lymphoma is one of the fastest growing malignancies in humans, with a very high growth fraction.

Clinical Features. The African form most often involves the maxilla or mandible. The involvement of abdominal organs, such as the kidneys, ovaries, or retroperitoneal structures, is slightly less common. In contrast, the sporadic form usually involves abdominal organs, with the most common involvement of the distal ileum, cecum, or mesentery, and less common involvement of other abdominal organs, pelvic organs, and facial bones.

The exact causes and mechanisms of Burkitt's lymphoma are not known. EBV is closely associated with the African form of Burkitt's lymphoma. Some have postulated that, because of immunosuppression caused by coexistent malaria or another infection, the host is unable to generate an adequate T-lymphocyte response (i.e. EBV-specific cytotoxic T cells)

against B cells that are infected latently with EBV. This subsequently results in excessive B cell proliferation.

About 90% of Burkitt's lymphomas carry a translocation of the c-myc oncogene from chromosome 8 to either the immunoglobulin (Ig) heavy-chain region on chromosome **14 [t(8;14)]** or one of the light-chain loci on chromosome 2 (kappa light chain) **[t(8;2)]** or chromosome 22 (lambda light chain) **[t(8;22)].** Overproduction of the c-myc product may change the lymphocytes into cancer cells.

In the African form of Burkitt's lymphoma, patients most often present with swelling of the affected jaw or other facial bones, loosening of the teeth, and swelling of the lymph nodes, which are nontender and rapidly growing, in the neck or below the jaw. Abdominal presentation is slightly less common (Fig. 2-88).

Patients with the sporadic form of Burkitt's lymphoma most commonly present with abdominal tumors causing swelling and pain in the affected area. Some patients present with symptoms of bowel obstruction secondary to an ileocecal intussusception caused by tumor growth.

Because of the rapid growth of the Burkitt tumor, patients may quickly manifest significant metabolic derangement and renal function impairment. Less common presentations of Burkitt's lymphoma include an epidural mass, skin nodules, CNS symptoms, and bone marrow involvement. Rare cases of Burkitt's lymphoma can present as acute leukemia (L3-ALL) with fever, anemia, bleeding, and adenopathy.

Major signs of Burkitt's lymphoma include a soft tissue mass associated with the involvement of the jaw or other facial bones, enlarged cervical lymph nodes, abdominal masses, and ascites.

Histologic Features. Burkitt's lymphoma is a monoclonal proliferation of B lymphocytes characterized by small noncleaved cells that are uniform in appearance and that produce a diffuse pattern of tissue involvement.

Burkitt cells are homogeneous in size and shape, with round to oval nuclei and slightly coarse chromatin, with multiple nucleoli, and with intensely basophilic vacuolated cytoplasm that contains neutral fat. Frequent mitotic figures usually are observed. A characteristic **starry sky** appearance is imparted by scattered macrophages with an abundant clear cytoplasm, often containing phagocytic cellular debris (Fig. 2-89).

Treatment and Prognosis. Before the advent of specific therapies, children with Burkitt's lymphoma died rapidly. With combination chemotherapy and CNS prophylaxis (intrathecal chemotherapy), the survival rate is now at least 60%. Patients with limited disease have a survival rate of 90%. Those with bone marrow and CNS involvement have a poor prognosis. Adults with the disease, especially those in the advanced stage, do more poorly than affected children.

(Courtesy of WHO, World Cancer Report, 2003).

Figure 2-89. Starry sky appearance.
Appearance of Burkitt's lymphoma.

Staging. Various staging systems have been proposed.

- **Stage I.** The lymphoma is only in one group of lymph nodes in one particular area of the body.
- **Stage II.** More than one group of lymph nodes is affected, but all the affected nodes are contained within either the upper half or the lower half of the body. The upper half of the body is above the sheet of muscle underneath the lungs (the diaphragm) and the lower half is below the diaphragm.
- **Stage III.** Lymphoma is present in lymph nodes in both the upper and lower parts of the body (i.e. in lymph nodes both above and below the diaphragm). Spleen is considered as a lymph node in this staging system.
- **Stage IV.** The lymphoma has spread beyond lymph nodes to other organs, i.e. to sites such as the nervous system, bone marrow, liver or lungs.

The tumour can be stained with antibodies to lambda light chains which should reveal a monoclonal tumor of B-cell origin. In over 90% of cases, the cells express IgM at the cell surface. The lymphoma cells are CD20+, CD5–, CD10+, bcl-2+.

Hodgkin's Disease

(Hodgkin's lymphoma, malignant lymphoma)

Hodgkin's disease (HD) is considered as one of the two main types of malignant lymphomas. Thomas Hodgkin first described Hodgkin's disease in 1832. it is a potentially curable malignant lymphoma with distinct histology, biologic behavior, and clinical characteristics.

The etiology of HD is unknown. Infectious agents, especially the Epstein-Barr virus (EBV), may be involved in the pathogenesis. In as many as 50% of HD cases, the tumor cells are EBV-positive. EBV positivity is higher with mixed cellularity Hodgkin disease (60–70%) than the nodular sclerosis Hodgkin disease (15–30%). Almost 100% of HIV-associated HD cases are EBV-positive.

Patients with HIV infection have a higher incidence of HD compared to the population without HIV infection. However, HD is not considered an AIDS-defining neoplasm.

Genetic predisposition may play a role in the pathogenesis. Approximately 1% of patients with HD have a family history of the disease. Siblings of an affected individual have a three- to seven-fold increased risk for developing HD. This risk is higher in monozygotic twins. HLA-DP alleles are more common in HD.

Clinical Features. Age-specific incidence rates have a bimodal distribution in both genders, peaking in young adults (aged 15–34 years) and older individuals (>55 years). HD is more common in males than in females, with an age standardized incidence of 1.8 cases per 100,000 population in males and 0.8 cases per 100,000 population in females. This male predominance is particularly evident in children, where 85% of the cases are in males. HD is more common among whites and less common among Asians. In developing countries, the incidence of the mixed-cellularity subtype in children is higher. On the other hand, in developed countries, young adults have the highest incidence of the nodular sclerosis subtype. Also, socioeconomic class is associated with a higher risk of HD. HD had a worldwide incidence of 59,000 cases annually (0.7% of all cancers) and accounts for 26,000 deaths (0.5% of all cancers).

The clinical signs and symptoms of Hodgkin's disease are extremely protean. The first manifestation in the majority of cases is painless enlargement of one or more cervical lymph nodes, not uncommon finding in other lymphomas or in cases of simple upper respiratory tract or oral infection. Palpable painless lymphadenopathy occurs in the cervical area (60–80%), axilla (6–20%), and, less commonly, in the inguinal area (6–20%) and Waldeyer ring or occipital nodes. The nodes are usually firm and rubbery in consistency, and the overlying skin is normal (Fig. 2-90).

Constitutional symptoms such as unexplained weight loss, fever, night sweats are present in about 40% of patients. Chest pain, cough, and/or shortness of breath may be present due to a large mediastinal mass or lung involvement. Rarely, hemoptysis is observed. Alcohol-induced pain at sites of nodal disease is specific for HD and occurs in less than 10% of patients. Patient may present with pruritus or intermittent fever. Back, abdomen or bone pain may occur rarely due to splenomegaly, hepatomegaly, pressure from enlarged lymph nodes, involvement of bone or vertebrae.

Oral Manifestations. Hodgkin's disease is primarily a disease of lymph nodes, and for this reason, seldom occurs as a disease primarily in the oral cavity. It is conceivable that the oral cavity could be involved secondarily, but this appears to be an exceedingly rare happening. A case of Hodgkin's disease secondarily involving the mandible and overlying alveolar mucosa has been reported by Forman and Wesson.

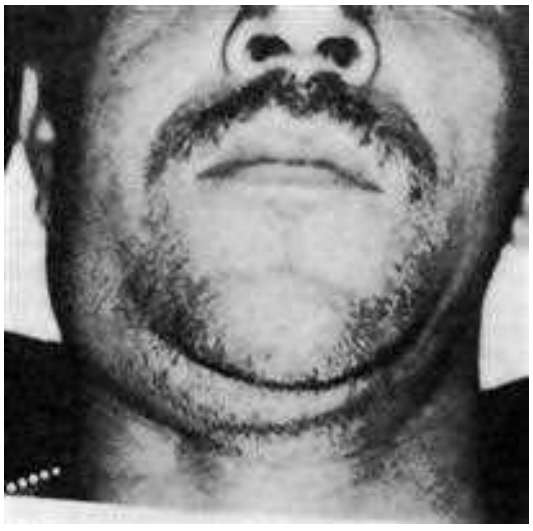

Figure 2-90. Hodgkin's disease.
There is cervical lymphadenopathy which is more pronounced on one side *(Courtesy of Dr Cesar Lopez).*

Histologic Features

1. ***Nodular sclerosis (NS) Hodgkin's disease*** comprises 60–80% of all cases. The morphology shows a nodular pattern. The broad bands of fibrosis divide the node into 'nodules'. The capsule is thickened. The characteristic cell is the lacunar-type RS cell, which has a monolobated or multilobated nucleus and a small nucleolus with abundant and pale cytoplasm. NS frequently is observed in adolescents and young adults and usually involves the mediastinum and other supradiaphragmatic sites.
2. ***Mixed-cellularity Hodgkin's disease*** comprises 15–30%. Histologically, the infiltrate is usually diffuse. RS cells are of the classic type (large, with bilobate, double or multiple nuclei, and a large eosinophilic inclusion like nucleolus). It commonly affects the abdominal lymph nodes and spleen. Patients with this histology typically have advanced-stage disease with systemic symptoms and immunodeficiency.

Characteristics of typical Reed–Sternberg cell

Characteristic malignant cells of Hodgkin's diseases are large cells known as Reed–Sternberg (RS) cells (typical and variant), 20–50 micrometers in diameter, abundant, amphophilic, finely granular/homogeneous cytoplasm; two mirror-image nuclei (owl eyes) each with an eosinophilic nucleolus and a thick nuclear membrane (chromatin is distributed at the cell periphery). One or two percent of these malignant cells are admixed within a reactive cell infiltrate composed of variable proportions of lymphocytes, histiocytes, eosinophils, and plasma cells. The Reed–Sternberg cells are identified as large often binucleated cells with prominent nucleoli and an unusual CD15+, CD30+ immunophenotype. In approximately 50% of cases, the Reed–Sternberg cells are infected by the Epstein-Barr virus. There are five recognized histologic types of Hodgkin's disease which form the basis for its classification (Fig. 2-91).

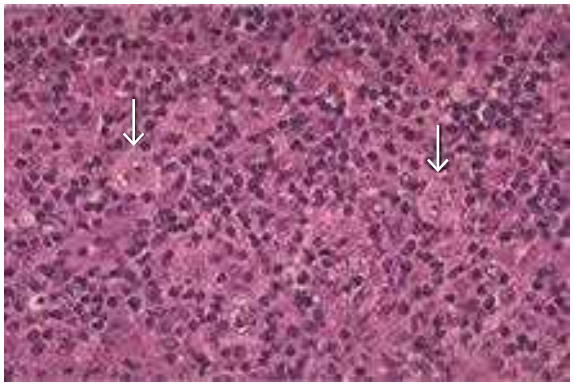

Figure 2-91. Reed-Sternberg cell.
Cells with large, pale nuclei containing purple nucleoli at the arrowheads. These are Reed–Sternberg cells that are indicative of Hodgkin's disease. Most of the cellular content of foci of Hodgkin's disease consists of reactive lymphoid cells.

3. ***Lymphocyte-depleted Hodgkin's disease*** makes up less than 1%. The infiltrate in lymphocyte-depleted Hodgkin disease (LDHD) is diffuse and often appears hypocellular. Large numbers of RS cells and bizarre sarcomatous variants are present. It is associated with older age and HIV positivity. Patients usually present with advanced-stage disease. EBV proteins are expressed in many of these tumors. Many cases of LDHD diagnosed in the past actually were non-Hodgkin's lymphomas, often of the anaplastic large-cell type.
4. ***Lymphocyte-rich classic Hodgkin's disease*** comprises 5%. In this type of HD, RS cells of the classic or lacunar type are observed, with a background infiltrate of lymphocytes. It requires immunohistochemical diagnosis. Some cases may have a nodular pattern. Clinically, the presentation and survival patterns are similar to those for mixed-cellularity Hodgkin's disease.
5. ***Nodular lymphocyte-predominant Hodgkin's disease*** constitutes 5%. In contrast to the other histological subtypes, the typical RS cells in nodular lymphocyte-predominant Hodgkin disease are not observed or appear infrequently. Instead, a variant of RS cells, the lymphocytic and histiocytic cells (L&H), or *popcorn cells* (their nuclei resemble an exploded kernel of corn), are seen within a background of inflammatory cells, predominantly benign lymphocytes. The L&H cells are positive for B-cell antigens, such as CD19 and CD20, but generally are negative for CD15 and CD30.

Treatment and Prognosis. It is now recognized that proper treatment of Hodgkin's disease can lead to long-term remission and even cure. Radiation therapy and combination chemotherapy have been clearly shown to be effective in the management of Hodgkin's disease. The most important prognostic determinants are the histologic type and the clinical stage of the disease. The lymphocyte predominant type has the most favorable prognosis, followed by nodular sclerosis, mixed cellularity and lymphocyte depletion, the least favorable. Localized (stage I) disease has a much better prognosis than disseminated (stage IV) disease. Patchefsky and his associates have reported that male gender, older age and systemic symptoms also are associated with poor prognosis. The five-year disease-specific survival for patients with stages I and II, III, and IV is 90%, 84%, and 65%, respectively.

Multiple Myeloma and other Plasma Cell Neoplasms

Multiple myeloma is the most common primary neoplasm of the skeletal system. The disease is a malignancy of plasma cells. Plasma cells are a subset of B-cells, which are the producers of humoral immunity factors termed antibodies. However, if malignant transformation occurs in a single plasma cell, its clones produce only a single type of immunoglobulin, and electrophoresis demonstrates a monoclonal peak corresponding to this particular immunoglobulin.

Pathogenesis. Multiple myeloma has been the prototype of monoclonal malignancies, in this case, of plasma cells; the

disease may result from a mutation of terminally differentiated B cells or even from early but committed B cells that manifest clinically as more differentiated plasma cells. The expression of multiple markers of different cell lineages (B and T) by plasma cells supports the possibility of either an aberrant expression of unexpected phenotypes, as in other malignancies, or a stem-cell precursor from which all hematopoietic cells arise.

No predisposing events appear to be important in the etiology of multiple myeloma. Some events that have been suggested include radiation exposure (in radiologists and radium-dial workers), occupational exposure (in agricultural, chemical, metallurgical, rubber plant, pulp, and paper workers and leather tanners), and chemical exposure to benzene, formaldehyde, hair dyes, paint sprays, and asbestos. None of these associations has proven to be statistically significant, and all have been contradicted by negative correlations. The initial report that survivors of the atomic bombings in Japan had an increased risk of developing myeloma has been refuted by longer follow-up.

Multiple studies have described the cytogenetics of myeloma. Although no karyotypic abnormalities are specific, frequent aberrations of chromosomes 1 and 14, the latter containing the heavy-chain immunoglobulin gene, have been noted. In addition, specific translocations have been described, including **t(11;14), t(14;18),** and **t(8;14).** Other chromosomal abnormalities include 6q-, 7q-, 5q-, **t(9;22)**, and 17p+. Abnormal expression of the bcl-2 protein has also been noted in patients without a t(14;18) translocation. Mutations of the ras oncogene and ***p53*** gene mutations have been reported, especially in patients with late disease. The ras mutation correlates with a low treatment response rate, and the p53 gene mutation has been noted in patients with extramedullary proliferation of plasma cells.

A variety of cytokines stimulate the growth of malignant plasma cells *in vitro*. Interleukin-6 (IL-6), considered the most important myeloma growth factor, binds to the IL-6 receptor on plasma cells, which is made up of an alpha chain (IL-6R) and a beta-transducer chain (gp130). IL-6 acts in concert with an extensive cytokine network (IL-1, IL-3, IL-7, IL-11, 6-colony-stimulating factor [CSF], granulocyte-macrophage colony-stimulating factor [GM-CSF, sargramostim (Leukine)], and tumor-necrosis factor [TNF]) to promote the growth of malignant plasma cells. Other factors (alpha interferon [IFN-alfa], gamma interferon [IFN-gamma], and IL-4) appear to inhibit plasma-cell growth, and some of these cytokines may play a role in therapy.

Although myeloma is not an inherited disease, there have been numerous case reports of it in the same family. However, a case-control study revealed no significant increase in myeloma among relatives of patients with multiple myeloma, other hematologic malignancies, or other cancers.

Clinical Features. Multiple myeloma is a disease of older people. Most patients who receive the diagnosis are aged 60–65 years. Only 3–5% of patients with multiple myeloma are younger than 45 years. The disease is rare in children. Men appear to be at increased risk of multiple myeloma compared to women. The annual incidence per 100,000 population is 6.4 among white men and 4.1 among white women. Among black men and women, the frequency doubles to 12.7 and 10.0, respectively, per 100,000 population. This racial difference is not explained by socioeconomic or environmental factors and is presumably due to unknown genetic factors.

Multiple myeloma is a diffuse disease of the bone marrow. Almost 90% of patients with myeloma have osseous involvement. The predominant sites of involvement are within the axial skeleton and include the vertebral column, ribs, skull, pelvis, and femur bone. Most patients have either a number of lytic foci or diffuse demineralization at the time of diagnosis. The underlying pathology of multiple myeloma is expansion of a single line of plasma cells that replace normal bone marrow and produce monoclonal immunoglobulins.

The clinical presentation of multiple myeloma is quite variable. Bone pain, especially from compression fractures of vertebrae or ribs, is the most common symptom. Findings that suggest a diagnosis of multiple myeloma include lytic bone lesions, anemia, azotemia, hypercalcemia, and recurrent infections. However, approximately 20% of patients with multiple myeloma are free of symptoms and are diagnosed by chance.

Extramedullary plasmacytoma. Patients with isolated plasma cell tumors of soft tissues, most commonly occurring in the tonsils, nasopharynx, or paranasal sinuses, should have skeletal X-rays and bone marrow biopsy. If these tests are negative, the patient has extramedullary plasmacytoma. About 25% of patients have serum and/or urine M-protein; this should disappear following adequate irradiation.

Macroglobulinemia. Macroglobulinemia is a proliferation of plasmacytoid lymphocytes secreting an IgM-protein. Patients often have lymphadenopathy and hepato-splenomegaly, but bony lesions are uncommon. There is no universally accepted staging system.

Oral Manifestations. Involvement of the jaws in cases of multiple myeloma has been reported on many occasions. Bruce and Royer studied a series of patients with this disease and concluded that the mandible is far more frequently involved than the maxilla, since nearly 95% of their cases evidenced mandibular lesions. Furthermore, the ramus, angle and molar region of the mandible were the most frequent sites of the lesions. These correspond to the most active hematopoietic areas. Conversely, in the Mayo series, 20 of the 28 cases with jaw lesions had maxillary involvement. Interestingly, two of the patients were only in the third decade of life. Cataldo and Meyer have confirmed the high frequency of jaw involvement in a series of 44 cases of multiple myeloma in which 70% of the patients who had jaw radiographs taken had maxillary or mandibular lesions.

Other signs and symptoms of jaw involvement include pain, swelling, expansion of the jaw, numbness and mobility of teeth. In addition, extraosseous lesions occur which may resemble gingival enlargements or epulides. Extension of the

disease to other sites outside the skeleton such as lymph nodes, skin and viscera also occurs.

It is impossible to compute the overall incidence of jaw involvement in patients with multiple myeloma, since most patients suffering from this disease do not receive a thorough oral examination with radiographs. Nevertheless, studies indicate that the incidence may be somewhat higher than formerly believed because many such lesions may be asymptomatic.

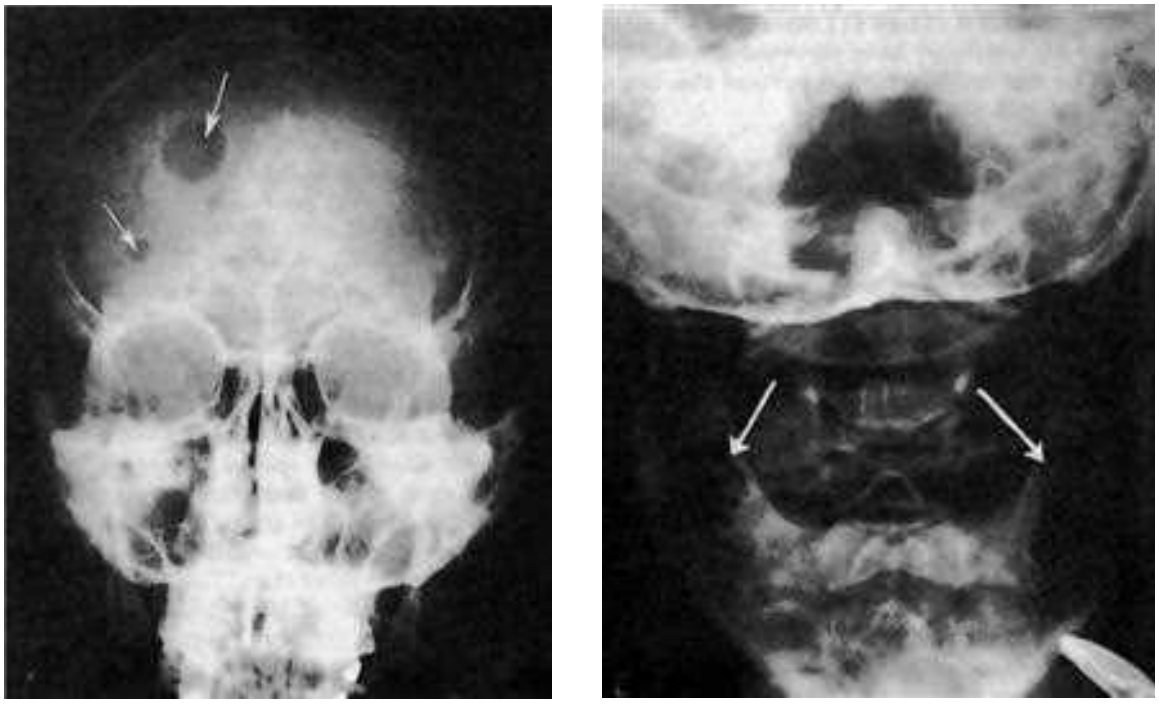
Radiographic Features. Radiographic examination will usually reveal numerous sharply punched-out areas in a variety of bones, which may include the vertebrae, ribs, skull, jaws and ends of long bones (Fig. 2-92). Note that these are all sites of active hematopoiesis. These lesions may vary in size from a few millimeters to a centimeter or more in diameter, but there is usually no peripheral bone reaction. Diffuse destructive lesions of bone may also occur.

Laboratory Features. Certain laboratory findings are of considerable importance in establishing the diagnosis of multiple myeloma. Many patients, but not all, exhibit a hyperglobulinemia **(monoclonal gammopathy)** resulting in a reversal of the serum albumin-globulin ratio and an increase in total serum protein to a level of 8–16 gm%. In addition, the presence of Bence Jones protein in the urine is noted in 60–85% of myeloma patients. This is an unusual protein which coagulates when the urine is heated to 40°–60° C and then disappears when the urine is boiled. It reappears as urine is cooled. Occasionally, Bence Jones protein is found in the urine of patients with diseases other than multiple myeloma, such as leukemia and polycythemia. Furthermore, its absence does not rule out the presence of multiple myeloma. Anemia is also a common finding in multiple myeloma. Kyle has thoroughly discussed the laboratory findings in the Mayo clinic cases.

The diagnostic laboratory finding in myeloma is monoclonal hypergammaglobulinemia. IgG myeloma is the most common, followed by IgA myeloma. As a result of bone destruction, hypercalcemia is a common manifestation and can be difficult to manage. Other laboratory abnormalities include hyperuricemia (resulting from elevated cell turnover), elevated sedimentation rate, and increased levels of alkaline phosphatase.

Monoclonal gammopathy of undetermined significance (MGUS). Patients with MGUS have an M-protein in the serum without findings of multiple myeloma, macroglobulinemia, amyloidosis, or lymphoma and with fewer than 10% plasma cells in the bone marrow. These patients are asymptomatic and should not be treated. They must, however, be followed carefully since about 2% per year will progress to develop one of the symptomatic B-cell neoplasms and may then require therapy.

Histologic Features. The usual lesion is composed of sheets of closely packed cells resembling plasma cells. These are round or ovoid cells with eccentrically placed nuclei exhibiting chromatin clumping in a 'cartwheel' or 'checkerboard' pattern (Figs. 2-93, 2-94). Two nuclei within a single cell membrane are seen occasionally, but mitotic activity is not great. A perinuclear halo may be present. Russell bodies are common



A B

Figure 2-92. Multiple myeloma.
(A) Numerous sharply punched-out areas are found in the skull film. **(B)** The anteroposterior radiograph of another patient shows multiple bilateral radiolucent jaw lesions *(B, Courtesy of Dr Clifford Brown)*.

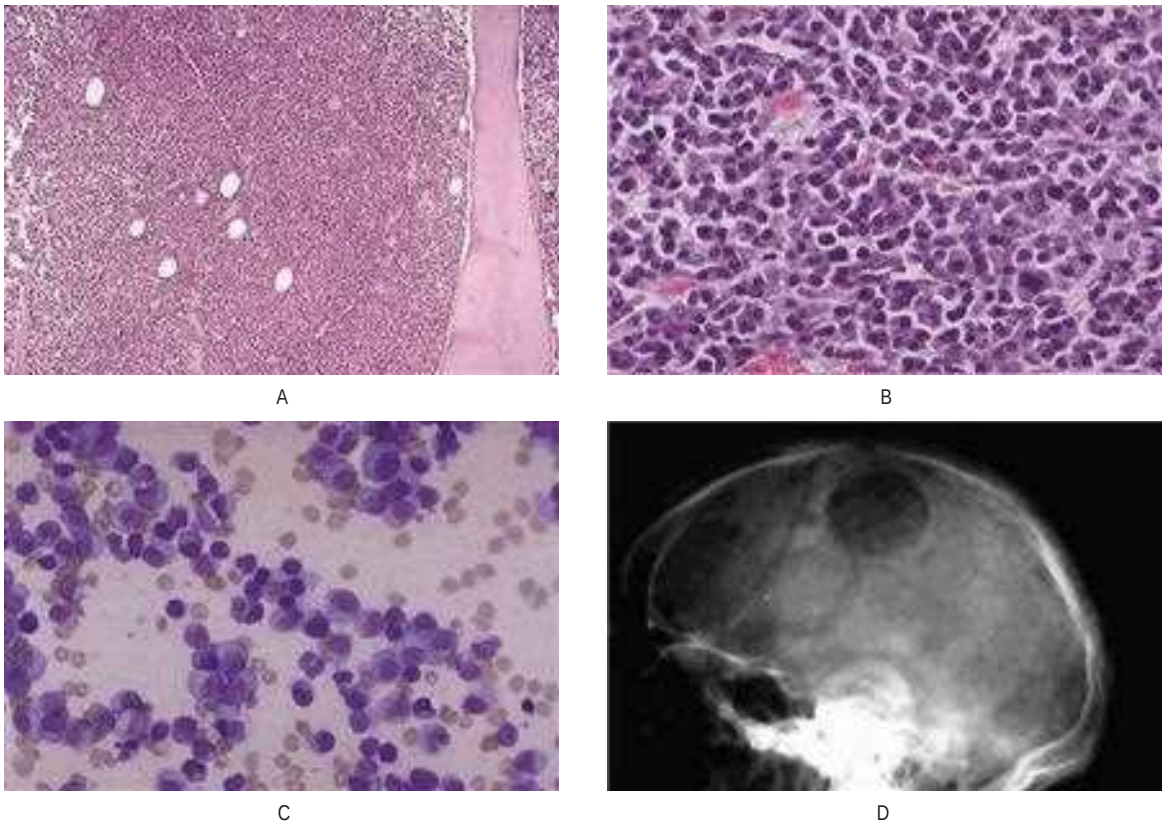


Figure 2-93. Multiple myeloma.
(A) At low power, the abnormal plasma cells of multiple myeloma fill the marrow. **(B)** At medium power, the plasma cells of multiple myeloma here are very similar to normal plasma cells, but they may also be poorly differentiated. Usually, the plasma cells are differentiated enough to retain the function of immunoglobulin production. Thus, myelomas can be detected by an immunoglobulin 'spike' on protein electrophoresis, or the presence of Bence Jones proteins (light chains) in the urine. Immunoelectrophoresis characterizes the type of monoclonal immunoglobulin being produced. **(C)** Here is a smear of bone marrow aspirate from a patient with multiple myeloma. Note that there are numerous plasma cells with eccentric nuclei and a perinuclear halo of clearer cytoplasm. **(D)** The rounded 'punched-out' lesions of multiple myeloma appear as lucent areas with this skull radiograph.

as in chronic inflammatory lesions with numerous typical plasma cells, although it was once thought that their absence in myeloma was noteworthy.

Chen has studied the ultrastructure of a mandibular plasma cell myeloma. He noted numerous mitochondria in a perinuclear distribution as well as prominent Golgi complexes. The latter are most likely responsible for the perinuclear halo which is observed by light microscopy. Wright and his coworkers have discussed the diagnostic value of the immunoperoxidase technique in distinguishing between inflammatory and neoplastic lesions of the jaws which are composed of plasma cells. Inflammatory plasma cell lesions are characterized by polyclonal staining, whereas monoclonal staining is indicative of neoplasia.

Treatment and Prognosis. The role of prophylactic bisphosphonate therapy in the reduction of osteoclastic activity and bone mineralization maintenance is under study.

Treatment choice is determined largely by the age and general health of the patient. Concurrent with the management of specific complications, chemotherapy should be instituted promptly to reduce the number of malignant plasma cells. However, despite the development of many different chemotherapeutic regimens, there has been little improvement in outcome during the past 25 years. Only 5–10% of patients live longer than 10 years. Infection, anemia and kidney failure are the most common immediate causes of death.

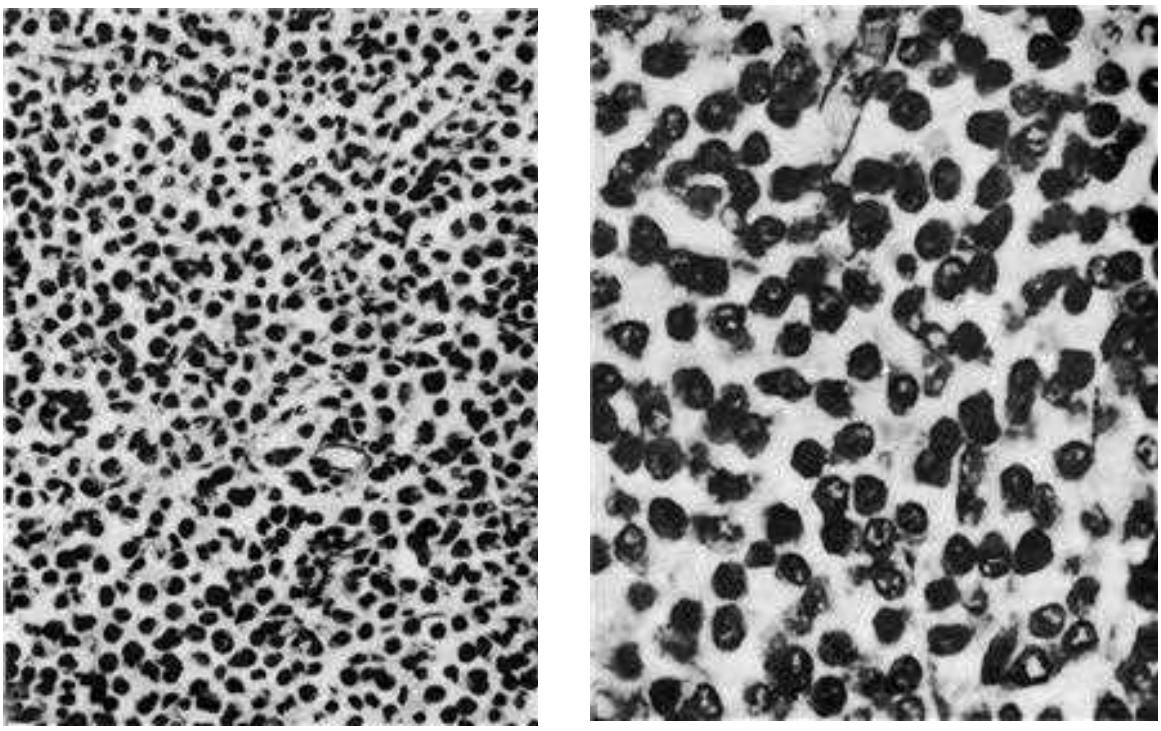
Extramedullary plasmacytoma is a highly curable disease, with progression-free survivals ranging from 70–87% at 10–14 years using radiation therapy (with or without previous resection).

Solitary Plasma Cell Myeloma
(Plasmacytoma)

A plasmacytoma is a discrete, solitary mass of neoplastic monoclonal plasma cells in either bone marrow or a soft tissue site. Solitary plasmacytomas can be divided into two groups according to location:

- Plasmacytoma of the skeletal system (solitary bone plasmacytoma).
- Soft tissue plasmacytoma (extramedullary plasmacytoma).

Clinical Features. The mean age for solitary bone plasmacytoma and soft tissue plasmacytoma is 55 years (range, 50–60 years), which is 10 years younger than multiple myeloma. Different studies show two-thirds of patients were men in plasmacytoma and three-fourths of soft tissue plasmacytoma



A B

Figure 2-94. Multiple myeloma.
(A) The uniform distribution of cells with very little stroma is characteristic of myeloma. **(B)**, Under high magnification, the resemblance of myeloma cells to inflammatory plasma cells is obvious.

cases were males. Solitary bone plasmacytoma may involve any bone, but it has a predisposition for the red marrow containing axial skeleton. Spinal disease is observed in 34–72% of cases. The thoracic vertebrae are most commonly involved, followed by lumbar, sacral, and cervical vertebrae. The rib, sternum, clavicle, or scapula is involved in 20% of cases.

Cytogenetic studies of solitary plasmacytoma have shown recurrent losses in chromosome **13,** chromosome arm **1p,** and chromosome arm **14q** and gains in chromosome arms **19p, 9q,** and **1q.** Interleukin 6 is still considered the principal growth factor in the progression of plasma cell disorders (Dimopoulos, 2000). The specific role of surface markers, adhesion molecules, and angiogenesis in solitary plasmacytoma need to be studied further. Solitary plasmacytoma could be considered an intermediate step in the evolution from monoclonal gammopathy of undetermined significance to multiple myeloma.

The most common symptom is pain at the site of the skeletal lesion due to bone destruction by the infiltrating plasma cells. In other cases, solitary bone plasmacytoma may be discovered during radiographic studies for another condition, or the patient presents with a painless swelling of the sternum, rib, or other bone.

Patients with vertebral involvement may also have evidence of spinal cord or nerve root compression. A few patients present with symptoms and signs of demyelinating polyneuropathy. Compression fractures of the thoracic and lumbar vertebral bodies usually result in severe spasms and back pain.

Although soft tissue plasmacytoma can occur in any site, 90% of tumors develop in the head and neck area, especially in the aerodigestive tract, without apparent primary bone involvement. Approximately 80% of cases involve the paranasal sinuses, pharynx, nasal cavity, or gums and oral mucosa. Soft tissue plasmacytoma presents as a mass growing in the aerodigestive tract (80% of the cases) with spread to lymph nodes, although other sites are affected as well. Because of the usual presentation as submucosal lesions of the upper aerodigestive tract, swelling, headache, nasal discharge, epistaxis, nasal obstruction, sore throat, hoarseness, dysphonia, dysphagia, dyspnea, epigastric pain, and hemoptysis are common symptoms. Symptoms from plasmacytomas in other tissues are associated with the site of the tumor, tumor size, and to compression and/or involvement of the surrounding structures. The etiology is thought to be due to long-term stimulation by inhaled irritants or viral infection.

Oral Manifestations. Occasional cases of solitary plasma cell myeloma of bone have been reported in the jaws, both maxilla and mandible. Caution must be exercised, however, in diagnosing a lesion of the jaws as solitary myeloma, since the finding of large numbers of plasma cells in granulomas associated with dental infection is common. It is in such cases that immunoperoxidase techniques may be of diagnostic value.

Extramedullary plasmacytoma may be situated on the gingiva, palate, floor of the mouth, tongue, tonsils and pillars

as well as the nasal cavity, nasopharynx and paranasal sinuses. The lesions are described as sessile or polypoid reddish masses in the mucous membranes, which become lobulated as they enlarge, but do not tend to ulcerate.

The nature of the extramedullary plasmacytoma is as obscure as that of the other forms of plasma cell lesions. It is undoubtedly different from the common plasma cell-containing granulomas and polyps which are commonly found in the upper air passages and oral cavity. Yet, though the majority of the reported cases of plasma cell tumors in this location remain localized lesions in the soft tissue, metastases have occurred to lymph nodes, bones and other sites. In a discussion of this disease by Kotner and Wang, it was pointed out that only 10–20% of patients develop regional lymph node metastases.

Corwin and Lindberg studied 12 patients with extramedullary plasmacytoma. Two of the 12 developed multiple myeloma. Thus these tumors should be regarded as serious and potentially fatal, although they have a much more favorable prognosis than multiple myeloma.

Radiographic Features. Radiographic examination of the bones in solitary plasma cell myeloma reveals one of the two types of lesions. One type is a purely destructive intramedullary lesion suggestive of metastatic carcinoma. The other type of lesion is an expansile one suggestive of a giant cell tumor. There is nothing pathognomonic or even characteristic of the radiographic picture of solitary myeloma.

Computed tomographic scan is used to depict the extent of the infiltrating lesion more clearly, but MRI is the best imaging study. The appearance of solitary bone plasmacytoma on MRI resembles that of other primary or secondary malignancies that produce lytic destruction of the bone with a focal area of bone marrow replacement, but MRI also may show unanticipated foci of bone marrow involvement.

Laboratory Features. Laboratory findings are interesting because few (24–72%) of the patients exhibit Bence Jones protein in the urine or serum. With disease progression, monoclonal protein may be found in the serum or urine in some patients. Furthermore, the characteristic hyperglobulinemia and anemia, so characteristic of multiple myeloma, are absent in solitary myeloma and extramedullary plasmacytoma.

Histologic Features. It has been stated previously that the histologic features of the solitary and multiple myeloma are similar. In the well-differentiated lesions of multiple myeloma it is impossible to distinguish between the two. The extramedullary plasmacytoma is also microscopically identical with the solitary myeloma. Nevertheless some cases of multiple myeloma present a variegated histologic picture which is not seen in solitary myeloma or the extramedullary plasmacytoma.

Treatment and Prognosis. Definitive local radiotherapy is the treatment of choice for solitary bone plasmacytoma. Treatment fields should be designed to encompass all disease shown by MRI or CT scanning and should include a margin of normal tissue.

The accepted treatment for extramedullary plasmacytoma is radiotherapy. When a lesion can be completely resected, surgery provides the same results as radiotherapy. Combined therapy (surgery and radiotherapy) also is an accepted treatment depending on the resectability of the lesion.

BENIGN TUMORS OF MUSCLE TISSUE ORIGIN

Leiomyoma

The leiomyoma is a benign tumor derived from smooth muscle and is found in a variety of anatomic sites, including the skin, subcutaneous tissues and the oral cavity. Most leiomyomas occur in the uterus, the so-called fibroids. Under the microscope, they are nearly identical in every site. Clinically, they are soft tissue tumors that present with pain. They are uncommon in the oral cavity probably because of the general absence of smooth muscle there except in blood vessel walls and, occasionally, in the circumvallate papillae of the tongue.

Clinical Features. The majority of cases of leiomyoma have occurred on the posterior portion of the tongue, although others have been found on the palate, cheeks, gingiva, lips and salivary glands. Of the reported cases, the majority of oral leiomyomas occur in adults in the middle decades of life, over 65% being found in patients older than 30 years of age, although cases are described in young children in the first decade.

The oral leiomyoma is a slow-growing, painless lesion which is superficial and often pedunculated. The presenting symptoms of some of the patients in the reported cases have been 'sore throat' or 'tumor in the throat'. The tumor does not ulcerate and resembles the normal mucosa in color and texture.

A **central leiomyoma** of the jaw is also known to occur but is exceedingly rare. A case in the mandible, with ultrastructural confirmation, has been reported by Goldblatt and Edesess, who have also reviewed the literature on the central lesions of bone.

Histologic Features. The leiomyoma is composed of interlacing bundles of smooth muscle fibers interspersed by varying amounts of fibrous connective tissue. The muscle nuclei are typically spindle-shaped with blunt ends and quite vesicular. The bundles of fibers appear to form whorls because of their fascicular arrangement in varying planes. Intracytoplasmic myofibrils are present and can be demonstrated by phosphotungstic acid-hematoxylin special stain. Masson's trichrome stain is also commonly used to differentiate between collagen and smooth muscle. Leiomyoma cells are positive for smooth muscle markers like desmin, vimentin, actin, myosin and alpha smooth muscle actin.

Treatment and Prognosis. This smooth muscle neoplasm is best treated by conservative surgical excision, since it does not tend to recur or become malignant.

Angiomyoma
(Vascular leiomyoma, angioleiomyoma)

Leiomyomas and angiomyomas have commonly been treated as two forms of the same basic lesion in the past and reported

together as an entity. Thus, some lesions are quite vascular, being composed of large numbers of blood vessels of an atypical nature with disoriented smooth muscle layers (the angiomyoma), while others are relatively avascular. The suggestion has even been made that there may be a progression of lesions: hemangioma, angioma with much nonstriated muscle, vascular leiomyoma, leiomyoma with many vessels and solid leiomyoma. Thus, it has been proposed that the vascular leiomyoma may be only a stage in the continuous process of smooth muscle proliferation. Most investigators nowadays believe that the angiomyoma probably represents a hamartomatous malformation, while the solid leiomyoma represents a true neoplasm and that, therefore, these two entities should be clearly separated. This has been discussed in detail by Damm and Neville. Since the two lesions have been combined in the literature, separation of their clinical characteristics at this time is not possible, although Reichart and Reznik-Schuler have reported the ultrastructure of an oral angiomyoma and discussed some of the cases classified under this term.

Rhabdomyoma

The term rhabdomyoma was introduced by Zenker (1864) to indicate a benign tumour showing skeletal muscle cell with varying degree of differentiation and maturity. Rhabdomyomas are currently defined as benign neoplasm of striated muscle tissue, consisting usually of polygonal frequently vacuolated glycogen containing cells with a fine granular deeply acidophilic cytoplasm resembling myofibril in cut section.

The term 'rhabdomyoma' was used for benign tumor, arising from the cardiac muscle, often associated with a hamartoma complex, including sebaceous adenomas, tuberous sclerosis, and hamartomas of the kidney and other organs. Seventy to 90% of extra cardiac rhabdomyomas are found in the head and neck region but it is still a rare neoplasm of the maxillofacial region. They are subdivided into adult, fetal and genital histological subtypes.

The etiology is unknown. However, clonal balanced translocation (reciprocal) has been found in chromosomes 15 and 17 in adult rhabdomyoma tumors of head and neck.

Clinical Features. The adult form of rhabdomyoma occurs primarily in the middle-aged in the 16–82 years old (mean age 52 years). There is a marked male predominance of almost 5:1. The most frequent head and neck sites of involvement are the pharynx and the oral cavity, although laryngeal lesions have also been reported. Within the mouth, the oral floor is most often affected, pharyngeal lesions occur most frequently in the base of the tongue and the soft palate.

Fetal rhabdomyoma usually occurs in newborns and young children, but the lesion has been reported in patients as old as 50 years of age. This type also has a strong male predilection. The most common sites are post- or, preauricular region, or face, followed by nasopharynx but not in the mouth.

Both tumor types present as a nodule or submucosal mass which can become several centimeters in size. Multinodular tumors have been described, with two or more discrete nodules closely adjacent to one another. Rarely, separate tumors may be found at different anatomic sites.

Histologic Features. The tumor is composed of large, round cells that have a granular, eosinophilic vacuolated cytoplasm and show irregular cross-striations. This cytoplasm is rich in glycogen and glycoprotein. A fibrous stroma is present and mitotic activity is extremely low. Many cases demonstrate occasional degeneration vacuoles or clear spaces between the tumor cells.

The fetal rhabdomyoma is comprised of less mature, somewhat pleomorphic, polygonal muscle cells admixed with spindle-shaped cells. This type is typically more cellular than the adult type and often has a myxoid stroma. Mitotic activity is minimal but the more pleomorphic examples can be mistaken for rhabdomyosarcoma.

Cross-striations and crystalline structures are more readily identified with the phosphotungstic acid-hematoxylin (PTAH) stain, and oil red O staining will often reveal intracellular lipid. Lesional cells are immunoreactive with myoglobin, desmin and vimentin. Muscle specific actin, myoglobin may show focal positivity.

Treatment and Prognosis. Both variants of rhabdomyoma are treated by conservative surgical excision. Recurrence has been reported but is uncommon. Malignant transformation has not been reported.

Granular Cell Myoblastoma

(Myoblastic myoma, granular cell tumor, granular cell schwannoma)

It is not clear whether or not granular cell tumor is a true neoplasm, a developmental anomaly, or a trauma-induced proliferation. The original interpretation of the tumor being of muscle origin (granular cell myoblastoma) has been abandoned. The basic cell of origin is now thought to be neural, although past reports frequently indicated an origin from striated muscle, or less frequently an origin from histiocytes, fibroblasts or pericytes. The tumor is widely distributed throughout the body, but more than half of all cases occur in the oral cavity. The other head and neck site likely to be involved is the larynx.

Clinical Features. The lesion is typically diagnosed between the ages of 30 and 60, but it can arise at any age. There is no gender predilection for oral cases, but overall almost twice as many cases are diagnosed in women as in men.

More than one third of all granular cell tumors occur on the lingual dorsum, usually as a sessile, painless, somewhat firm, immovable nodule less than 1.5 cm in greatest diameter. Lesions often demonstrate pallor or yellowish discoloration and typically have a smooth surface.

Other oral and pharyngeal sites of involvement include the soft palate, uvula, labial mucosa, oral floor and gingiva. As many as 15% of patients will have granular cell tumors of multiple anatomic sites, with as many as 50 individual lesions in one patient.

Histologic Features. The granular cells are large polygonal, oval or bipolar cell of about 20–40 μ in diameter with abundant, fine or coarsely granular eosinophilic cytoplasm, and a small, pale-staining or vesicular nucleus eccentrically located in the cell. The cell membrane is moderately distinct (Fig. 2-95).

Granular cells often occur in ribbons separated by fibrous septa, giving the appearance of infiltrating or 'invading' into underlying tissues, especially muscle, with the bipolar shape being more frequently noted at the leading edge. The cells may also appear to be streaming off from or metaplastically arising from underlying muscle fibers. Older lesions tend to become desmoplastic with a few scattered nests of granular cells in a densely fibrotic background. Granular cells demonstrating nuclear enlargement, hyperchromatism and pleomorphism, or with mitotic activity or increased cellularity, are elements of the malignant variant of this tumor.

Ultrastructural studies have described the cytoplasmic granules as autophagic vacuoles containing cellular debris, including mitochondria and fragmented endoplasmic reticulum, as well as myelin. Background stroma is minimal.

Granular cells are positive for S100 protein, neuron-specific enolase (NSE), laminin and myelin basic proteins. Staining is negative for neurofilament proteins and glial fibrillary acidic protein (GFAP). Granules are PAS positive and diastase resistant.

It is particularly common for the surface of the lesion to be covered by a layer of stratified squamous epithelium exhibiting remarkable pseudoepitheliomatous hyperplasia which has been confused with epidermoid carcinoma.

Treatment and Prognosis. Conservative excision is the treatment of choice for granular cell tumor. Recurrence is seen in fewer than 7% of cases thus treated, even if granular cells extend beyond the surgical margins of the biopsy sample. A few reported metastasizing granular cell tumors have appeared to be histologically benign, and for this reason, tumors that recur, grow rapidly or reach a size greater than 5 cm should be viewed with grave suspicion.

Congenital Epulis of the Newborn

Congenital granular cell lesion or 'congenital epulis' is a rare lesion of the newborn. It is also known as **Neumann's tumor,** is benign in nature, mostly occurs as a single tumor but rarely as multiple. The histogenesis and natural clinical history of the lesion remain obscure. Even with the advent of modern histopathological techniques, it has not been possible to depict specific cellular features unique to this lesion.

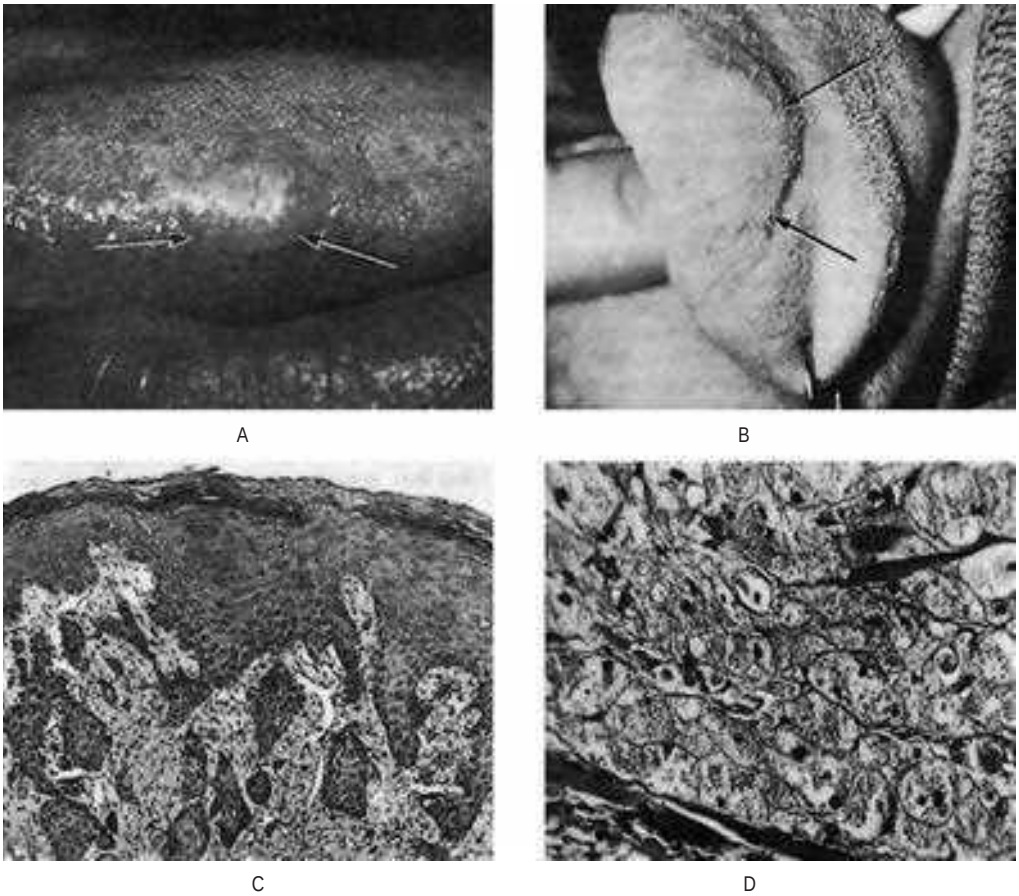


Figure 2-95. Granular cell myoblastoma.
(A) The lesion appears as a small nodular growth on the lateral border of the tongue. **(B)** The tumor may become quite large. **(C)** The low-power photomicrograph illustrates the remarkable overlying pseudoepitheliomatous hyperplasia, which may be mistaken for epidermoid carcinoma. **(D)** Under higher magnification the granular nature of the cells comprising the lesion can be seen. *(B, Courtesy of Dr Ronald Vincent)*.

A B

Figure 2-96. Congenital epulis of the newborn.
The nodular lesion of the maxilla **(A)**, present at birth, was composed of large, closely packed cells with an eosinophilic, granular cytoplasm **(B)**.

The congenital epulis of the newborn bears an unusual resemblance to the granular cell myoblastoma and is considered by some persons to be the same lesion. Nevertheless, there are certain features of the congenital epulis which are distinctly different from the granular cell myoblastoma, and as has been suggested by Custer and Fust, it is most likely a separate pathologic entity.

The congenital epulis is present at birth, as the name implies, and in this regard is distinctly different from the granular cell myoblastoma. It has been suggested that a protuberant mass of the maxilla, the typical site of the congenital epulis, would be more obvious than a lesion in the substance of the tongue, the usual site of the granular cell tumor, and thus would be apt to be discovered at a far earlier age than the tongue lesion. On this basis, it is conceivable that the two tumors are similar in nature, although actually the maxilla has been found to be the most unusual site for the occurrence of a granular cell tumor.

A number of workers have suggested that these congenital epulides are malformations of the dental blastema and should be regarded as a type of embryonal hamartoma and not a true neoplasm. The basis for such a belief is the presence of numerous epithelial rests in some sections of these tumors. Remember, however, that such epithelial inclusions are remnants of the dental lamina and may be found normally in most jaws of infants. Their occurrence in the congenital epulis is more likely to be coincidental than associated with the development of the lesion. Other theories of origin include the fibroblastic, histiocytic, myogenic and neurogenic. These have been discussed in a centennial review of the congenital epulis by Fuhr and Krogh.

Clinical Features. This tumor is present at birth and is located on the maxillary or mandibular gingiva, although it is somewhat more common on the maxilla than the mandible, by a ratio of approximately 2:1.

It is usually a pedunculated lesion found in the incisor region, apparently arising on the crest of the alveolar ridge or process (Fig. 2-96A). It may vary considerably in size from just a few millimeters in diameter to several centimeters. Of 40 cases reported in the literature and reviewed by Custer and Fust, only three occurred in males. Of the 113 cases reported since the original description of a congenial epulis by Neumann in 1871, 80.5% were females, 10.6% were males and 8.9% were of unstated sex, according to the review of Fuhr and Krogh.

Histologic Features. The congenital epulis is histologically similar to the granular cell tumor, although pseudoepitheliomatous hyperplasia does not occur in the former lesion. Thus sheets of large, closely packed cells showing fine, granular, eosinophilic cytoplasm comprise the tumor mass (Fig. 2-96B). Neither mitoses nor cross-striations are visible, but capillaries are numerous. In fact, the vascular component is much more prominent than in the granular cell tumor. Study by means of special staining techniques has not been highly informative.

An electron microscopic study of a congenital epulis by Kay and his associates revealed junctional complexes between some of the granular cells which suggested that they might be of epithelial origin, although the studies were not entirely conclusive. However, Lack and his associates reported that their ultrastructural findings strongly supported a mesenchymal histogenesis. In addition, their tissue assay for estrogen receptors was negative, but considering the marked predilection of the lesion for females, a hormonal factor could not be ruled out in its development. Congenital epulis is negative for S100 and other markers found in the granular cell tumor.

Treatment. The treatment for the congenital epulis is surgical excision with little possibility of recurrence. However, Welbury has suggested, on the basis of a few scattered reports, that the natural history of this lesion is one of spontaneous regression and that no treatment is required unless dictated by feeding or respiratory problems.

MALIGNANT TUMORS OF MUSCLE TISSUE ORIGIN

Leiomyosarcoma

The leiomyosarcoma is a malignant tumor of smooth muscle origin. It is very rare in the oral cavity and whether it develops through malignant transformation of a leiomyoma or de novo is not known. It probably arises at these sites from smooth

muscle cells, especially those found in blood vessel walls, and from undifferentiated mesenchymal cells.

Clinical Features. Leiomyosarcoma typically presents as painful, lobulated, fixed mass of the submucosal tissues in a middle-aged or older individual. It is exceedingly rare in children. Lesions are usually less than 2 cm in diameter at diagnosis and are slow-growing, but secondary ulceration of the mucosal surface has been reported. The cheek and floor of mouth were the most common sites. No gender predilection was apparent in these cases.

Histologic Features. Leiomyosarcoma is composed of fascicles of interlacing spindle-shaped cells with abundant eosinophilic cytoplasm and moderately large, centrally located, cigar-shaped or blunt-ended nuclei, often with mild atypia. Cellularity and cellular differentiation can vary considerably between tumors and between different areas of the same tumor. The well-differentiated lesion shows the spindled cells streaming or interweaving in fascicles in a fashion similar to that seen in leiomyoma. Nuclear palisading may be seen in several areas of the tumor, ischemic areas show stromal fibrosis and hyalinization (Fig. 2-97).

The epithelioid variant, called **malignant leiomyoblastoma** or **epithelioid leiomyosarcoma,** is most prevalent in the gastrointestinal and genitourinary tracts and has rarely been reported in oral or pharyngeal locations.

Treatment and Prognosis. Radical surgery is the treatment of choice for leiomyosarcoma, with adjunctive chemotherapy or radiotherapy used occasionally. The prognosis is poor, with numerous recurrences and distant metastases. Overall five-year survival is approximately 35–50%.

Intracellular myofibrils are readily discerned with the Masson trichrome stain, longitudinal striations of myofibrils may be seen within lesional cells with the PTAH stain and reticulin staining of well-differentiated lesions will demonstrate a delicate meshwork of reticulin fibers surrounding individual tumor cells (or clusters of tumor cells, in the case of epithelioid lesions). Well differentiated lesions are strongly positive for desmin, and alpha smooth muscle actin. Glycogen granules can be demonstrated with PAS staining.

The presence of mitoses is a hallmark of malignancy (at least 1 mitotic figure per 10 high power fields), lesions with 5 or more mitotic figures per 10 high-power fields should definitely be considered malignant.

Epithelioid leiomyosarcoma demonstrates numerous rounded epithelioid cells with either eosinophilic or clear cytoplasm. These cells seldom display obvious myoblastic differentiation and are easily demonstrated with the PAS-diastase reaction; electron microscopy will usually show the classic features of leiomyoblasts.

The study done by Wang R et al. suggest that **13q14–q21** loss and **5p14** gain at diagnosis could be used to identify patients with leiomyosarcoma who are likely to have a shorter survival time and who might benefit from early treatment intensification.

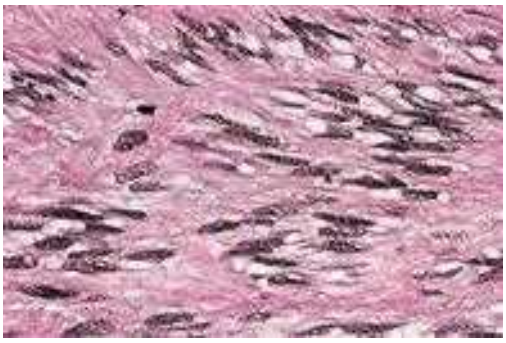

Figure 2-97. Leiomyosarcoma of oral cavity.

Rhabdomyosarcoma

The rhabdomyosarcoma, the malignant tumor of striated muscle, is a relatively uncommon tumor in the oral cavity. According to Rubin, it is derived from primitive mesenchyme that retained capacity for skeletal muscle differentiation. The first published example of rhabdomyosarcoma was probably a tongue lesion reported in 1854.

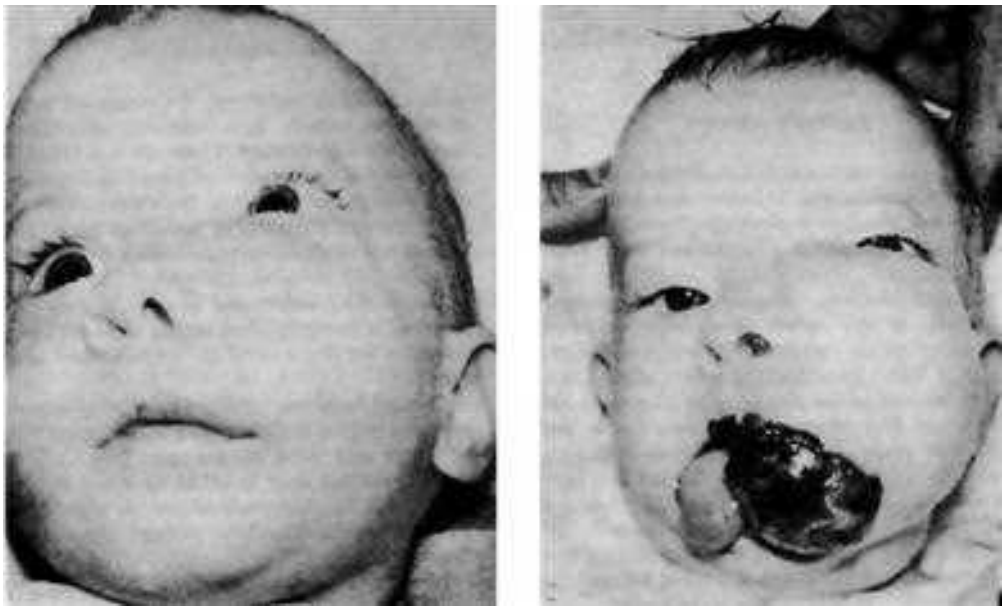
There are four separate types of rhabdomyosarcoma based on histologic appearance, and many of the clinical features are quite characteristic of certain of these. The four forms of rhabdomyosarcoma are:

- Pleomorphic
- Alveolar
- Embryonal
- Botryoid.

The embryonal form of rhabdomyosarcoma is recognized as having a marked predilection for occurrence in the head and neck area.

Clinical Features

Embryonal rhabdomyosarcoma. This is the most common subtype observed in children, accounting for 60–70% of all rhabdomyosarcoma cases in this age group. These tumors can occur at any site, but they are most commonly observed either in the genitourinary region or the head and neck region. They occur more commonly in the head and neck area than any of the other forms. Stobbe and Dargeon have pointed out that this neoplasm arises chiefly from the orbital, facial, and cervical musculature. Of 15 cases reported by Stobbe and Dargeon, the sites of occurrence included the orbit and inner canthus, the tonsil, soft palate, mastoid, internal ear and parotid, zygoma, and temporal and cervical regions. The average age of this group of patients was six years, ranging from 16 months to 16 years, with no gender predilection. In another review of 37 cases of this tumor by Moore and Grossi, the cheek, mandible and gingiva were found to be additional sites of occurrence. The youngest patient in this series was seven weeks, although there is one case on record of an infant born with an embryonal



A B

Figure 2-98. Embryonal rhabdomyosarcoma.
The rapidity of growth of this type of neoplasm can be judged by the fact that the two illustrations of this lesion, originating in the buccal mucosa, were taken only 14 days apart.

rhabdomyosarcoma of the floor of the mouth. In a series of 48 patients with embryonal rhabdomyosarcoma reported by Lawrence and his associates, the ages at diagnosis ranged from 16 days to 14 years, with a mean of five years. Finally, a series of 11 cases of embryonal rhabdomyosarcoma of the oral soft tissues have been reported by O'Day and his associates. The age of these patients ranged between 2 and 41 years of age, with a mean of 16 years. Of these oral tumors, four were in the soft palate, three in the cheek and one each in the upper and lower labial folds, lower buccal fold and lateral aspect of the tongue (Fig. 2-98).

Botryoid rhabdomyosarcoma (sarcoma botryoides) has been long recognized as a malignant tumor of the vagina, prostate, and base of the bladder in young children. Today, it is generally accepted as a variant of embryonal rhabdomyosarcoma and has been reported also involving the maxillary sinus, nasopharynx, common bile duct and middle ear. This tumor accounts for 10% of all rhabdomyosarcoma cases. It was formerly separated out as an entity because of its unusual clinical growth pattern.

Alveolar rhabdomyosarcoma. This subtype making up about 20% of all rhabdomyosarcomas in an analysis of 110 cases by Enzinger and Shiraki, is reported to occur much earlier in life, generally between 10 and 20 years of age with a median of 15 years. However, the range in this group was five months to 58 years. While the majority of cases of this type also occurred in the extremities, approximately 18% were found in the head and neck region.

Pleomorphic rhabdomyosarcoma (least common of all rhabdomyosarcoma) is a form of the tumor which, according to Patton and Horn, occurs more frequently in the extremities than in other sites and is generally seen in older individuals. In a series of 19 cases reported by these authors, the average age was 53 years.

The chief presenting complaint of the patient with rhabdomyosarcoma, generally irrespective of the histologic type, is usually swelling, but pain may be present if there is nerve involvement. Depending upon the site of the lesion, the following phenomena may be recognized: divergence of an eye, abnormal phonation, dysphagia, cough, aural discharge or deviation of the jaw. The lesions are occasionally ulcerated and may invade underlying bone and develop distant metastases. The most common site of presentation is head and neck region (35 %).

In embryonal rhabdomyosarcoma, the loss of heterozygosity of chromosome **11p15** was identified and in alveolar type unique translocation occurs between the **FKHR** gene on chromosome **13** and either the **PAX3** gene on chromosome **2** (70%) or the **PAX7** gene on chromosome **1** (30%). Individuals with the **PAX7** translocation are younger and may have longer event-free survival than those with the **PAX3** translocation (Marcus KC, 2001).

Histologic Features

Embryonal rhabdomyosarcoma has been described by O'Day and his coworkers as exhibiting a mixture of four cell types:

- Eosinophilic spindle cells, usually arranged in interlacing fascicles.
- Round eosinophilic cells, large and intermediate in size, with a small nucleus and a granular eosinophilic cytoplasm, generally interspersed among other cell types.

- Broad elongated eosinophilic cells, occasionally with cross-striations.
- Small round and spindle cells with dark-staining nuclei and little cytoplasm (Fig. 2-99C).

The more well-differentiated tumors demonstrate elongated, strap-shaped or tadpole-shaped rhabdomyoblasts. The background stroma consists of moderately loose to dense fibrous tissue and may be quite scant, myxoid zones are commonly seen in the stroma.

Pleomorphic rhabdomyosarcoma is composed chiefly of spindle cells in a haphazard arrangement. These cells are generally large and show considerable variation in appearance. The nuclei are ovoid or elongated with packed chromatin. A characteristic feature of this form of tumor is the large bizarre cells, the nuclei situated often in an expanded end of the cell, the 'racquet' cell. 'Strap' and 'ribbon' cells typically show processes of long streaming cytoplasm. Mitoses, particularly atypical, are common. The cytoplasm is eosinophilic, and intracytoplasmic longitudinal fibrils as well as transverse cross-striations may be seen. Cytoplasmic vacuoles are also present as a result of large amounts of glycogen in the cell (Fig. 2-99A). This tumor is often so undifferentiated that the identification of the cell of origin is difficult or impossible. Positive immunostains for desmin and myoglobin are very helpful in such cases.

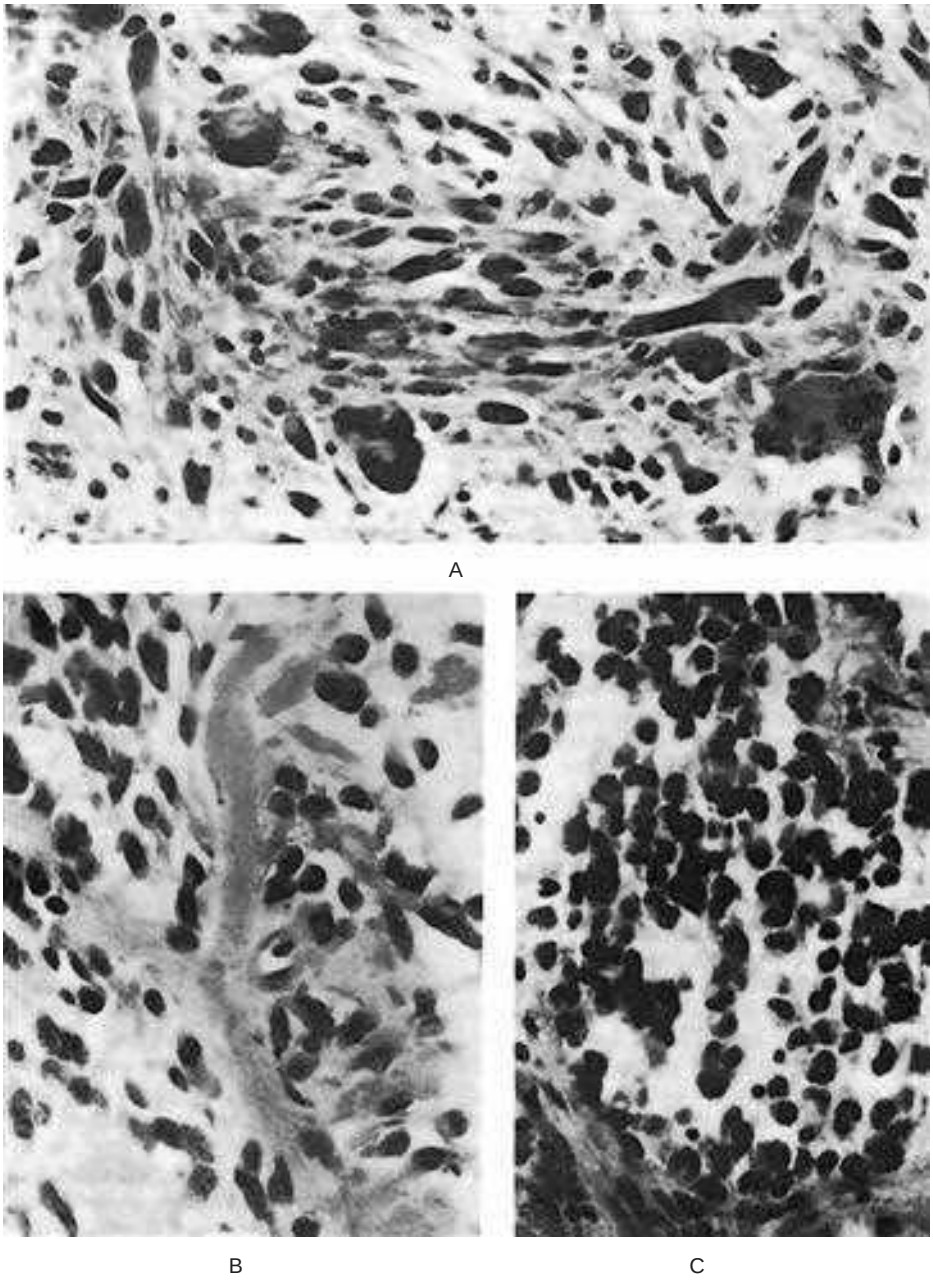


Figure 2-99. Rhabdomyosarcoma.
(A) Pleomorphic type. **(B)** Embryonal type. **(C)** Alveolar type.

Alveolar rhabdomyosarcoma is comprised of relatively small, poorly differentiated round and oval cells aggregated into irregular clusters or nests separated by fibrous septa. Degenerated cells in the center of the clusters show lack of cohesiveness, while the peripheral cells adhere in a single layer to the septal walls. Multinucleated giant cells may be seen and mitotic figures are common and sometimes bizarre. It is differentiated from the alveolar soft part sarcoma by its less regular tissue pattern and more pleomorphic cells.

An occasional variant, referred to as the **botryoid type,** demonstrates a diffuse myxoid or mucoid matrix with sparsely scattered primitive mesenchymal cells. The characteristic feature of this type is a peripheral zone of increased cellularity, sometimes known as the **'cambium layer'**.

Regardless of the histologic subtype, special stains are often quite useful for differentiating rhabdomyosarcoma from other neoplasms. The trichrome stain colors rhabdomyoblasts bright red while myofilaments and cross-striations are stained by PTAH (deep purple color). Myxoid stroma may be positive for hyaluronidase with acid mucopolysaccharide staining, although many other tumors also have positive stroma with these stains.

Treatment and Prognosis. Rhabdomyosarcoma is treated by radical surgical excision followed by multiagent chemotherapy. Postoperative radiotherapy is used for those cases which cannot be completely resected.

Alveolar Soft-Part Sarcoma
(Malignant granular cell myoblastoma)

The alveolar soft-part sarcoma is a tumor of uncertain histogenesis originally described under this name by Christopherson and his coworkers in 1952. It is a rare tumor, thought by some investigators to be of striated muscle origin, although it differs in some respects from the alveolar type of rhabdomyosarcoma. Other workers believe that it may be of neural origin and a variant of malignant granular cell tumor or a malignant nonchromaffin paraganglioma. Studies showed alveolar soft-part sarcomas are myogenic by immunophenotyping in a number of cases. In recent years, pathologists have shown this tumor to be a variant of a rhabdomyosarcoma, a sarcoma of skeletal muscle. Chromosome rearrangement at **17q25** and **Xp11.2** in alveolar soft-part sarcoma was demonstrated.

Clinical Features. The initial report of Christopherson indicated that this is predominantly a tumor of females, occurring usually in the teens or early 20s. A study of 53 cases by Lieberman and his associates has confirmed these findings. Of the 53 patients, 34 were female and 19 were male. The average age of their male patients was 30 years but that of their female patients, only 20 years. Occasional cases in older adults are reported.

Approximately one in four lesions occur in the head and neck region, usually the oral cavity, pharynx and orbit. However, the greatest predilection is for the muscles of the extremities, although lesions in the tongue and floor of the mouth have been reported by Caldwell and his associates. Only one of the 53 cases reported by Lieberman and his associates was intraoral and this occurred in the tongue. Font and his associates have reported 17 cases involving the orbit. The lesions are usually slow-growing, well-circumscribed masses with no distinguishing gross features.

Histologic Features. This tumor is composed of large cells with a finely granular cytoplasm that is not as eosinophilic as the cell of the rhabdomyosarcoma. The lesional cell is large and polygonal with a distinct cell border, a vesicular nucleus, and dense, abundant granular, eosinophilic or vacuolated cytoplasm. There is minimal variation in size and shape between cells and mitotic activity is sparse. These cells have a uniform pseudoalveolar or organoid pattern, arranged in relation to numerous delicate endothelium-lined vascular channels and septa (Fig. 2-100). The pattern is reminiscent of that seen in the nonchromaffin paraganglioma.

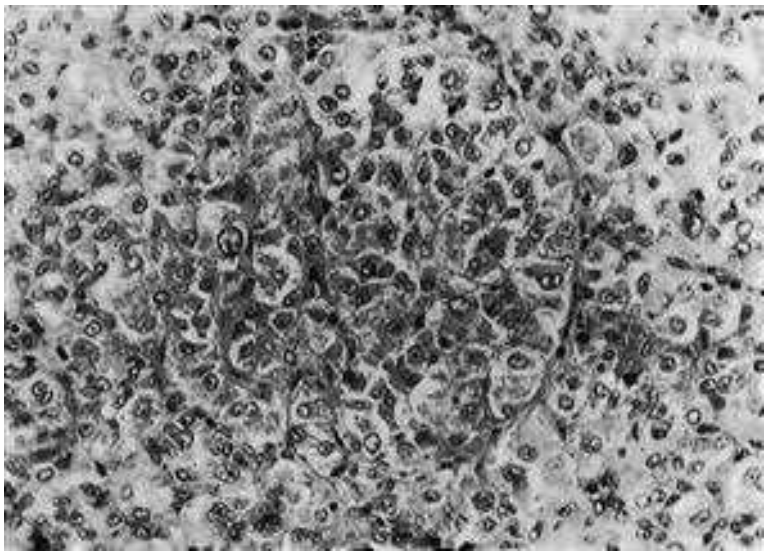

Figure 2-100. Alveolar soft-part sarcoma.

Vascular invasion is a frequent finding. Reticulin stains will enhance the organoid arrangement of the tumor cells.

Marshall and Horn reported that the alveolar soft-part sarcoma consistently showed a strongly positive periodic acid-Schiff (PAS) reaction before and after treatment with diastase, similar to the benign granular cell myoblastoma, but in contrast to the alveolar rhabdomyosarcoma in which the PAS-positive material is removed by digestion with diastase. This PAS-positive material in the cytoplasm of the alveolar soft-part sarcoma, described by Font and his coworkers as a highly characteristic and virtually pathognomonic finding of this lesion, represents crystalline structures composed of a protein-carbohydrate complex. They appear to form by coalescence of peculiar membrane-bound granules that exhibit acid-phosphatase activity.

Treatment and Prognosis. Radical surgical excision is the accepted treatment for this lesion because of the high frequency of recurrence, metastases and death of patients. Marshall and Horn reported the recurrence or metastatic rate as 70%, five-year survival being uncommon. Lieberman and his coworkers stated that they knew of no lifetime cures.

BENIGN TUMORS OF NERVE TISSUE ORIGIN

Traumatic Neuroma
(Amputation neuroma)

Traumatic (post-traumatic) or amputation neuroma is not a true neoplasm, but rather an exuberant attempt at repair of a damaged nerve trunk, i.e. a hyperplasia of nerve fibers and their supporting tissues. It most frequently follows accidental or purposeful sectioning of a nerve and may be incidental to difficult extraction. Cases also have occurred after an accident in which the lip or tongue was deeply lacerated by the teeth and nerve fibers were inadvertently severed.

Degeneration of the distal portion of the nerve after severance of the nerve fibers begins with swelling, fragmentation and disintegration of the axis cylinders and myelin sheaths. Macrophages serve to remove this tissue debris. The neurilemmal sheaths or tubes shrink until the distal degenerated fibers consist only of strands of connective tissue and the neurilemma. The nerve does not disappear completely.

Repair of a damaged nerve begins with proliferation of the axis cylinders, the cells of the neurilemmal sheaths and the endoneurium. Regeneration is facilitated by the persistence of the neurilemmal tubes, since new fibers proliferate through them and Schwann cells multiply around them.

Reinnervation usually occurs; unless the proliferating proximal end meets some obstruction, such as scar tissue or a malaligned bone, in which case the nerve continues to proliferate into an unorganized bulbous or nodular mass of nerve fibers and Schwann cells in varying proportions. This constitutes a traumatic neuroma. The pathogenesis of this lesion has been reviewed by Swanson.

Clinical Features. The oral traumatic neuroma usually appears as a small nodule or swelling of the mucosa, typically near the mental foramen, on the alveolar ridge in edentulous areas or on the lips or tongue (Fig. 2-101). A central lesion within the substance of the bone associated with a nerve trunk may also occur. This is a slowly growing lesion and seldom reaches a size greater than a centimeter in diameter (Fig. 2-101A, B).

Digital pressure may cause considerable pain locally, and in some instances along the course of the nerve involved. Reflex neuralgia with distant pain associated with the face, eyes and head has been recorded. Traumatic neuroma has been discussed in detail by Robinson and Slavkin and by Sist and Greene, who also reported 31 cases.

The **palisaded, encapsulated neuroma** is not a form of traumatic neuroma but may represent a primary hyperplasia of nerve fibers, the axons and their sheath cells. An alternative theory is that it represents a benign neoplasm. The lesion was first described by Reed and his coworkers as a clinically distinctive, solitary, benign cutaenous tumor occurring with equal frequency in both sexes and limited in its anatomic distribution (with rare exceptions) to areas bordering mucocutaneous junctions predominantly on the face. A case on the lower lip has been reported by Tomich and Moll.

Histologic Features. The histologic appearance of the neuroma is characteristic and shows a mass of irregular and often interlacing neurofibrils and Schwann cells situated in a connective tissue stroma scant or predominant. Much of this connective tissue is probably derived from the perineurium. The proliferating nerve fibers themselves may occur either in small discrete bundles or spread diffusely throughout the tissue (Fig. 2-101C, D). Care must be taken to differentiate this lesion from both the neurofibroma and neurilemmoma. The histologic, histochemical and ultrastructural aspects of wallerian degeneration of nerves have been described by Fisher and Turano and by Sist and Greene.

Treatment and Prognosis. Because of the progressive nature of this lesion and the associated pain, it is best treated by surgical excision along with a small proximal portion of the involved nerve. Recurrence is not common even though the sectioning of the nerve during treatment is similar to the injury that preceded the development of the tumor.

Multiple Endocrine Neoplasia Syndrome
(MEN syndrome [MEN III, MEN IIb])

The multiple endocrine neoplasia (MEN) syndromes are characterized by tumors of neuroendocrine origin. The type, MEN III syndrome, also called MEN IIb syndrome or multiple mucosal neuroma syndrome, was initially described by Wagenmann in 1922.

The disease is associated with adrenal pheochromocytoma, medullary thyroid carcinoma, diffuse alimentary tract ganglioneuromatosis, and multiple small submucosal neuroma nodules of the upper aerodigestive tract. The disease is inherited

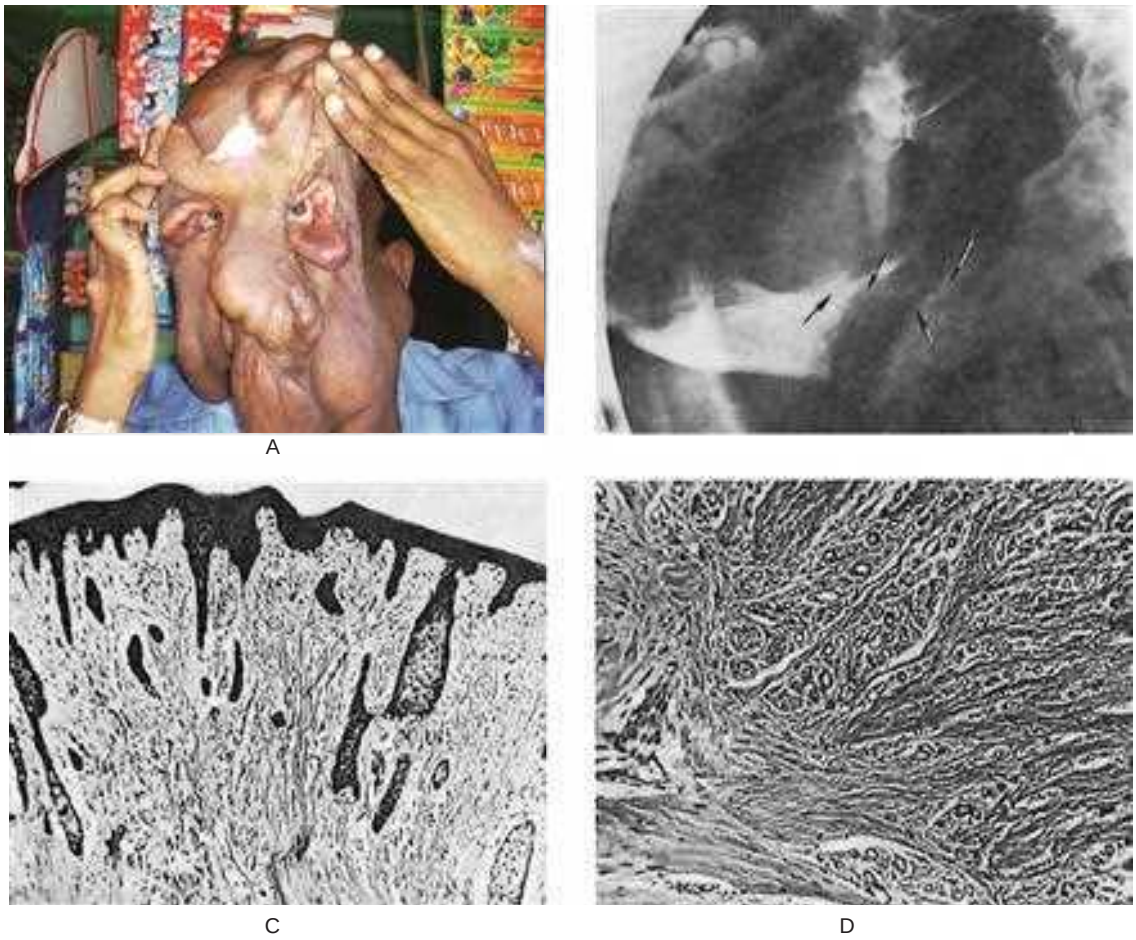

Figure 2-101. Traumatic neuroma.
(A) The patient presented with several pedulous tumour masses of the facial skin. The patient had sustained a fracture of the mandible many years previously that had resulted in the abnormal course of the mandibular nerve seen in the lateral jaw radiograph **(B)**. This nerve was subsequently sectioned for 'relief of pain'. The photomicrographs **(C, D)** reveal the hyperplasia of nerve fibers in a fibrous stroma. *(A, Courtesy of Dr K Murugesan, Maxillofacial Surgeon, Chennai)*

as an autosomal dominant trait, although many cases appear to be spontaneous mutations.

The affected individual has a tall, lanky, marfanoid body type, with a narrow face and perhaps with muscle wasting. The adrenal and thyroid tumors typically do not present until after puberty while the oral mucosal neuromas usually develop during the first decade of life. Mucosal neuromas are extremely rare, perhaps unheard of, outside of the MEN III syndrome. MEN syndromes are caused by mutations of the RET protooncogene, an important regulator of neural crest development and the receptor of glial derived neurotrophic factor (*GDNF)*.

Clinical Features. The oral mucosal neuroma of this disease presents as a 2–7 mm yellowish-white, sessile, painless nodule of the lips, anterior tongue and buccal commissures. Usually there are two to eight (or more) neuromas, with deeper lesions having normal coloration. There may be enough neuromas in the body of the lips to produce enlargement and a 'bumpy lip' appearance. Similar nodules may be seen on the eyelids, sometimes producing eversion of the lid, and on the sclera. Facial skin, especially around the nose, may also be involved.

Abnormal laboratory values are part of this syndrome. When a medullary thyroid carcinoma is present, serum and urinary calcitonin levels are elevated. When a pheochromocytoma is present, there often is an increase in the serum levels of vanillylmandelic acid (VMA) and altered epinephrine/norepinephrine ratios.

Histologic Features. The mucosal neuroma is comprised of a partially encapsulated aggregation or proliferation of nerves, often with thickened perineurium, intertwined with one another in a plexiform pattern. This tortuous pattern of nerves is seen within a background of loose endoneurium-like fibrous stroma. Individual nerves flow in fascicles of two or three fibers and are histologically normal except for occasional hyperplasias and bulbous expansions.

Inflammatory cells are not seen in the stroma and dysplasia is not present in the neural tissues. There may be close microscopic similarity with traumatic neuroma, but the streaming fascicles of mucosal neuroma are usually more uniform and the intertwining nerves of the traumatic neuroma lack the thick perineurium of the mucosal neuroma.

Luxol fast blue staining is used to identify myelin nerve fibers, and lesional cells react immunohistochemically for S100 protein, collagen type IV, vimentin, NSE, and neural filaments. More mature lesions will react also for EMA (epithelial membrane antigen), indicating a certain amount of perineurial differentiation. Early lesions have a stroma rich in acid mucopolysaccharides, hence, will stain positively with alcian blue.

Treatment and Prognosis. The mucosal neuromas of this syndrome are asymptomatic and self-limiting, and present no problem requiring treatment. They may, however, be surgically removed for esthetic purposes or if they are being constantly traumatized. It is strongly suggested that other family members may also be evaluated for MEN III.

Neurofibroma

(Neurofibromatosis, von Recklinghausen's disease of the skin, fibroma molluscum)

The neurofibroma is a benign tumor of nerve tissue origin, derived from the cells that constitute the nerve sheath. Neurofibroma is seen either as a solitary lesion or as part of the generalized syndrome of neurofibromatosis (von Recklinghausen disease of the skin). The solitary form does not differ from the disseminated form or the multiple form of the disease except that systemic and hereditary factors present in the disseminated form are absent in the solitary type.

The cell of origin for neurofibroma has not been definitively identified, but is generally believed to arise from the perineural fibroblasts which are neuroectodermal in origin. The cause of solitary neurofibroma is unknown. However, neurofibromatosis is inherited as an autosomal dominant trait with a high degree of penetrance but variable expressivity. As many as 50% of cases are reported to be the result of spontaneous mutation. Recently, two subsets have been defined: one is associated with the neurofibromatosis type 1 (NF1), gene mutations of the tumor suppressor genes coding for neurofibromin on chromosome 17q11.2, and the other is associated with the neurofibromatosis type 2 (NF2), gene mutations of the tumor suppressor genes coding for **schwannomin** on chromosome **22q12.1**.

Clinical Features. Neurofibromatosis, though not an exceedingly common disease, is by no means a clinical rarity. It has been reported in all races and does not exhibit a significant consistent sex predilection for occurrence. The hereditary nature of the disease has been recognized for many years and it is now known that it is inherited as a simple autosomal dominant trait with variable penetrance and a 50% mutation rate. It occurs with a frequency of one case in approximately 3,000 births in the general population. The birth incidence of NF1 lies between 1 in 2,500–3,300 and its prevalence in the population is 1 in 5,000. The birth incidence of NF2 lies between 1 in 33,000–40,000 with a prevalence within the population of 1 in 210,000.

The great clinical significance of neurofibromatosis, aside from the cosmetic problem, lies in the fact that in some patients malignant transformation subsequently occurs in one or more of their lesions. The incidence of sarcomatous transformation in neurofibromatosis has been placed at approximately 15% of all cases by Hosoi and by Preston and his coworkers. The type of sarcoma has been variously described as fibrosarcoma, spindle cell sarcoma and neurogenic sarcoma. However, solitary neurofibromas seldom undergo malignant transformation. Preston and his coinvestigators have reported other associated pathologic lesions, including osseous changes, mental disorders, congenital defects and ocular disease occurring in approximately 20% of their patients.

Oral Manifestations. Oral lesions occur in patients with von Recklinghausen's disease of skin, but the percentage of patients presenting such manifestations is not definitely known. In the series reported by Preston and his associates, intraoral neurofibromas were present in 7% of the patients. In contrast, Cherrick and Eversole reported that 20% of a series of 19 cases of intraoral neurofibroma occurred in association with von Recklinghausen's disease.

Discrete, nonulcerated nodules, which tend to be of the same color as the normal mucosa, may be noted, usually occurring on the buccal mucosa, palate, alveolar ridge, vestibule and tongue (Fig. 2-102A, B). Other cases exhibit diffuse masses of tissue which may involve the palate, buccal tissues and alveolar ridges and are composed of the same type of tissue as that seen in the isolated lesions. In addition, macroglossia due to diffuse involvement of the tongue is well recognized and has been reviewed by Ayres and his associates. Chen and Miller have also reported a series of 55 cases of benign nerve tumors of the oral cavity and noted the preponderance of neurofibroma over the neurilemmoma.

Occasional cases of neurofibroma located centrally within the jaw are seen. These are generally in the mandible, associated with the mandibular nerve, and radiographically show a fusiform enlargement of the mandibular canal. Involvement of the trigeminal nerve may cause facial pain or paresthesia. Ellis and his associates have also discussed central nerve sheath tumors of the jaws and found that very few of these reported were associated with multiple neurofibromatosis.

Histologic Features. The neurofibroma exhibits considerable variation in histologic structure but is generally composed of a proliferation of delicate spindle cells with thin, wavy nuclei intermingled with neurites in an irregular pattern as well as delicate, intertwining connective tissue fibrils. Cellular and myxoid patterns predominate; organoid features are not present. Melanocytes may sometimes be found in the tumor and mast cells are common. The lesions may or may not be well circumscribed.

In plexiform neurofibroma, the pattern may be that of distorted masses of myxomatous peripheral nerve tissue still within the perineural sheath are scattered within a collagen-rich matrix (Fig. 2-103). This histologic picture is considered to be virtually diagnostic of neurofibromatosis, even in the absence of other manifestations. There are reports of the existence of solitary plexiform neurofibromas unassociated with any

Figure 2-102. Neurofibroma.
(A) The patient presented several pendulous, pigmented tumor masses of the skin. **(B)** Neurofibroma of the palate in a patient without apparent neurofibromatosis. **(C)** Multiple neurofibromas of the face. **(D)** Neurofibromatosis showing spindled, wavy nuclei in fascicular form.

established syndromes, occurring in the oral cavity (tumors on the buccal mucosa and gingiva) (Alatli C et al, 1996).

The lesional cells are uniformly positive for S100 protein, signifying that they originate from neural crest-derived tissue. Antibodies to epithelial membrane antigen, CD57, and collagen IV are of secondary value and are used only when histologic differentiation with other neural tumors is difficult.

Treatment. Solitary oral neurofibromas are usually treated by surgical excision, depending on the extent and the site. Surgical removal may result in recurrence, and multiple recurrences have been associated with malignant transformation (5–15%). However, for neurofibromas associated with neurofibromatosis, surgical removal is attempted only for functional or cosmetic reasons. Genetic counseling and evaluation of other family members should be performed for those suspected to be affected by a syndrome.

Neurolemmoma

(Neurilemmoma, perineural fibroblastoma, schwannoma, neurinoma, lemmoma)

The neurolemmoma is a rather common tumor accepted by most investigators today to be derived from Schwann cells. Neurites are not a component of the tumor as in the neurofibroma but may be found on the surface of the tumor. Tissue culture studies by Murray and Stout, who cultivated this tumor *in vitro,* lend credence to the idea of the Schwann cells as the source of origin.

Figure 2-103. Plexiform neurofibroma of the gingiva.
Abundant nerve tissue in fascicles and collagenous fibrous stroma in ordered arrangement.

Clinical Features. Available clinical evidence indicates that the neurolemmoma is a slowly growing lesion and is usually of long duration at the time of presentation by the patient. An occasional tumor does exhibit a relatively rapid course, however, the lesion does occur with some frequency in patients with neurofibromatosis. It may arise at any age, cases having been reported even during the first year of life as well as in elderly patients. There is no gender predilection.

Despite the fact that these tumors originate from nerve tissue, they are usually painless unless they are causing pressure on adjacent nerves rather than on the nerve of origin. The presenting symptom of the majority of patients is only the presence of a tumor mass.

Oral Manifestations. The head and neck are rather common regions for the development of this neoplasm, as shown by the report of Ehrlich and Martin, and a variety of oral and paraoral locations have been the site of development of the neurolemmoma. Furthermore, in a series of 303 patients with benign solitary neurolemmomas reported by Das Gupta and his associates, 136 occurred in the head and neck. Reported cases of intraoral soft-tissue neurolemmomas have been reviewed by Hatziotis and Asprides with the following frequency of occurrence: tongue, 59 cases; palate, 11 cases; floor of mouth, 10 cases; buccal mucosa, 9 cases; gingiva, 6 cases; lip, 6 cases; and vestibule, 5 cases. Other cases have involved the maxillary sinus and salivary glands, as well as the retropharyngeal, nasopharyngeal and retrotonsillar areas.

In addition, the neurolemmoma has been reported as a central lesion within bone, chiefly the mandible, apparently arising from the mandibular nerve. Eighteen such cases have been reviewed by Eversole, which Ellis and his coworkers have added additional cases.

The soft-tissue lesion is usually a single, circumscribed nodule of varying size that presents no pathognomonic features (Fig. 2-104A, B). It may resemble any of a number of benign oral soft-tissue lesions. The central lesions in bone may produce considerable destruction of bone with expansion of the cortical plates and thus resemble a more serious lesion (Fig. 2-104C). Pain and paresthesia may accompany these central lesions of bone.

Histologic Features. The microscopic picture of the neurolemmoma is characteristic and can seldom be confused with that of other lesions. The tumor is classically described as being composed of two types of tissue, Antoni type A and Antoni type B. Antoni type A tissue is made up of cells with elongated or spindle-shaped nuclei which are aligned to form a characteristic palisading pattern, while the intercellular fibers are arranged in parallel fashion between rows of nuclei. These fibers in some planes will give the impression of occurring in whorls or swirls. Antoni type B tissue does not exhibit this characteristic palisading, but rather a disorderly arrangement of cells and fibers with areas of what appears to be edema fluid and with the formation of microcysts. Verocay bodies, small hyaline structures, are also characteristically present in this tumor (Fig. 2-104D). Of great importance is the fact that in nearly all instances the tumor is encapsulated.

Treatment and Prognosis. The treatment of the neurolemmoma is surgical excision. Like other nerve tumors, this lesion is not responsive to X-ray radiation. Since it is an encapsulated tumor, little difficulty is usually encountered in its complete removal, but it has been suggested that in instances in which complete removal cannot be accomplished, a portion of tumor may be left without risk of recurrence. Such a procedure is of poor clinical practice, however, except possibly in cases in which complete removal of the tumor would necessitate extensive sacrifice of structures and results in deformity. Recurrence is uncommon.

The neurolemmoma does not undergo malignant transformation, as may the neurofibroma after numerous episodes of surgical tampering.

Melanotic Neuroectodermal Tumor of Infancy

(Pigmented ameloblastoma, melanoameloblastoma, retinal anlage tumor, melanotic progonoma, melanotic epithelial odontoma, pigmented teratoma, atypical melanoblastoma, melanotic adamantinoma, pigmented epulis, retinal choristoma, retinoblastic teratoma, congenital melanocarcinoma)

The melanotic neuroectodermal tumor of infancy (MNTI) is a relatively uncommon osteolytic-pigmented neoplasm that primarily affects the jaws of newborn infants. Initially it was reported by Krompecker in 1918 as a congenital melanocarcinoma. Various theories suggested its origin from the odontogenic apparatus, the pigmented anlage of the retina, or the sensory neuroectodermal tissues.

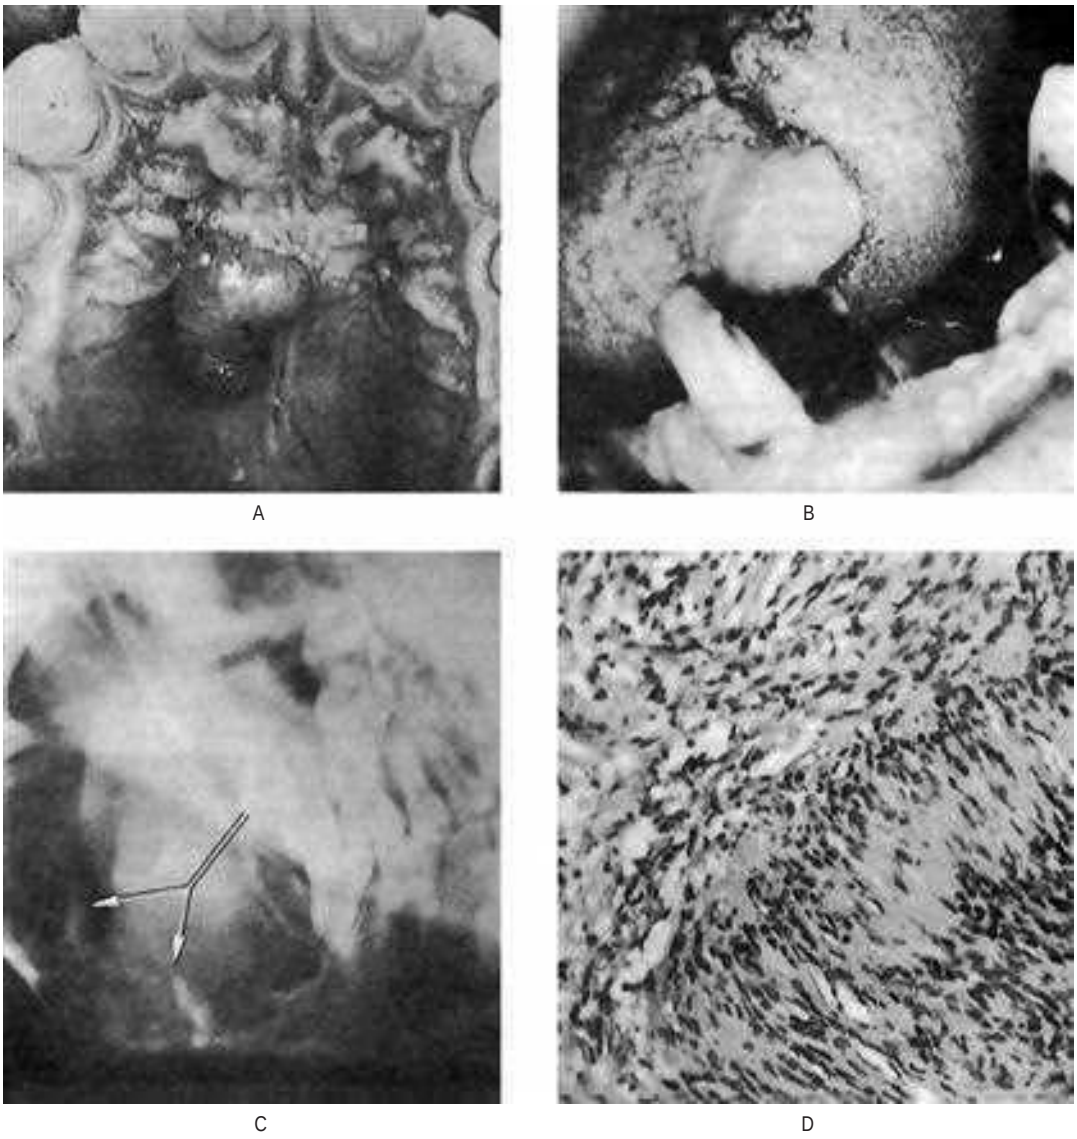

Figure 2-104. Neurolemmoma.
(A) Palate. **(B)** Tongue. **(C)** Central in bone, probably originating from mandibular nerve. **(D)** The microscopic features are characteristic *(A, Courtesy of Dr Charles A Waldron, and B, of Dr Robert Ewbank).*

In 1966, Borello and Gorlin reported a case with high urinary excretion of vanillylmandelic acid (VMA), suggesting a neural crest origin, and they proposed the term melanotic neuroectodermal tumor of infancy. Since then, numerous histochemical, immunohistochemical, electron microscopic, and tissue culture studies have supported the neural crest origin and confirmed the preferred term of melanotic neuroectodermal tumor of infancy.

Clinical Features. More than 90% of cases present within the first year of life, usually from age one to six months. The mean age of patients with MNTI is 4.3 months. Although extremely rare, cases of MNTI have been reported in adults. The sexual predilection is nearly equal, with a male-to-female ratio of 6 : 7.

More than 90% of MNTI occur in the head and neck region, with most on the anterior part of the maxillary ridge. Other common sites include the skull, the mandible, the epididymis, and the brain. Rare lesions have been reported in the shoulder, the skin, the femur, the mediastinum, and the uterus.

The majority of reported cases have been rapidly growing, nonulcerated, darkly pigmented lesions which have given a radiographic appearance of an invasive malignant neoplasm. In its typical premaxillary position, the tumor can displace or destroy the developing deciduous and permanent dentition. It can present as unilocular, or rarely as multiloculated radiolucency.

All the hematologic and blood chemistry values are within the normal range. The only finding in some but not all patients with MNTI is an increase in the urinary level of VMA, but shows no correlation with its clinical behavior. Elevated VMA has been reported in other tumors of neural crest origin, such as pheochromocytoma, ganglioneuroblastoma, retinoblastoma, and neuroblastoma.

Immunohistochemistry is of assistance in cases that are more difficult to diagnose. The cuboidal cells express cytokeratin as well as melanoma-associated antigen (HMB45), but they are usually negative for S100. Some cells are also positive for vimentin, epithelial membrane antigen, glial fibrillary acidic protein, neuron specific enolase (NSE), and synaptophysin.

Electron microscopic examination demonstrates ultrastructural evidence of neural, epithelial, and melanocytic features. Fine, delicate cytoplasmic fibers are suggestive of neurofibrils, reminiscent of glial tissue. Typically, some of the cells demonstrate neurosecretory granules. Evidence exists of basal laminae and interdigitating desmosomal attachments to adjacent cells, which is suggestive of epithelial features in some cells. Melanosomes are noted in many of the cuboidal cells.

When polygonal cells were cultured *in vitro* they developed long dendritic processes suggestive of their neural crest origin. However, no molecular or genetic basis to link MNTI to neuroblastoma is apparent.

Histologic Features. The microscopic appearance of this tumor is characteristic due to its distinct biphasic pattern. It is usually a nonencapsulated, infiltrating tumor mass of cells arranged in a pattern of alveolus-like spaces lined by cuboidal or large polygonal cells, which have pale abundant cytoplasm and nuclei with finely dispersed chromatin, many of which contain melanin pigment. Fontana stain can be used to demonstrate the melanin pigment. The central portions of the alveolar spaces contain many small round neuroblast-like cells which show little cytoplasm and exhibit a round, deeply staining nucleus. A moderately vascular fibrous stroma supports the tumor cells (Figs. 2-105, 2-106).

Treatment and Prognosis. The treatment of choice for MNTI is surgical excision, and it is usually curative. This treatment can usually be accomplished with a partial maxillectomy. Many clinicians advocate a 5 mm margin of healthy tissue to be included with the surgical specimen.

Local recurrence has been documented in 10–60% of patients. Overall, the average recurrence rate is 15–20%. Approximately 1% of tumors are malignant, with only rare tumors producing metastases.

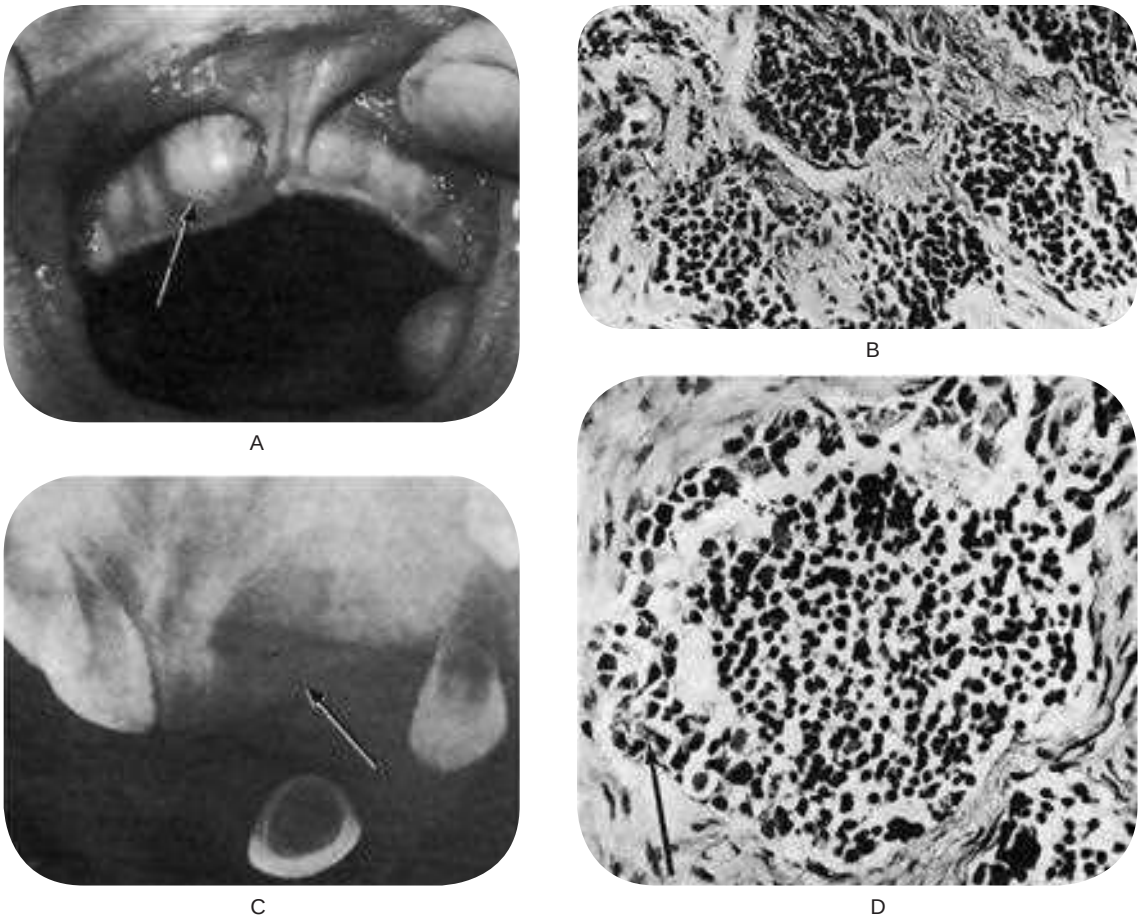

Figure 2-105. Melanotic neuroectodermal tumor of infancy.

MALIGNANT TUMORS OF NERVE TISSUE ORIGIN

Malignant Peripheral Nerve Sheath Tumor

(Malignant schwannoma, malignant neurilemmoma, neurogenic sarcoma, neurofibrosarcoma)

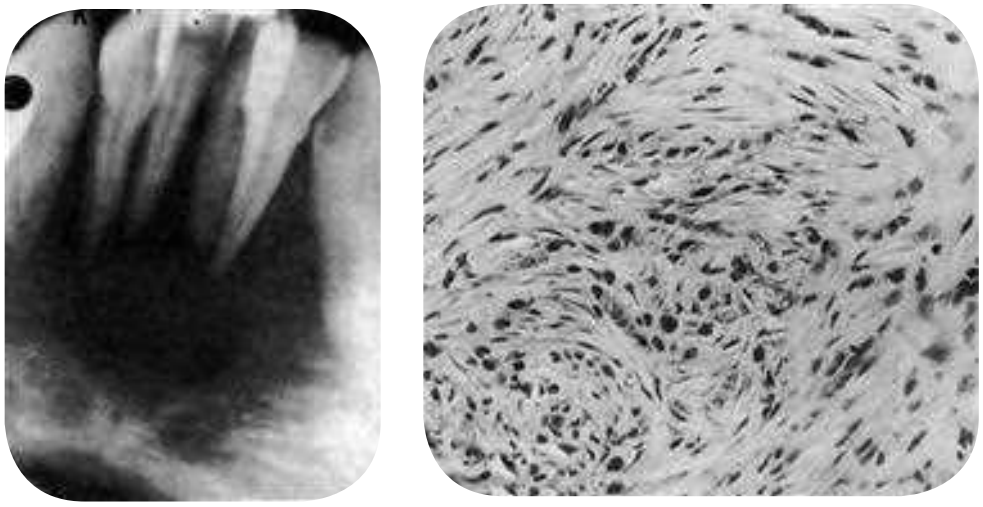
Malignant peripheral nerve sheath tumor (MPNST) is now the preferred name for the spindle cell malignancy of peripheral nerve Schwann cells. It represents approximately 10% of all soft tissue sarcomas and its diagnosis has been called 'one of the most difficult and elusive diagnoses in soft tissue diseases'. Up to half of all cases of MPNST are diagnosed in persons with neurofibromatosis I (4% of patients with neurofibromatosis I). About one in 10 cases are associated with irradiation. The preferred site is the lower extremities, but a small percentage of these lesions occur in the head and neck region, usually associated with the large cranial nerves, especially the trigeminal nerve.

Clinical Features. These tumors commonly occur in persons of 20–50 years of age, but children and elderly persons may also be affected. Lesions which develop in persons with neurofibromatosis I typically occur a decade or more earlier than those in nonsyndrome patients. There is a slight predilection toward males in sporadic cases, but within the subgroup of patients with neurofibromatosis I, 80% of lesions are found in males. The most common head and neck area of involvement is the neck, but its occurrence in oral cavity is extremely rare. When it occurs in the oral cavity it is usually seen arising from the tongue or soft palate. The lip, gingiva, palate and buccal muosa have been sites of involvement. In the central tumors, the mandible or mandibular nerve is more frequently affected than the maxilla.

In some instances there is no complaint other than the presence of a mass, although in other cases pain and/or paresthesia, muscle weakness are present. At surgery, attachment to a major nerve trunk is not unusual, and the surgeon may notice cystic degeneration or hemorrhage within the lesional stroma.

Radiographic Features. The radiograph may reveal a diffuse radiolucency characteristic of a malignant infiltrating neoplasm (Fig. 2-107). On the other hand, the appearance may be that of only a smooth radiolucency, such as dilatation of the mandibular canal when the tumor is originating from this nerve. When this appearance prevails, the lesion may be mistaken on the radiograph for a benign one.

Histologic Features. The MPNST resembles fibrosarcoma in its overall organization, but the spindled lesional cells demonstrate the wavy or comma-shaped outline and nuclear contour of Schwann cells. The cytoplasm of lesional cells is usually indistinct and slightly eosinophilic. Cellular and nuclear pleomorphism may be quite pronounced and mitotic activity is usually high. Spindle cells are arranged in sweeping fascicles interspersed with hypocellular and myxoid regions.



A B

Figure 2-107. Malignant schwannoma of the mandible.
(Courtesy of Dr Charles H Redish and Dr Norman S Klein).

Histologically MPNST may be classified into three major categories with **epithelioid, mesenchymal** or **glandular** characteristics.

The **epithelioid** variant demonstrates plump, rounded or ovoid epithelioid cells scattered throughout the spindled lesional cells, usually in rather small numbers and in well defined clusters. These cells may have vesicular or hyperchromatic nuclei and may bear slight resemblance to the cells of the amelanotic melanoma.

Some MPNST lesions show rhabdomyoblastic differentiation leading to the common use of the diagnostic term **Triton tumor.** The spindle cells are interspersed with large, plump, rounded or strap cells with eosinophilic, fibrillar cytoplasm and with cross-striations in the cytoplasm. These cells may be clustered and must be distinguished from simple entrapment of striated muscles fibers.

The **glandular** MPNST contains areas with usually well-differentiated ductal structures lined by simple, stratified, cuboidal or columnar epithelial cells with occasional goblet cells. The lumen may contain PAS-positive, diastase-resistant mucus.

Rare MPNST cases contain multiple sarcomatous tissue types, especially osteosarcoma, chondrosarcoma and angiosarcoma. These have sometimes been indistinguishable from the malignant mesenchymoma of soft tissue.

MPNSTs may resemble fibrosarcoma and may require immunohistochemistry and EM evaluation to discern useful diagnostic differences. The other sarcomas most closely resembling this tumor are leiomyosarcoma and monophasic synovial sarcoma. In the oral cavity, the synovial sarcoma is so rare as to be excluded from the differential diagnosis, while the spindle cell of the leiomyosarcoma has a more distinct eosinophilic cytoplasm and a quite blunted nucleus.

Distinguishing the MPNST from a benign nerve sheath tumor is usually not difficult, but some neurofibromas may be quite cellular and may contain occasional pleomorphic cells. In such cases, presence or absence of mitotic activity is usually the determining feature.

Treatment and Prognosis. The MPNST of the oral region is treated by wide surgical excision, but local recurrences are common and hematogenous metastasis occurs in at least half of treated cases. The tumor is resistant to radiotherapy and chemotherapy, and those occurring in neurofibromatosis I behave in a more aggressive fashion than those not associated with the syndrome. Overall, the five-year survival for MPNST is 40–75%.

Olfactory Neuroblastoma

(Esthesioneuroblastoma, esthesioneuroepithelioma)

The olfactory neuroblastoma is a rare tumor apparently originating from the olfactory apparatus, and therefore, found most frequently in the nasal cavity and nasopharynx. Occasional cases have been reported either originating in or invading the maxillary sinus. Such examples have been described by Church and Uhler and by Mashberg and his associates.

Clinical Features. The lesion generally appears as a painful swelling in the area of the nasal fossa. It is an invasive, destructive tumor, but only rarely metastasizes, chiefly to cervical lymph nodes and lungs. In contrast to other types of neuroblastoma, this lesion usually occurs in adults rather than children.

Histologic Features. The appearance of the tumor characteristically is one of densely packed masses of small darkly staining cells each with a poorly defined eosinophilic cytoplasm and a regular round vesicular nucleus, sometimes with stippled chromatin. Rosette formation is common. This is a pseudoglandular structure lined by a single layer of nonciliated columnar cells with a basal nucleus and a cuticular border at the apex of the cell. These resemble the sustentacular and olfactory cells of the olfactory mucosa. Eosinophilic neurofibrils extend into the lumen from the cell borders. Pseudorosettes also occur. Mitotic figures are often present, but not in large numbers. The stroma has a fibrillar neuroid pattern. The difficulty in microscopic diagnosis, however, has been emphasized by Oberman and Rice.

Treatment. The treatment is generally surgery, radiation or both in combination. Although recurrence of the lesion is rather common, its prognosis is generally fair. In a series of nearly 100 cases reviewed by Skolnik and his coworkers, the five-year survival rate was 52%.

Metastatic Tumors of Jaws

(Metastatic tumors to oral cavity, metastatic tumors to the oral mucosa)

Metastatic tumors to the oral region are uncommon and may occur in the oral soft tissues or jawbones. Because of their rarity, metastatic tumors to the oral region are challenging to diagnose. Therefore, they should be considered in the differential diagnosis of inflammatory and reactive lesions that are common to oral region.

Even though the oral region is not a preferred site for metastatic deposits, approximately 30% of oral metastases are the first sign of the disease. In such cases, tumor cells bypass the filtration of the lungs, probably through the valveless vertebral venous plexus.

The pathogenesis of the metastatic process in the jawbones is not clear. In the skeleton, bones with red marrow are the preferred sites for metastatic deposits. Jawbones have little active marrow, especially in elderly persons. Remnants of hematopoietic active marrow can be detected in the posterior areas of the mandible. Since the mode of spread is usually hematogenous, tumor cells tend to be deposited in this vascular medullary tissue.

In dentulous patients, 80% of the metastatic tumors to the oral soft mucosa are found in the attached gingiva, whereas in edentulous patients, metastatic lesions are equally distributed between the tongue and the alveolar mucosa, and with much less frequency, the remaining mucosa. The rich capillary network of chronically inflamed gingiva has been suggested as a mechanism that entraps malignant cells. The proliferating capillaries have

a fragmented basement membrane through which tumor cells can more easily penetrate.

Clinical Features. Most metastatic tumors to the oral region occur in patients aged 40–70 years. On average, patients with metastases to the jawbones are younger (aged 45 years) than those with metastases to the oral soft tissues (aged 54 years).

Metastatic tumors to the oral region are uncommon and account for approximately 1% of all malignant oral tumors. However, autopsies of patients with carcinoma reveal a higher frequency of metastatic deposits in the jawbones, which are not manifested clinically. Metastatic tumors to the jawbones are more frequently reported than those in the oral mucosa (Fig. 2-108).

The most common primary sources of metastatic tumors to the oral region are cancers in the breast, lung, kidney, bone, or colorectum. The breast is the most common primary site for tumors that metastasize to the jawbones, whereas the lung is the most common source for cancers that metastasize to the oral soft tissues (Tables 2-19, 2-20).

In female patients, the most common primary cancers that metastasize to the oral region are those in the breasts, followed with much lower frequency by those in the female genital organs, colorectum, bone, and kidneys (Table 2-20).

In its early manifestation, gingival metastasis resembles hyperplastic or reactive lesions (e.g. pyogenic granuloma, peripheral giant cell granuloma, fibrous epulis) and in other oral soft tissue locations, especially in the tongue, the metastatic lesion manifests as a submucosal mass.

The metastatic lesions of the jaw may be completely asymptomatic. Usually, however, the patient is aware of slight discomfort or pain, followed in many cases by paresthesia or anesthesia of the lip or chin due to involvement of the mandibular nerve. The teeth in the affected area may become loose and extruded. Unfortunately, these teeth may be extracted simply because they are loose without an attempt by the dentist to learn the cause of this phenomenon. In such cases, the main symptom is a soft tissue mass extruding from a recent extraction wound and accompanied by pain. In some cases, pain described as a toothache has been the chief complaint of the patient. A definite swelling or expansion of the jaw is also an almost constant finding.

With the progression of the disease, oral metastatic lesions (especially those in soft tissues) cause progressive discomfort. Pain, bleeding, superinfection, dysphagia, interference with mastication, and disfigurement are some of the main patient complaints.

Radiographic Features. Metastatic lesions produce no pathognomonic radiographic appearance. Although most of such metastases produce osteolytic lesions and thus appear as a radiolucency on the radiograph, certain tumors produce

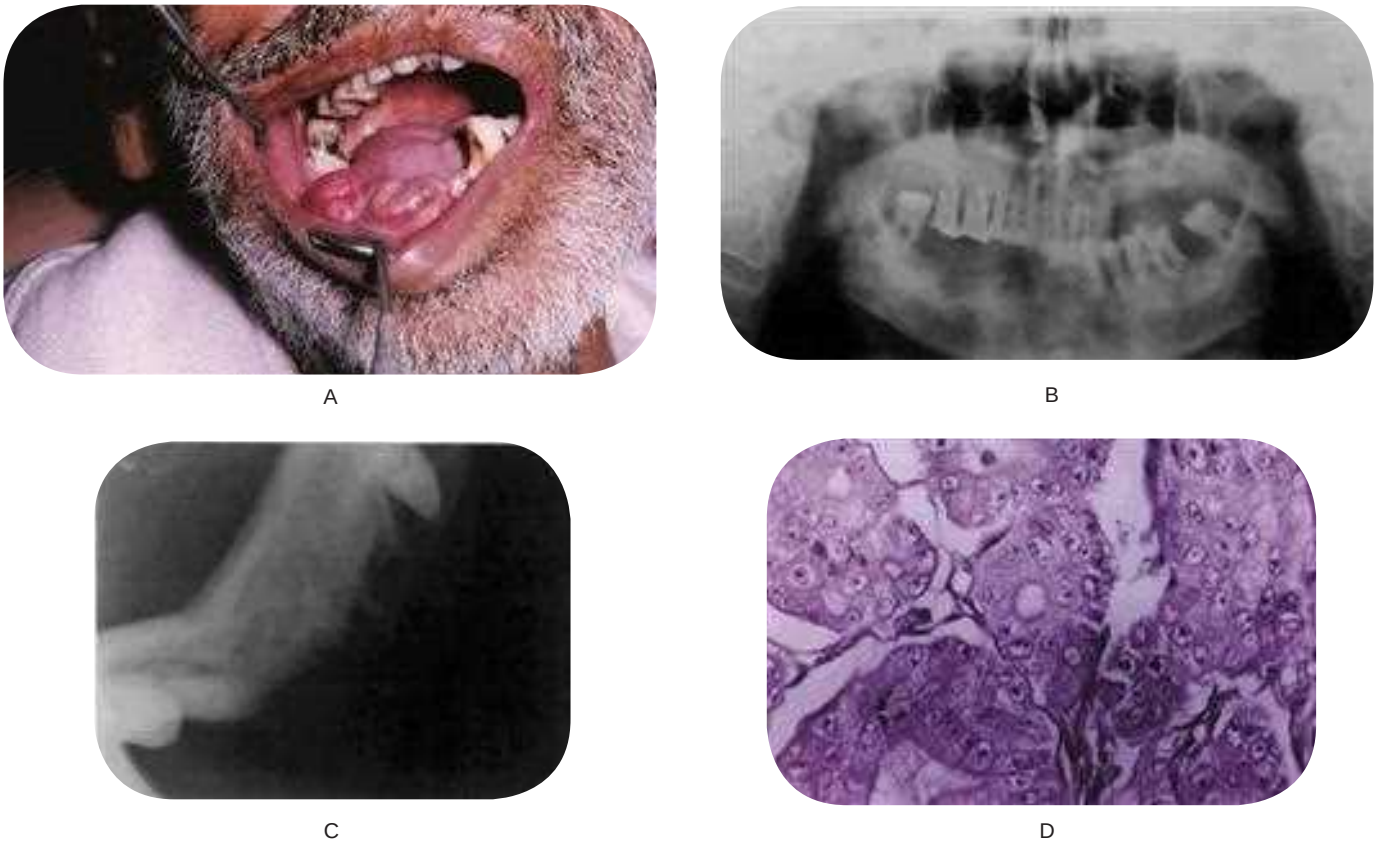


Figure 2-108. (A) Metastatic carcinoma of the lower alveolus. (B) Primary from prostate. (C) An osteolytic lesion of the mandible. (D) Photomicrograph of metastatic carcinoma of the alveolus.

Table 2-19: Metastatic tumors to the oral region in men

Metastatic site and origin	Percentage
Oral mucosa	
Lung	35.0
Kidney	16.0

osteoblastic lesions or lesions characterized by the production of bone. Such lesions are manifested as radiopaque or sclerotic areas and are most often associated with carcinoma of the prostate, and occasionally, of the breast and lung. The metastases in the radiograph may be relatively well demarcated and confined or they may exhibit diffuse, poorly outlined involvement of a considerable portion of bone. Because of the destruction of bone which may occur, pathologic fracture is occasionally seen. Lack of radiographic changes does not exclude the possible presence of a small metastatic deposit in the jawbone.

Histologic Features. The diagnosis is always based on histologic findings in the biopsy specimen. The clue to the diagnosis is the resemblance of the metastasis to the primary tumor. If history of a previous tumor exists, current histologic findings should compare with those of the preexisting primary malignant tumor. In some cases, histochemical staining, immunohistochemical tests, and electron microscopy should be performed to identify the primary source of the metastatic tumor.

Several primary intraoral malignancies (especially those originating from salivary glands) have histologic features similar to those of tumors in distant organs: for example, primary ductal carcinoma of a salivary gland origin versus metastatic breast carcinoma, primary intraoral clear cell carcinoma versus metastatic renal cell carcinoma, primary intraoral squamous cell carcinoma versus metastatic squamous cell carcinoma from the lung, or primary intraoral malignant melanoma versus metastatic malignant melanoma. Malignant soft tissue tumors may originate intraorally, but, because of their rarity, one should always consider a metastatic origin.

Treatment and Prognosis. Oral metastases usually indicate widespread disease. Treatment modalities are limited to palliation. In some cases, surgical treatment, sometimes combined with radiation therapy and/or chemotherapy, can improve the patient's quality of life. Adequate surgical treatment can improve the prognosis in some cases in which the oral region is the only metastatic site.

CHAPTER 3

Tumors of the Salivary Glands

■ T"TCLGPFTCP

CHAPTER OUTLINE

Tumors of the salivary glands constitute a heterogeneous group of lesions of great morphologic variation, and for this reason, present many difficulties in classification. Since these tumors are relatively uncommon, early investigators were handicapped by insufficient material for study. With the publication of several large series of cases, accompanied by serious discussions of the nature of tumors of the salivary glands based upon a cumulative clinical experience of many years, considerable progress has been made in broadening our knowledge of these lesions. Among these studies have been those of Evans and Cruickshank, Thackray and Lucas, and WHO.

Foote and Frazell were among the first investigators to provide a usable classification of salivary gland tumors. Spiro and his associates, Thackray and Sobin, and Batsakis have proposed classifications for practical use that are based on clinical behavior or specific histologic criteria. However, Eversole has proposed a histogenetic classification of salivary gland tumors, implicating two cell types as possible progenitors: the intercalated duct cell and the excretory duct reserve cell. The various types of salivary gland tumors are best distinguished by their histologic patterns. The clinical behavior of these various lesions may be based, as in most tumors, on the type of tumor as well as on the method of treatment utilized.

It is important to recognize that neoplasms may arise not only from the major salivary glands, but also from any of the numerous, diffuse, intraoral accessory salivary glands. Thus one may expect to see tumors originating from the glands in the lip, palate, tongue, buccal mucosa, floor of the mouth and retromolar area. Salivary gland tumors are much more common on the hard palate than on the soft, probably because there are a greater number of gland aggregates on the hard palate than on the soft palate. With only occasional exceptions, any type of tumor which occurs in a major salivary gland may also arise in an intraoral accessory gland. Thus, in the following discussion, the general features described under each tumor will hold true for both major and minor salivary gland lesions. There appear to be no truly specific, recognized tumors native only to the intraoral glands. Annual incidence of salivary gland tumors around the world is stated to be 1–6.5 cases per 100,000 people. Most studies have shown that minor salivary gland tumors are more common in females than males, with a ratio range from 1.2 : 1–1.9 : 1. Eneroth has presented data on over 2,300 tumors of the major salivary glands (Table 3-1), while a complete review of the intraoral minor salivary gland tumors has been published by Chaudhry and his coworkers, with much valuable information obtained from the analysis of over 1,300 cases (Table 3-2).

Benign tumors of the salivary gland need no treatment other than surgical removal. Malignant tumors, on the other hand, may require radiation or chemotherapy or both after surgery. Surgery for salivary gland tumors removes all or most of the affected glands, not just the tumor. When performing surgery on these glands, great care is taken to identify and protect the nerves that pass through or near these glands and supply the muscles of the face, mouth and tongue. These nerves are stretched during surgery, which results in a temporary weakness on part of the face in up to 15% of patients. This weakness is temporary and usually disappears in one to three months. Occasionally, malignant tumors invade the nerves that supply part or all of the muscles of the face. When this occurs, a portion of the nerve is surgically removed with the tumor, and a nerve graft is used to rebuild the nerve.

Table 3-1: Occurrence of major salivary gland tumors

	Parotid	Submaxillary	Total	
			No.	Percentage
Benign tumors				
Pleomorphic adenoma	1,658	102	1,760	75.6
Papillary cystadenoma lymphomatosum	101	4	105	4.5
Oxyphilic cell adenoma	21	1	22	0.9
Malignant tumors				
Carcinoma in pleomorphic adenoma	32	3	35	1.5
Mucoepidermoid carcinoma	88	6	94	4.0
Adenoid cystic carcinoma	49	26	75	3.2
Acinic cell carcinoma	66	1	67	2.9
Mucus-producing adenopapillary carcinoma	52	–	52	2.2
Solid undifferentiated carcinoma	84	15	99	4.3
Epidermoid carcinoma	7	12	19	0.8
Total	2,158	170	2,328	100.0

Data from CM Eneroth: Salivary gland tumors in the parotid gland, submandibular gland and the palate region. Cancer, 27: 1415, 1971.

Table 3-2: Occurrence of intraoral accessory salivary gland tumors

	Palate	Lip			Cheek	Tongue	Retromolar	Others	Total	
		Upper	Lower	NS					No.	Percenage
Benign tumors										
Pleomorphic adenoma	476	105	13	15	38	18	40	28	733	55.7
Simple adenoma	18	2	0	0	0	4	0	0	24	1.8

BENIGN TUMORS OF THE SALIVARY GLANDS

Pleomorphic Adenoma
(Mixed tumor)

Pleomorphic adenoma is a benign neoplasm consisting of cells exhibiting the ability to differentiate to epithelial (ductal and nonductal) cells and mesenchymal (chondroid, myxoid and osseous) cells. This tumor has been referred to by a great variety of names through the years (e.g. mixed tumor, enclavoma, branchioma, endothelioma, enchondroma), but the term 'pleomorphic adenoma' suggested by Willis characterizes closely the unusual histologic pattern of the lesion. It is almost universally agreed that this tumor is not a 'mixed' tumor in the true sense of being teratomatous or derived from more than one primary tissue. Its morphologic complexity is the result of the differentiation of the tumor cells, and the fibrous, hyalinized, myxoid, chondroid and even osseous areas are the result of metaplasia or are actually products of the tumor cells per se. Pleomorphic adenoma is the most common salivary gland tumor (Table 3-3).

Histogenesis. Numerous theories have been advanced in explaining the histogenesis of this bizarre tumor. Currently, these center around the myoepithelial cell and a reserve cell in the intercalated duct. Ultrastructural studies have confirmed the presence of both ductal and myoepithelial cells in pleomorphic adenomas. It follows that possibly either or both may play active roles in the histogenesis of the tumor. Hubner and his associates have postulated that the myoepithelial cell

is responsible for the morphologic diversity of the tumor, including the production of the fibrous, mucinous, chondroid and osseous areas. Regezi and Batsakis postulated that the intercalated duct reserve cell can differentiate into ductal and myoepithelial cells and the latter, in turn, can undergo mesenchymal metaplasia, since they inherently have smooth muscle like properties. Further differentiation into other mesenchymal cells then can occur. Batsakis has discussed salivary gland tumorigenesis, and while still implicating the intercalated duct reserve cell as the histogenetic precursor of the pleomorphic adenoma, stated that the role of the myoepithelial cell is still uncertain and that it may be either an active or passive participant histogenetically. Finally, Dardick and his associates have questioned the role of both ductal reserve and myoepithelial cells. They state that a neoplastically altered epithelial cell with the potential for multidirectional differentiation may be histogenetically responsible for the pleomorphic adenoma.

Pleomorphic adenomas have shown consistent cytogenetic abnormalities, chiefly involving the chromosome region **12q13-15.** The putative pleomorphic adenoma gene (**PLAG1**) has been mapped to chromosome **8q12**. Many other genes have also been implicated; however, cytogenetic or molecular studies do not as yet have an established role in the diagnosis of pleomorphic adenoma.

Clinical Features. Pleomorphic adenoma is the most common tumor of salivary glands. The parotid gland is the most common site of the pleomorphic adenoma; 90% of a group of nearly 1,900 such tumors reported by Eneroth. It may occur in any of the major glands or in the widely distributed intraoral accessory salivary glands; however its occurrence in the sublingual gland is rare. In the parotid this tumor most often presents in the lower pole of the superficial lobe of the gland, about 10% of the tumors arise in the deeper portions of the gland. Approximately 8% of pleomorphic adenomas involve the minor salivary glands, the palate is the most common site (60–65%) of minor salivary gland involvement. It occurs more frequently in females than in males, the ratio approximating 6 : 4. The majority of the lesions are found in patients in the fourth to sixth decades with the average age of occurrence of about 43 years, but they are also relatively common in young adults and have been known to occur in children. The clinical behavior of this tumor in children is similar to that in adults (Table 3-4).

Table 3-4: TNM/AJCC 1997 staging (clinical staging)

TX: primary tumor cannot be assessed
- T0: No evidence of primary tumor
- T1: Tumor 2 cm or less in greatest dimension without extraparenchymal extension*
- T2: Tumor > 2 cm but < 4 cm in greatest dimension without extraparenchymal extension*
- T3: Tumor having extraparenchymal extension* without seventh nerve involvement and/or more than 4 cm but no more than 6 cm in greatest dimension
- T4: Tumor invades base of skull, seventh nerve, and/or exceeds 6 cm in greatest dimension
- N0: No regional node metastasis
- Nx: Regional nodes cannot be assessed
- N1: Single ipsilateral node, < 3 cm
- N2a: Single ipsilateral node, > 3 cm and < 6 cm
- N2b: Multiple ipsilateral nodes, < 6 cm
- N2c: Contralateral or bilateral nodes, < 6 cm
- N3: Node > 6 cm
- M0: No distant metastasis
- Mx: Metastasis cannot be assessed

Minor salivary gland tumors are staged according to their site of origin.
Microscopic evidence alone does not constitute extraparenchymal extension for classification purpose.
**Extraparenchymal extension is clinical or macroscopic evidence of invasion of skin, soft tissues, bone or nerve.*

Figure 3-1. Pleomorphic adenoma of submaxillary gland.

The history presented by the patient is usually that of a small, painless, quiescent nodule which slowly begins to increase in size, sometimes showing intermittent growth (Fig. 3-1). The pleomorphic adenoma, particularly of the parotid gland, is typically a lesion that does not show fixation either to the deeper tissues or to the overlying skin (Fig. 3-2 A). It is usually an irregular nodular lesion which is firm in consistency, although areas of cystic degeneration may sometimes be palpated if they are superficial. The skin seldom ulcerates even though these tumors may reach a fantastic size, lesions having been recorded which weighed several kilograms (Fig. 3-2 B). Pain is not a common symptom of the pleomorphic adenoma, but local discomfort is frequently present. Facial nerve involvement manifested by facial paralysis is rare.

The pleomorphic adenoma of intraoral accessory glands seldom is allowed to attain a size greater than 1–2 cm in diameter. Because this tumor causes the patient difficulties in mastication, talking and breathing, it is detected and treated earlier than tumors of the major glands. The palatal glands are frequently the site of origin of tumors of this type (Fig. 3-3), as are the glands of the lip (Fig. 3-4) and occasionally other sites. Except for size, the intraoral tumor does not differ remarkably from its counterpart in a major gland. The palatal pleomorphic adenoma may appear fixed to the underlying bone, but is not invasive. In other sites the tumor is usually freely movable and easily palpated. Recurrent lesions, however, occur as multiple nodules and are less mobile than the original tumor (Table 3-5).

Histologic Features

Macroscopic features. The mixed tumors generally appear as an irregular to ovoid mass with well-defined borders. The tumors in major glands have either an incomplete fibrous capsule or are unencapsulated whereas in the minor glands they are unencapsulated. The cut surface may be rubbery, fleshy, mucoid or glistening with a homogeneous tan or white color. Areas of hemorrhage and infarction may be noted occasionally.

Microscopic features. Morphologic diversity is the most characteristic feature of this neoplasm. Microscopically, benign mixed tumors are characterized by variable, diverse, structural histologic patterns, seldom do individual cases resemble each other, considerable variation is also seen within a single tumor. Pleomorphic adenomas demonstrate combinations of glandular epithelium and mesenchyme like tissue and the proportion of each component varies widely among individual tumors. Foote and Frazell (1954) categorized the tumor into the following types:

A B

Table 3-6: Typical features of benign and malignant salivary gland tumors

Benign salivary gland tumors	Malignant salivary gland tumors
• Slow growing	• Sometimes fast growing
• Soft or rubbery consistency	• Sometimes hard consistency
• 85% of parotid tumors are benign	• 45% of minor glands are malignant
• Do not ulcerate	• May ulcerate and invade bone
• No associated nerve signs	• May cause cranial nerve palsies (e.g. parotid tumor causes facial palsy, adenoid cystic carcinoma can cause multiple nerve lesions especially of lingual, facial or hypoglossal nerves)

- Principally myxoid
- Myxoid and cellular components present in equal proportion
- Predominantly cellular
- Extremely cellular.

The epithelial component forms ducts and small cysts that may contain an eosinophilic coagulum, the epithelium may also occur as small cellular nests, sheets of cells, anastomosing cords and foci of keratinizing squamous or spindle cells. Myoepithelial cells are a major component of pleomorphic adenoma. They have a variable morphology, sometimes appearing as angular or spindled, while some cells are more rounded with eccentric nuclei and hyalinized eosinophilic cytoplasm resembling plasma cells (earlier referred to as **hyaline cells**) (Fig. 3-5). Myoepithelial-cells are also responsible for the characteristic mesenchyme like changes; these changes are brought about by extensive accumulation of mucoid material around individual myoepithelial cells giving a myxoid appearance. Vacuolar degeneration of these myoepithelial cells then results in a cartilaginous appearance (Fig. 3-6). Foci of hyalinization, bone and even fat can be noted in the connective tissue stroma of many tumors. When the

Neoplastic cells are seen arranged in ductal pattern, sheets and islands. Stroma is delicately collagenous with myxoid areas. Few cells show vacuolar degeneration and are chondroid in appearance **(A and B)**.

pleomorphic pattern of the stroma is absent, and the tumor is highly cellular, it is often referred to as a 'cellular adenoma'. When myoepithelial proliferation predominates, the diagnosis of 'myoepithelioma' (q.v.) is generally made.

Treatment and Prognosis. The accepted treatment for this tumor is surgical excision. The intraoral lesions can be treated somewhat more conservatively by extracapsular excision. Since these tumors are radioresistant, the use of radiation therapy is of little benefit and is therefore contraindicated.

Rarely, a malignant tumor may arise within this tumor, a phenomenon known as *carcinoma ex pleomorphic adenoma.* There is a second class of tumors which are called *metastasizing benign mixed tumors.* These tumors have a histologically benign appearance but usually have a history of multiple local recurrences. Metastases occur several years after the initial diagnosis and may occur to the lungs, regional lymph nodes, skin, and bone. The usual clinical course is good but there are cases which have an aggressive clinical course leading to death in 22% of cases. Fortunately this last category of tumors is very rare.

Myoepithelioma
(Myoepithelial adenoma)

The term myoepithelioma was first used by Sheldon in 1943. The myoepithelioma is an uncommon salivary gland tumor which accounts for less than 1% of all major and minor salivary tumors. Nonetheless, it is important in that the component cell constitutes a prominent place in salivary gland neoplasia. Many authorities, including Batsakis, consider the myoepithelioma to be a 'one-sided' variant at the opposite end of the spectrum from the pleomorphic adenoma.

Clinical Features. There are no clinical features which can serve to separate the myoepithelioma from the more common pleomorphic adenoma. It occurs in adults with an equal gender distribution. The parotid gland is most commonly involved and the palate is the most frequent intraoral site of occurrence. Sciubba and Brannon reported lesions in the retromolar glands and the upper lip.

Histologic Features. The tumor is composed exclusively, or almost exclusively, of neoplastic myoepithelial cells. The neoplastic cells are predominantly spindle-shaped or plasmacytoid. Epithelioid or clear cells may also be present (Figs. 3-7, 3-8). Either a single cell type predominates in a tumor or there may be a combination of cell types. The tumor is often difficult to diagnose definitively at the light microscopic level. Myoepithelioma does not contain the characteristic chondromyxoid stroma of pleomorphic adenoma. Myoepithelioma consisting predominantly of spindle cells tends to be more cellular than the tumor consisting of predominantly plasmacytoid cells. Definitive diagnosis lies in the ultrastructural identification of myoepithelial cells. The myoepithelial cell exhibits a basal lamina and fine intracytoplasmic myofilaments. Desmosomes are encountered between adjacent cells.

Treatment and Prognosis. The tumor is treated by surgical excision. The same surgical principles apply as in treating pleomorphic adenomas. Only one recurrence was noted in 16 cases in which follow-up was available.

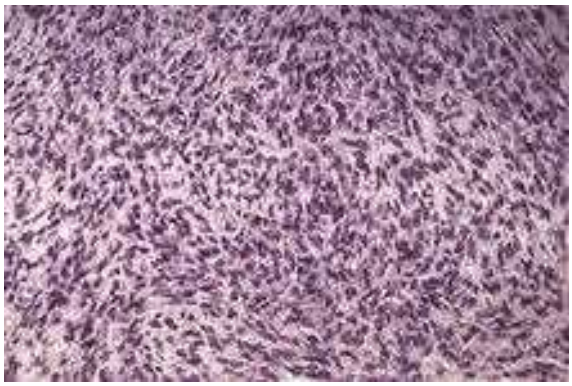

Figure 3-7. Myoepithelioma composed of spindle-shaped myoepithelial cells.

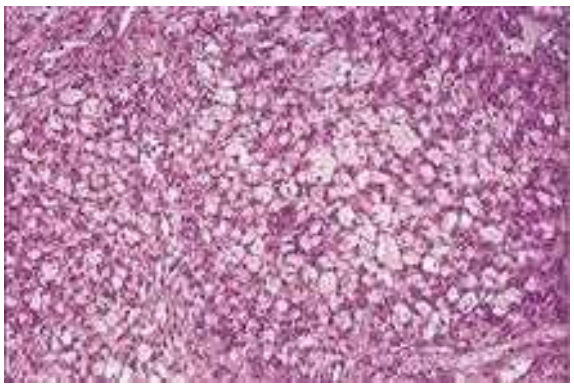

Figure 3-8. Myoepithelioma.
The cells are present in groups separated by a loose, myxoid stroma.

Basal Cell Adenoma

Basal cell adenoma is a neoplasm of a uniform population of basaloid epithelial cells arranged in solid, trabecular, tubular, or membranous patterns. The basal cell adenoma was first reported as distinct entity by Kleinsasser and Klein in 1967. Batsakis is credited with reporting the first case in the American literature in 1972, and suggested that the intercalated duct or reserve cell is the histogenetic source of the basal cell adenoma.

Clinical Features. Basal cell adenomas tend to occur primarily in the major salivary glands, particularly the parotid gland. In the series reported by Batsakis and associates, 48 of 50 tumors were in the parotid gland and two were in the submaxillary gland. The tumors are usually painless and are characterized by slow growth. They occur chiefly in adults, the average age of the patients is 57.7 years with the peak of incidence seen in the sixth decade. However, the tumor can occur in younger persons, Canalis and his coworkers reported a basal cell adenoma in the submaxillary gland of a newborn male. There is a 2 : 1 female predilection for the occurrence of this tumor. These tumors appear as a firm swelling which may be cystic and compressible. These tumors are clinically indistinguishable from mixed tumors and their greatest dimension is usually less than 3 cm.

Histologic Features

Macroscopic features. Basal cell adenoma occurs as a single well-defined nodule, the membranous type may be multifocal. Tumors in major salivary gland have a well defined capsule, whereas intraoral tumors are less well defined. The cut surface often is homogeneous with gray to brown in color, and may have cystic areas.

Microscopic features. The basal cells that make up this lesion are fairly uniform and regular; two morphologic forms can be seen. One is a small cell with scanty cytoplasm and round deeply basophilic nucleus. The other cell is large with eosinophilic cytoplasm and an ovoid pale staining nucleus. Basal cell adenomas can be divided on the basis of their morphologic appearances into four subtypes:

- Solid
- Tubular
- Trabecular
- Membranous.

Solid type. The most common type of basal cell adenoma is the solid variant. The basaloid cells form islands and cords that have a broad, rounded, lobular pattern. These cells are sharply demarcated from the connective tissue stroma by basement membrane. This feature contrasts with the melting type of growth characteristic of pleomorphic adenoma.

Tubular type. This pattern exhibits multiple small, round duct like structures. These tubules are lined by two distinct layers of cells, with inner cuboidal ductal cells surrounded by an outer layer of basaloid cells. The tubular variant is the least common; however, tubule formation either alone or with basal cell masses, can be found in most basal cell adenomas, at least focally (Fig. 3-9).

Trabecular type. This subtype has the same cytologic features as the solid type, but the epithelial islands are narrower and cord like and are interconnected with one another, producing a reticular pattern (Fig. 3-10).

Membranous type. This is a distinct subtype of basal cell adenoma characterized by the presence of abundant, thick, eosinophilic hyaline layer that surrounds and separates the epithelial islands. Electron microscopy has shown that this hyaline material is reduplicated basement membrane. The epithelial islands are arranged in large lobules and appear to mould to the shape of other lobules to resemble a jigsaw puzzle pattern.

Treatment and Prognosis. The tumor is treated by excision and recurrences are seldom seen.

Warthin's Tumor

(Papillary cystadenoma lymphomatosum, adenolymphoma)

Warthin's tumor is the second most common tumor in the salivary glands. This tumor was first recognized by Albrecht in 1910 (quoted by Ellis and Auclair 1991) and later described by Warthin in 1929. This unusual type of salivary gland tumor

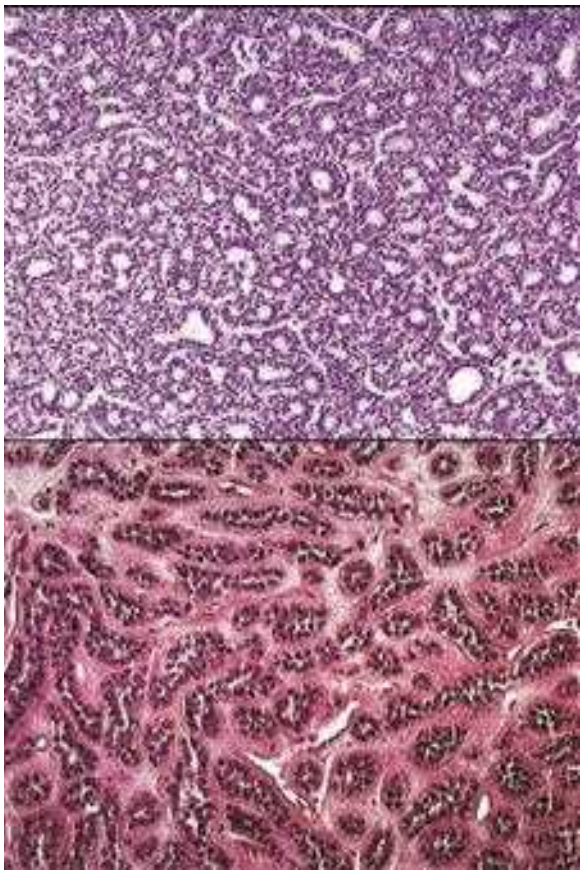

Figure 3-9. Basal cell adenoma — Tubular variant.

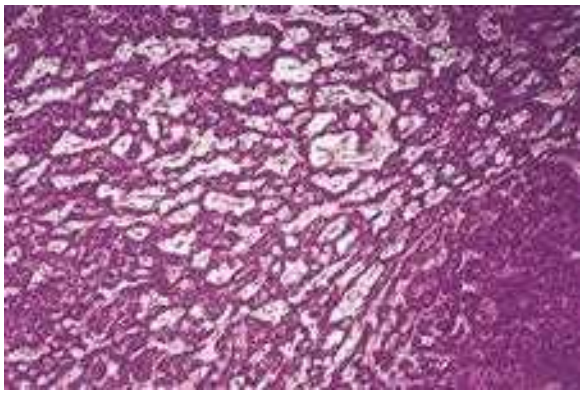

Figure 3-10. Basal cell adenoma has a trabecular pattern.

occurs almost exclusively in the parotid gland, although occasional cases have been reported in the submaxillary gland. The intraoral accessory salivary glands are rarely affected.

Histogenesis. Numerous theories have been advanced to account for the peculiar nature of this tumor. The currently accepted theory is that the tumor arises in salivary gland tissue entrapped within paraparotid or intraparotid lymph nodes during embryogenesis. However, Allegra has suggested that the Warthin's tumor is most likely a delayed hypersensitivity disease, the lymphocytes being an immune reaction to the salivary ducts which undergo oncocytic change. Hsu and coworkers recently studied the tumor immunohistochemically and have suggested that the lymphoid component of the tumor is an exaggerated secretory immune response.

A strong association between development of this tumor and smoking is documented. The exact mechanism by which smoking may predispose patients to Warthin's tumor is unclear. However, several studies have shown that a high percentage of Warthin's tumor patients smoke. Epstein-Barr virus has also been implicated in the pathogenesis of this tumor; however there are many conflicting reports.

Clinical Features. Warthin's tumor was traditionally considered a disease of men. However, recent reports have identified a substantial percentage of patients who are women. This tumor commonly presents in the sixth and seventh decades and average age of the patients at the time of diagnosis of the lesion was 62 years. The tumor is generally superficial, lying just beneath the parotid capsule or protruding through it. Seldom does the lesion attain a size exceeding 3–4 cm in diameter. It is not painful, is firm to palpation and is clinically indistinguishable from other benign lesions of the parotid gland.

Histologic Features

Macroscopic features. It is a smooth, somewhat soft parotid mass and is well encapsulated when located in the parotid. The tumor contains variable number of cysts that contains a clear fluid. Areas of focal hemorrhage may also be seen.

Microscopic features. This tumor is made up of two histologic components: epithelial and lymphoid tissue. As the name would indicate, the lesion is essentially an adenoma exhibiting cyst formation, with papillary projections into the cystic spaces and a lymphoid matrix showing germinal centers (Fig. 3-11). The cysts are lined by papillary proliferations of bilayered oncocytic epithelium. The inner layer cells are tall columnar with finely granular and eosinophilic cytoplasm due to presence of mitochondria and slightly hyperchromatic nuclei. The outer layer cells are oncocytic triangular and occasionally fusiform basaloid

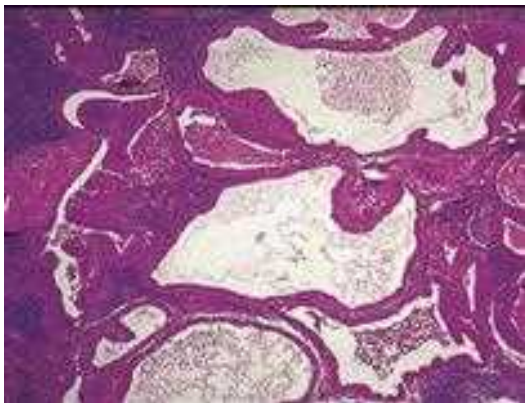

Figure 3-11. Warthin's tumor.
Figure shows cystic spaces partially filled with homogeneous fluid circumscribed by double rows of oncocytes having a stroma richly infiltrated by lymphoid tissue.

Figure 3-12. Papillary cystadenoma lymphomatosum.
Photomicrograph illustrating cystic cavity (1), epithelium (2), lymphocytes and (3), lymphoid follicle *(Courtesy of Dr Frank Vellios)*.

cells. Focal areas of squamous metaplasia and mucous cell prosoplasia may be seen. There is frequently an eosinophilic coagulum present within the cystic spaces, which appears as a chocolate-colored fluid in the gross specimen. The abundant lymphoid component may represent the normal lymphoid tissue of the lymph node within which the tumor developed or it may actually represent a reactive cellular infiltrate which involves both humoral and cell mediated mechanisms (Fig. 3-12).

Treatment and Prognosis. The accepted treatment of the papillary cystadenoma lymphomatosum is surgical excision. This can almost invariably be accomplished without injury to the facial nerve, particularly since the lesion is usually small and superficial. These tumors are well encapsulated and seldom recur after removal.

Malignant transformation is exceedingly rare in either the epithelial or lymphoid component. Cases of mucoepidermoid carcinoma involving Warthin's tumor of the parotid gland have been reported; however, a direct transition from Warthin's tumor to mucoepidermoid carcinoma was not identified.

Oncocytoma
(Oncocytic adenoma, oxyphilic adenoma, acidophilic adenoma)

Oncocytoma is a rare benign tumor composed of oncocytes with granular eosinophilic cytoplasm and a large number of atypical mitochondria. This rare salivary gland tumor is a small benign lesion, which usually occurs in the parotid gland. Except that it does not generally attain any great size, it does not differ in its clinical characteristics from other benign salivary gland tumors. For this reason, a clinical diagnosis is difficult if not impossible to establish. The name 'oncocytoma' is derived from the resemblance of these tumor cells to apparently normal cells which have been termed 'oncocytes' and which are found in a great number of locations, including the salivary glands, respiratory tract, breast, thyroid, pancreas, parathyroid, pituitary, testicle, fallopian tube, liver and stomach. These cells are predominantly seen in duct linings of glands in elderly persons, but little is actually known of their mode of development or significance (Fig. 3-13). Electron microscopic studies have shown that the cytoplasm of the oncocyte is choked with mitochondria. Ionizing radiation is the predisposing condition.

Clinical Features. The oncocytoma is somewhat more common in women than in men and occurs almost exclusively in elderly persons. Chaudhry and Gorlin, who reviewed the literature, found 29 cases of oncocytoma and added four new cases to those reported. Only occasionally does this tumor arise before the age of 60 years, 80% of cases occurring between the ages of 51 and 80 years. The tumor usually measures 3–5 cm in diameter and appears as a discrete, encapsulated mass which is sometimes nodular. Pain is generally absent.

An interesting condition called diffuse multinodular oncocytoma or 'oncocytosis' of the parotid gland has been described by Schwartz and Feldman. This condition is characterized by nodules of oncocytes which involve the entire gland or large portions of it.

Histologic Features. The oxyphilic adenoma is characterized microscopically by large cells which have an eosinophilic cytoplasm and distinct cell membrane and which tend to be arranged in narrow rows or cords (Fig. 3-13). The oncocytes are arranged in sheets or nests and cords, which form alveolar or organoid pattern. Some degree of cellular atypia, nuclear hyperchromatism and pleomorphism is accepted as compatible with benignancy in oncocytoma. These cells, exhibiting few mitotic figures, are closely packed, and there is little supportive stroma (Fig. 3-14). Lymphoid tissue is frequently present, but does not appear to be an integral part of the lesion. Ultrastructural studies of parotid oncocytomas by Tandler and associates and Kay and Still have shown that the cells are engorged with enlarged and morphologically altered mitochondria.

A variant of the oxyphilic adenoma is sometimes seen in intraoral salivary glands, particularly in the buccal mucosa and upper lip. This has been termed, an oncocytic cystadenoma since it is a tumor like nodule composed chiefly of numerous dilated duct like or cyst like structures lined with oncocytes. In recurrent tumors, there may be marked clear cell change and these tumors may be referred to as **clear-cell oncocytoma**.

Treatment and Prognosis. The treatment of choice is surgical excision, and the tumor does not tend to recur. Malignant transformation is uncommon, but malignant oncocytoma is now a well-established entity. Johns and associates reviewed the literature on malignant oncocytomas

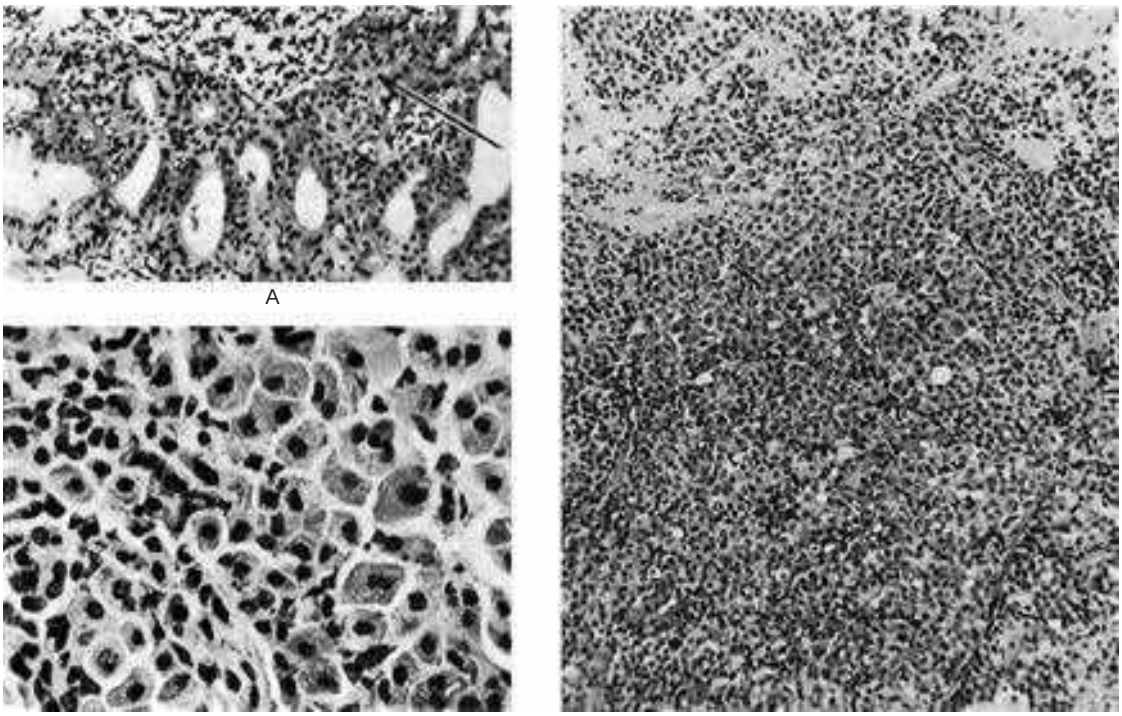

Figure 3-13. Oxyphilic adenoma.

and reported three additional cases. Other well-documented cases have been those of Lee and Roth, and Gray and his coworkers.

Canalicular Adenoma

Canalicular adenoma is an uncommon neoplasm composed of columnar epithelial cells arranged in a single or double layer forming branching cords in a loose stroma. The bilayer shows an intermittent separation, which forms structures resembling lumen or canaliculi.

Clinical Features. This lesion originates primarily in the intraoral accessory salivary glands, and in the vast majority of cases, it occurs in the upper lip. However, cases are known in which the lesion occurred in the palate, buccal mucosa and lower lip. Only one was noted in the parotid gland in the series reported by Nelson and Jacoway. The tumor occurs in adults far more common in patients of age 34–65 years; this tumor is seen more commonly in females with a ratio of 1.8 : 1. The tumor generally presents as a slowly growing, well-circumscribed, firm nodule which, particularly in the lip, is not fixed and may be moved through the tissue for some distance. Occasionally, two separate and distinct tumors may occur in the upper lip of an individual.

Histologic Features. The canalicular adenoma has a strikingly characteristic picture. It is composed of long columns or cords of cuboidal or columnar cells in a single layer. These single layers of cells are parallel, forming long canals. Sometimes rows of cells are closely approximated and appear as a double row of cells showing a 'party wall'. In some instances,

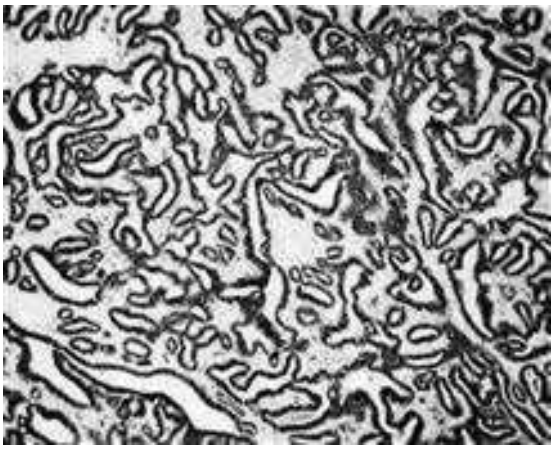

Figure 3-15. Canalicular adenoma.

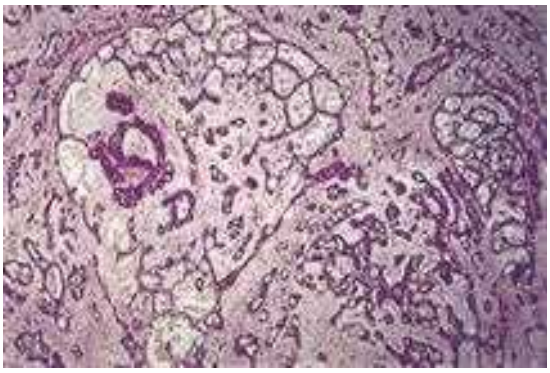

Figure 3-16. Canalicular adenoma.
The tumor shows single rows of cells that are arranged in parallel lines which form long lumina that have a 'canalicular' appearance.

cystic spaces of varying sizes are enclosed by these cords. The cystic spaces are usually filled with an eosinophilic coagulum. The supporting stroma is loose and fibrillar with delicate vascularity (Fig. 3-15). The tumor has, at times, been mistaken for an adenoid cystic carcinoma and care should be taken to prevent this error (Fig. 3-16). As Mader and Nelson have pointed out, the adenoid cystic carcinoma rarely occurs in the upper lip and is seldom freely movable. Occasionally the tumor may be multifocal and foci of tumor cells are found outside the main lesion.

Treatment and Prognosis. The tumor can be treated by enucleation or simple surgical excision; recurrence is rare.

Sebaceous Adenoma

Sebaceous adenoma is a rare benign tumor that accounts for 0.1% of all salivary gland neoplasms and slightly less than 0.5% of all salivary adenomas. The mean age at initial clinical presentation was 58 years (range 22–90 years). This tumor is more common in men. In a series of cases reported by Ellis et al (1991), 12 tumors were located in the parotid gland, 4 in the buccal mucosa, two in the submandibular gland, and three in the area of lower molars or retromolar region. The tumors ranged in size from 0.42–3.0 cm in diameter.

The tumors are commonly encapsulated or sharply circumscribed, and they vary in color from grayish-white to pinkish-white to yellow or yellowish gray. These tumors are composed of sebaceous cell nests with minimal atypia and pleomorphism and no tendency to invade local structures. Many tumors are microcystic or may be composed predominantly of ectatic salivary ducts with focal sebaceous differentiation. The sebaceous glands may vary markedly in size and in tortuosity and are usually embedded in a fibrous stroma. Occasionally tumors demonstrate marked oncocytic metaplasia, and histiocytes and/or foreign body giant cells may be seen focally. Lymphoid follicles, cytologic atypia, cellular necrosis, and mitosis are not observed in sebaceous adenomas.

Conservative excision seems to be the treatment of choice. No recurrences have been reported.

Ductal Papilloma

The term ductal papilloma is used to identify a group of three rare benign papillary salivary gland tumors. They represent adenomas with unique papillary features and arise from the salivary gland duct system. There are three types with unique histopathological features. These are inverted ductal papilloma, intraductal papilloma, and sialadenoma papilliferum.

Inverted Ductal Papilloma. Inverted ductal papilloma was first described by White et al, in 1982. It is a very rare tumor and has been described only in minor salivary glands of adults. The lower lip is the most frequently involved site followed by buccal vestibular mucosa. Inverted ductal papillomas appear to arise from the excretory ducts near the mucosal surface. Clinically, these tumors are seen as submucosal nodules which may have a pit or indentation in the overlying surface mucosa. These tumors do not show any gender predilection.

Histologically, it consists of basaloid and squamous cells arranged in thick, bulbous papillary proliferations that project into the ductal lumen. The lumen of the tumor is often narrow and in some tumors communicates with the exterior of the mucosal surface through a constricted opening.

Intraductal Papilloma. Intraductal papilloma is an ill-defined lesion that often is confused with papillary cystadenoma. It usually occurs in adults, with a mean age of occurrence being 54 years and is common in the minor salivary glands. The lower lip is the most frequently involved site followed by upper lip, palate and buccal mucosa. No gender predilection has been noted. Intraductal papilloma presents clinically as a submucosal swelling. These tumors appear to arise from the excretory ducts at a deeper level than the inverted ductal papilloma.

Microscopically, it exhibits a unicystic dilated structure. The cyst wall is lined by a single or double row of cuboidal and columnar cells, which extend into the cyst lumen as papillary projections having thin fibrovascular cores.

Sialadenoma Papilliferum. Sialadenoma papilliferum most commonly involves the minor salivary gland. This has a more complex histology, with a biphasic growth pattern of exophytic papillary and endophytic components. This tumor usually affects adults, the average age of the patients is 56 years. A male predilection is seen. The clinical presentation is unique as nearly all salivary gland neoplasms manifest as subsurface nodular swellings whereas sialadenoma papilliferum occurs as an exophytic, papillary surface lesion. The clinical impression in most cases is squamous papilloma of the mucosa.

Microscopically, these tumors display both an exophytic and an endophytic proliferation of ductal epithelium. The surface of the lesion is formed of papillary projections of epithelium supported by fibrovascular cores, covered by parakeratotic stratified squamous epithelium. The fibrovascular cores have an inflammatory cell infiltrate of lymphocytes, plasma cells and neutrophils. The ductal epithelium continues downwards into the deeper connective tissues. Multiple ductal lumina are seen, which are lined by a double row of cells consisting of a luminal layer of tall columnar cells resting on a cuboidal basal layer.

Treatment. Surgical excision is curative and these tumors are not known to recur.

Cystadenoma

Cystadenomas of the salivary glands are benign neoplasms in which the epithelium demonstrates adenomatous proliferation that is characterized by formation of multiple cystic structures. Several morphologic variants of cystadenoma have been described of which papillary cystadenoma and mucinous cystadenoma are important. The papillary cystadenoma (PC) is defined as a cystadenoma in which the cystic space is filled with papillary projections. WHO described papillary cystadenoma as "a tumor that closely resembles Warthin's tumor but without the lymphoid elements, constituting multiple papillary projections and a greater variety of epithelial lining cells." If mucous cells predominate in the cell population of the lining epithelial cells, the tumor is termed as mucinous cystadenoma.

Clinical Features. Cystadenoma is widely distributed among major and minor salivary glands. Most of the minor salivary gland tumors are seen in lips, buccal mucosa, palate and the tonsillar area. This is more common in females than males (2:1) and occurs in older age, most common in the eighth decade of life. Clinically, it presents as a slow growing painless slightly compressible swelling. Some of the nodules are clinically similar to mucocele.

Histologic Features. Epithelial proliferation (Fig. 3-17) results in various sized cystic structures. The lining of these cystic structures varies from flattened to tall columnar cells, and cuboidal, mucous and oncocytic cells may also be seen. The lining thickness varies from one to three epithelial cells. Limited papillary growth with central connective tissue core is seen. Eosinophilic or slightly hematoxyphilic secretions are seen in the stroma. Dense fibrous connective tissue stroma with scattered inflammatory cells is present.

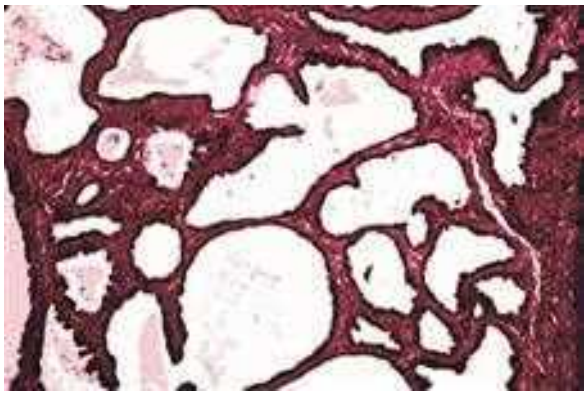

Figure 3-17. Cystadenoma.
Low-power photomicrograph of cystadenoma showing multicystic epithelial proliferation. The connective tissue stroma is scanty.

Treatment and Prognosis. No large series of cystadenoma with follow up information has been reported. At least one recurrence has been noted. The likelihood of recurrence is low. A conservative surgical procedure ensures complete removal.

MALIGNANT TUMORS OF THE SALIVARY GLANDS

Acinic Cell Carcinoma
(Acinar cell or serous cell adenoma, adenocarcinoma)

Most salivary gland tumors arise from the epithelium of the duct apparatus, but occasionally lesions seem to show acinar cell differentiation. Acinic cell carcinoma is a malignant epithelial neoplasm in which the neoplastic cells express acinar differentiation. Some authors advocate the existence of both benign and malignant acinic cell neoplasms, whereas others are of the opinion that all acinic cell neoplasms are malignant. Unfortunately, the criteria for distinguishing between benign and malignant acinar cell tumors, if such a distinction exists, have not been clearly established. In an extensive study of acinic cell tumors of the major salivary glands by Abrams and his coworkers, it was concluded that most investigators believe that all tumors of this type have at least a low-grade malignant potential. By conventional use, the term acinic cell carcinoma is defined by cytologic differentiation towards serous acinar cells (as opposed to mucous acinar cells), whose characteristic feature is cytoplasmic PAS-positive zymogen-type secretory granules. In AFIP data of salivary gland neoplasms, acinic cell carcinoma is the third most common malignant salivary gland epithelial neoplasm after mucoepidermoid carcinoma and adenocarcinoma. In this data, acinic cell carcinoma comprised 17% of primary malignant salivary gland tumors or about 6% of all salivary gland neoplasms (cited by Ellis GL, Auclair PL, Gnepp DR, 1991).

Clinical Features. The acinic cell carcinoma closely resembles the pleomorphic adenoma in gross appearance, tending to be encapsulated and lobulated. Although this tumor has been reported occurring chiefly in the parotid, with more than

Figure 3-18. Acinic cell adenocarcinoma of the palate.

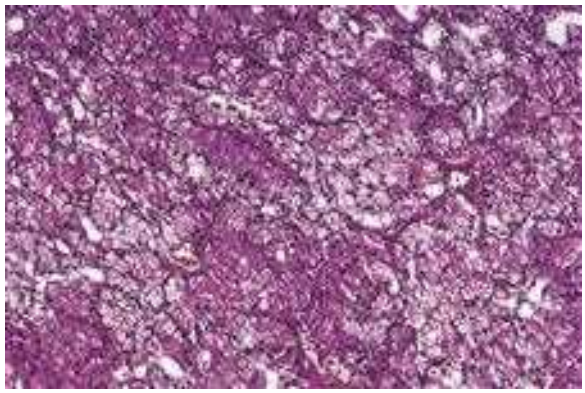

Figure 3-19. Acinic cell adenocarcinoma.

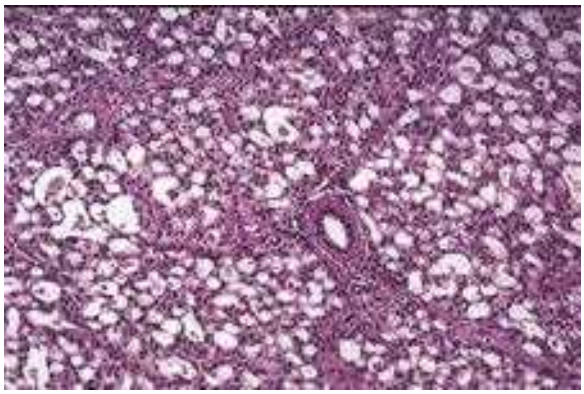

Figure 3-20. Acinic cell adenocarcinoma.
This group of moderately well differentiated acinar type cells in an acinic cell adenocarcinoma of the parotid gland have uniform, dark, round, eccentric nuclei and a basophilic cytoplasm. Occasional cells have cytoplasmic vacuoles.

80% of the cases occurring in the parotid gland, it does occur occasionally in the other major glands and in the accessory intraoral glands (Fig. 3-18). The most common intraoral sites are the lips and buccal mucosa. The acinic cell carcinoma occurs predominantly in persons in middle age or somewhat older, the mean age being 44 years. It has also been encountered in 12% of the patients before the age of 20 years. Women were affected more than men (3 : 2). This tumor presents as a slowly growing, mobile or fixed mass of various durations. Usually asymptomatic but pain or tenderness is seen in over one third of the patients. Facial muscle weakness may be seen. Patients with bilateral synchronous tumors have been reported.

Histologic Features. The acinic cell carcinoma, which is frequently surrounded by a thin capsule, may be composed of cells of varying degrees of differentiation. Well-differentiated cells bear remarkable resemblance to normal acinar cells, whereas less differentiated cells resemble embryonic ducts and immature acinar cells. Abrams and his associates have described four growth patterns: (1) solid, (2) papillary-cystic, (3) follicular, and (4) microcystic. In general, one pattern predominates, although combinations can occur. The most characteristic cell seen has the features of the serous acinar cells, with abundant granular basophilic cytoplasm and a round darkly stained eccentric nucleus. Other cells seen are the intercalated duct like cells, which are smaller and the vacuolated cells which seem to be unique to acinic cell carcinomas among salivary gland neoplasms.

Connective tissue stroma is delicately fibrovascular collagenous tissue. Lymphoid elements are commonly found in parotid acinic cell carcinomas, a feature which is helpful in the diagnosis. Such features are not found in the intraoral tumors. Apparently the acinic cell carcinoma can arise from embryologically entrapped salivary gland tissue in lymph nodes in or near the parotid compartment. Although 'clear cells,' have been described in acinic cell carcinomas, they most likely represent cells altered by fixation or they may actually represent the component cells of a clear cell carcinoma (q.v.), a recently recognized entity (Figs. 3-19, 3-20).

Treatment and Prognosis. The treatment of the acinic cell carcinoma in most cases has been surgical. Perzin and LiVolsi recommend total excision of parotid gland tumors with preservation of the facial nerve unless it is involved. Lymph node dissection is indicated only in the presence of clinical involvement and not as a routine procedure. Radiation therapy has not been shown to be of therapeutic value. Intraoral tumors are treated by surgical excision. Poor prognostic features included pain or fixation; gross invasion; and microscopic features of desmoplasia, atypia, or increased mitotic activity. Neither morphologic pattern nor cell composition was a predictive feature.

Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma is a malignant epithelial tumor, first studied and described as a separate entity by Stewart, Foote and Becker in 1945. As the name implies, the tumor is composed of both mucus-secreting cells and epidermoid-type cells in varying proportions. Columnar and clear cells are also seen, and often demonstrate prominent cystic growth. It is the most common malignant neoplasm observed in the major and minor salivary glands. Mucoepidermoid carcinoma represents 29–34% of malignant tumors originating in both major and minor salivary glands. This carcinoma of the salivary glands accounts for 5% of all salivary gland tumors. The parotid

gland is the most common site of occurrence. Intraorally, mucoepidermoid carcinoma shows a strong predilection for the palate.

Clinical Features. Mucoepidermoid carcinoma occurs with a slight female predilection. It occurs primarily in the third or fifth decades of life, with an average age of 47 years, but can occur in virtually all decades. It is the most common malignant salivary gland tumor of children. Prior exposure to ionizing radiation appears to substantially increase the risk of developing mucoepidermoid carcinoma.

The tumor of low-grade malignancy usually appears as a slowly enlarging, painless mass which simulates the pleomorphic adenoma. Unlike the pleomorphic adenoma; however, the low-grade mucoepidermoid carcinoma seldom exceeds 5 cm in diameter, is not completely encapsulated and often contains cysts which may be filled with a viscid, mucoid material. In addition to palate intraoral tumors occur on the buccal mucosa, tongue and retromolar areas. Because of their tendency to develop cystic areas, these intraoral lesions may bear close clinical resemblance to the mucous retention phenomenon or mucocele, especially those in the retromolar area (Fig. 3-21).

The tumor of high-grade malignancy grows rapidly and does produce pain as an early symptom. Facial nerve paralysis is frequent in parotid tumors. The patient may also complain of trismus, drainage from the ear, dysphagia, numbness of the adjacent areas and ulceration, noted particularly in tumors of the minor salivary glands. The mucoepidermoid carcinoma is not encapsulated, but tends to infiltrate the surrounding tissue, and in a large percentage of cases, it metastasize to regional lymph nodes. Distant metastases to lung, bone, brain and subcutaneous tissues are also common.

Histologic Features. The mucoepidermoid carcinoma is composed of mucous secreting cells, epidermoid type (squamous) cells and intermediate cells. The mucous cells are of various shapes and have abundant, pale, foamy cytoplasm that stains positively for mucin stains. The epidermoid cells have squamoid features, demonstrate a polygonal shape, intercellular bridges and rarely keratinization. A population of cells that is often more important in recognizing mucoepidermoid carcinoma is a group of highly prolific, basaloid cells referred to as the intermediate cells. These cells are larger than basal cells and smaller than the squamous cells and are believed to be the progenitor of epidermoid and mucous cells. Occasionally clusters of clear cells can be present. These clear cells are generally mucin and glycogen free. Epidermoid cells, together with intermediate and mucous cells line cystic spaces or form solid masses or cords. Epidermoid and mucous cells may be arranged in a glandular pattern. The cysts may rupture liberating mucus which may pool in the connective tissue and evoke an inflammatory reaction (Fig. 3-22).

Figure 3-21. Mucoepidermoid carcinoma of palate.
(Courtesy of Dr Neelakandan RS, Department of Oral and Maxillofacial Surgery, Meenakshi Ammal Dental College, Chennai).

Mucoepidermoid carcinomas are graded as low-grade, intermediate-grade, and high-grade.

Low-grade tumors show well formed glandular structures and prominent mucin filled cystic spaces, minimal cellular atypia and a high proportion of mucous cells (Fig. 3-23).

Intermediate-grade tumors have solid areas of epidermoid cells or squamous cells with intermediate basaloid cells. Cyst formation is seen but is less prominent than that observed in low-grade tumors. All cell types are present, but intermediate cells predominate.

High-grade tumors consist of cells present as solid nests and cords of intermediate basaloid cells and epidermoid cells. Prominent nuclear pleomorphism and mitotic activity is noted. Cystic component is usually very less (<20%). Glandular component is rare although occasionally it may predominate. Necrosis and perineural invasion may be present.

Variants of Tumor

Sclerosing mucoepidermoid carcinoma. Although mucoepidermoid carcinoma is the most common primary malignancy of the salivary glands, the sclerosing morphologic variant of this tumor is extremely rare, with only six reported cases. As its name suggests, sclerosing mucoepidermoid carcinoma is characterized by an intense central sclerosis that occupies the entirety of an otherwise typical tumor, frequently with an inflammatory infiltrate of plasma cells, eosinophils, and/or lymphocytes at its peripheral regions.

The sclerosis associated with these tumors may obscure their typical morphologic features and result in diagnostic difficulties. Tumor infarction and extravasation of mucin resulting in reactive fibrosis are two mechanisms that have been suggested as the cause of this morphologic variant.

Intraosseous mucoepidermoid carcinoma. Mucoepidermoid carcinoma may originate within the jaws. This tumor type is known as central mucoepidermoid carcinoma. It is thought to form by the malignant transformation of the epithelial lining of odontogenic cysts. The tumor presents as an asymptomatic radiolucent lesion and is histologically of low-grade malignancy. The mandible is three times more commonly affected than the maxilla.

Treatment and Prognosis. Conservative excision with preservation of the facial nerve, if possible, is recommended for low- and intermediate-grade mucoepidermoid carcinomas of the parotid gland. The affected submandibular gland should

be removed entirely. Radical neck dissection is performed in patients with clinical evidence of cervical node metastasis and is considered in any patient with a T3 lesion. Treatment for the minor glands is also primarily surgical. Some investigators have recommended postoperative irradiation only for high-grade malignancies, including high-grade mucoepidermoid carcinomas of the parotid glands. Few studies have assessed the role of chemotherapy and showed that high-grade mucoepidermoid carcinoma may show sensitivity similar to that of squamous cell carcinoma. Low-grade lesions had a five-year cure rate of 92%, whereas the intermediate-grade and high-grade lesions had a 49% 5-year cure rate.

Adenoid Cystic Carcinoma

(Cylindroma, adenocystic carcinoma, adenocystic basal cell carcinoma, pseudoadenomatous basal cell carcinoma, basaloid mixed tumor)

Adenoid cystic carcinoma (formerly known as 'cylindroma') is a slow-growing but aggressive neoplasm with a remarkable capacity for recurrence. It is characterized by proliferation of ductal (luminal) and myoepithelial cells in cribriform, tubular, solid and cystic patterns. In a review of its case files, the AFIP found adenoid cystic carcinoma to be the fifth most common malignant epithelial tumor of the salivary glands after mucoepidermoid carcinoma; adenocarcinoma, acinic cell carcinoma; and polymorphous low-grade adenocarcinoma (PLGA). However, other series report adenoid cystic carcinoma to be the second most common malignant tumor.

Clinical Features. The salivary glands most commonly involved by this tumor are the parotid, the submaxillary and the accessory glands in the palate and tongue (Fig. 3-24). The adenoid cystic carcinoma occurs most commonly during the fifth and sixth decades of life, but it is by no means rare even in the third decade. It is seen more commonly in females. Many of the patients exhibit clinical manifestations of a typical malignant salivary gland tumor: early local pain, facial nerve paralysis in the case of parotid tumors, fixation to deeper structures and local invasion. Some of the lesions, particularly the intraoral ones, exhibit surface ulceration. There may be clinical resemblance in some cases to the pleomorphic adenoma. Adenoid cystic carcinoma has a marked tendency to spread through perineural spaces and usually invades well beyond the clinically apparent borders.

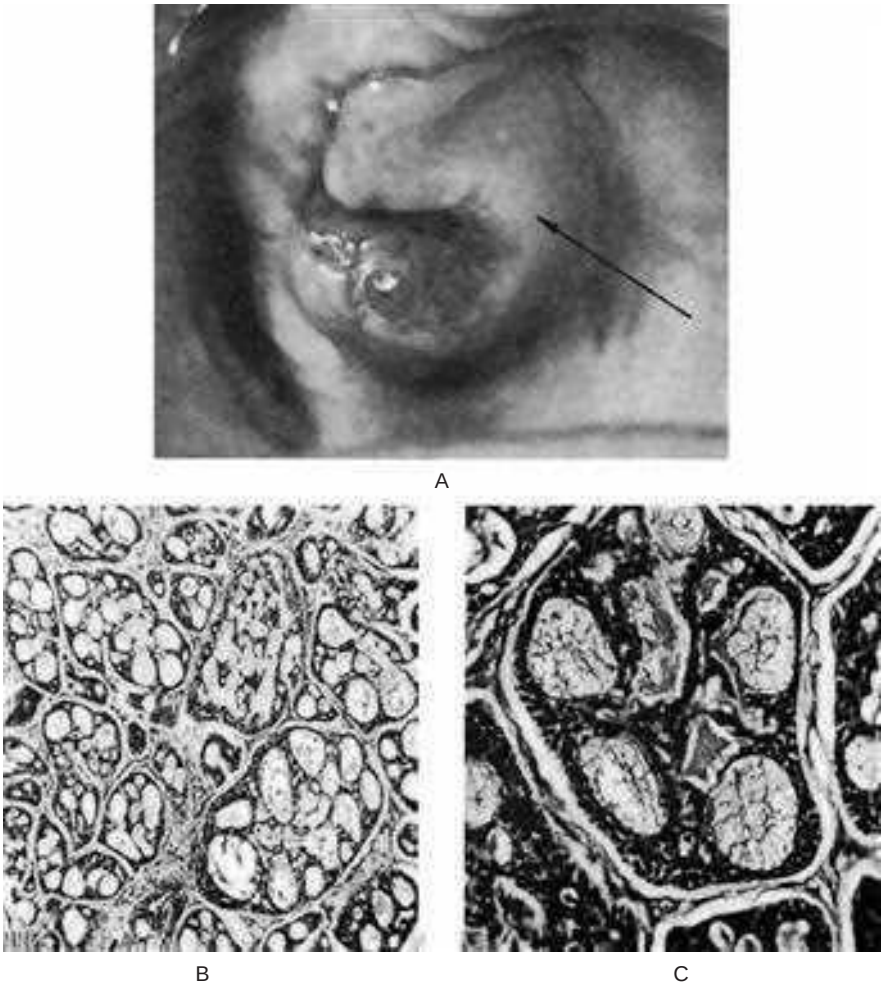

Figure 3-24. Adenoid cystic carcinoma of palate in edentulous patient.
(A) Clinical picture. **(B)** Low-power photomicrograph showing pattern of tumor. **(C)** High-power photomicrograph showing greater detail.

Histologic Features. Adenoid cystic carcinoma is composed of myoepithelial cells and ductal cells which have a varied arrangement. Morphologically, three growth patterns have been described: cribriform (classic), tubular, and solid (basaloid). The tumors are categorized according to the predominant pattern. The **cribriform pattern** shows basaloid epithelial cell nests that form multiple cylindrical cyst like patterns resembling a **Swiss cheese** or **honey comb** pattern, which is the most classic and best recognized pattern. The lumina of these spaces contain periodic acid-Schiff (PAS) positive mucopolysaccharide secretion. The **tubular pattern** reveals tubular structures that are lined by stratified cuboidal epithelium. The **solid pattern** shows solid groups of cuboidal cells with little tendency towards duct or cyst formation. The cribriform pattern is the most common, whereas the solid pattern is the least common. Solid adenoid cystic carcinoma is a high-grade lesion with reported recurrence rates of up to 100% compared with 50–80% for the tubular and cribriform variants.

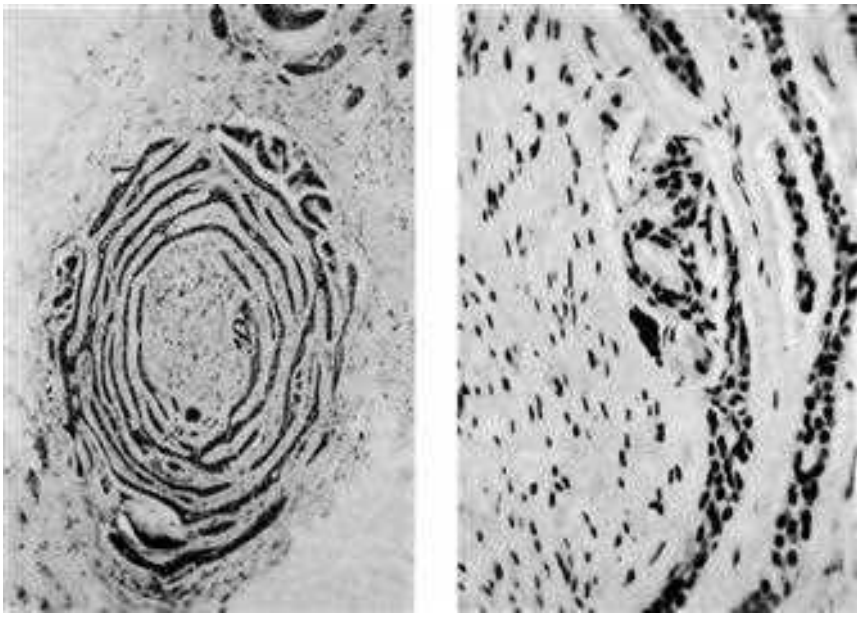
Variants

Dedifferentiation of adenoid cystic carcinoma. Dedifferentiated adenoid cystic carcinomas are a recently defined, rare variant of adenoid cystic carcinoma characterized histologically by two components: conventional low-grade adenoid cystic carcinoma and high-grade 'dedifferentiated' carcinoma. Because of frequent recurrence and metastasis, the clinical course is short, similar to that of adenoid cystic carcinomas with a predominant solid growth pattern. Histologically, the low-grade adenoid cystic carcinoma merges gradually into an extensive dedifferentiated component that is composed of solid sheets and cords of anaplastic tumor cells with focal gland formation. Immunohistochemically, the dedifferentiated component (but not the adenoid cystic carcinoma component) shows strong overexpression of p53 protein and cyclin D1, as well as a higher Ki67 index. Molecular studies confirmed the presence of p53 gene mutation selectively in the dedifferentiated component, suggesting a pivotal role of p53 gene alteration in the dedifferentiation process of adenoid cystic carcinoma.

Treatment and Prognosis. The treatment of the adenoid cystic carcinoma is chiefly surgical, although in some cases surgery has been successfully coupled with X-ray radiation. Radiation alone is not recommended. In general, this tumor is a slowly growing lesion which tends to metastasize only late in its course. The cure rate for patients with this disease, though varying somewhat from series to series, is discouragingly low. Factors influencing prognosis are the site of occurrence and the histologic pattern of the tumor (Fig. 3-25). Conley and Dingman (1974) found that there is a marked difference in the clinical behavior of major and minor gland adenoid cystic carcinomas. Only 28% of 78 patients with minor gland tumors were alive with no evidence of disease in a 4–14-year follow-up study. Sixty-four percent of 54 patients with major gland tumors studied over a comparable period were alive and free of disease.

Polymorphous Low-Grade Adenocarcinoma

Polymorphous low-grade adenocarcinoma (PLGA) is a malignant epithelial tumor that is essentially limited in occurrence to minor salivary gland sites and is characterized by bland, uniform nuclear features; diverse but characteristic



A B

Figure 3-25. Adenoid cystic carcinoma.
The perineural invasion by tumor cells is evident *(Courtesy of Dr James K Jacoby).*

architecture; infiltrative growth; and perineural infiltration. This is a recently recognized type of salivary gland tumor first described in 1983. Evans and Batsakis first used the term polymorphous low-grade adenocarcinoma in 1984 to describe this tumor. This tumor includes those entities, which were previously termed as terminal duct carcinoma, lobular carcinoma, papillary carcinoma and trabecular carcinoma.

Clinical Features. In minor gland sites polymorphous low-grade adenocarcinoma is twice as frequent as adenoid cystic carcinoma, and, among all benign and malignant salivary gland neoplasms, only pleomorphic adenoma and mucoepidermoid carcinoma are more common. The average age of patients is reported to be 59 years, with 70% of patients between the ages of 50 and 79 years. The female to male ratio is about 2 : 1. In the AFIP case files, over 60% of tumors occurred in the mucosa of either the soft or hard palates, approximately 16% occurred in the buccal mucosa, and 12% in the upper lip. Polymorphous low-grade adenocarcinoma typically presents as a firm, nontender swelling involving the mucosa of the hard and soft palates (often at their junction), the cheek, or the upper lip. Discomfort, bleeding, telangiectasia, or ulceration of the overlying mucosa may occasionally occur.

Histologic Features. Microscopically polymorphous low-grade adenocarcinoma is characterized by infiltrative growth with diverse morphology and uniform cytologic features. The tumors are well circumscribed but unencapsulated and infiltrate into adjacent structures. The polymorphic nature of the lesion refers to the variety of growth patterns it assumed which includes solid, ductal, cystic and tubular. In some tumors, a cribriform pattern can be produced, which resembles adenoid cystic carcinoma. The tumor is composed of cuboidal to columnar isomorphic cells that have uniform ovoid to spindle- shaped nuclei. Scant to moderate amounts of eosinophilic cytoplasm can be seen. The tumor stroma varies from mucoid to hyaline and in some cases, tumor nests are separated by fibrovascular stroma. Perineural invasion is common that makes this tumor mistaken as adenoid cystic carcinoma.

Treatment. Polymorphous low-grade adenocarcinoma is best treated by conservative wide surgical excision. This neoplasm typically runs a moderately indolent course. Although the tumor can recur, sometimes multiple times over many years, distant metastases have not been reported. The overall prognosis is good. Perineural invasion does not appear to affect the prognosis.

Epithelial-Myoepithelial Carcinoma

(Adenomyoepithelioma, clear cell adenoma, tubular solid adenoma, monomorphic clear cell tumor, glycogen-rich adenoma, glycogen-rich adenocarcinoma)

Epithelial-myoepithelial carcinoma is an uncommon, biphasic low-grade epithelial neoplasm composed of variable proportions of ductal and large, clear-staining, differentiated myoepithelial cells. It comprises approximately 1% of all epithelial salivary gland neoplasms.

Clinical Features. This is predominantly a tumor of the parotid gland. In the AFIP case files, the mean age of patients is about 60 years and women are more often affected than men. Localized swelling with a history of steady increase in size over a period of time is the common symptom, but occasionally patients experience facial weakness or pain. Nasal obstruction and facial deformity may represent major complaints of patients with maxillary involvement. Some studies have suggested that patients with these tumors are at increased risk for a second primary malignancy—either in the salivary glands or in a separate site (breast and thyroid have been reported).

Histologic Features. The histologic features of this tumor may vary greatly from solid lobules that are separated by bands of hyalinized fibrous tissue to irregular, papillary cystic arrangements with tumor cells which partially or completely fill cystic spaces but most tumors show a multinodular growth pattern with islands of tumor cells separated by dense bands of fibrous connective tissue. The islands of tumor cells are composed of small ducts lined by cuboidal epithelium that is surrounded by clear cells which interface with a thickened, hyaline-like basement membrane. The inner luminal cuboidal cells have finely granular, dense eosinophilic cytoplasm and central or basally located nucleus. The outer, clear myoepithelial cells vary in shape from columnar to ovoid and have a vesicular nucleus located towards the basement membrane.

Treatment. Surgery is considered the primary mode of treatment. Even with complete surgical resection recurrences and distant metastases remain a concern and may occur from a few months to years after initial surgery.

Basal Cell Adenocarcinoma

(Basaloid salivary carcinoma, carcinoma ex monomorphic adenoma, malignant basal cell adenoma, malignant basal cell tumor, basal cell carcinoma)

Basal cell adenocarcinoma of salivary glands is an uncommon and recently described entity occurring almost exclusively at the major salivary glands. It is a low-grade malignant neoplasm that is cytologically similar to basal cell adenoma, but is infiltrative and has a small potential for metastasis.

Clinical Features. In AFIP case files spanning almost 11 years, basal cell carcinoma comprised 1.6% of all salivary gland neoplasms and 2.9% of salivary gland malignancies. Nearly 90% of tumors occurred in the parotid gland. The average age of patients is reported to be 60 years. Basal cell adenocarcinoma predominantly occurs at the seventh decade without gender preference. The tumors affecting the minor salivary glands occur most frequently at the oral cavity (buccal mucosa, palate) and the upper respiratory tract. Similar to most salivary gland neoplasms, swelling is typically the only sign or symptom experienced. A sudden increase in size may occur in a few patients.

Histologic Features. As seen with basal cell adenoma, basal cell adenocarcinoma can also be histologically divided into four subtypes: (1) solid, (2) ductal, (3) trabecular, and (4) membranous.

The prevalent histologic tumor pattern is represented by solid neoplastic aggregates with a peripheral cell palisading arrangement frequently delineated by basement membrane like material. Few areas with trabecular or membranous arrangement may be seen. The neoplastic clusters are formed by two cell populations: the small dark cell type, which is predominant and a large pale cell type. Generally, the small dark cells are present peripherally to the larger paler cells. The tumor extends into the surrounding tissues by local infiltration as nodules, nests and cords. Perineural and vascular invasion is noticed in a few cases.

Treatment and Prognosis. Basal cell carcinomas are low-grade carcinomas that are infiltrative, locally destructive, and tend to recur. They only occasionally metastasize. Surgical excision with a wide enough margin to ensure complete removal of the tumor is the primary treatment. Regional lymph node dissection is recommended only if there is evidence of metastatic disease. The overall prognosis for patients with this tumor is good.

Sebaceous Carcinoma

Sebaceous carcinoma is a malignant neoplasm consisting chiefly of sebaceous cells, which are arranged in sheets and/or nests with different degrees of pleomorphism, nuclear atypia and invasiveness.

Clinical Features. This tumor shows bimodal age distribution, peak incidence of tumor occurrence is found in the third decade and seventh and eighth decades of life (range 17–93 years). The male and female incidence of occurrence is almost equal. Most of the reported cases have arisen in the parotid gland. The chief complaint is that of painful masses, with varying degrees of facial nerve paralysis, and occasionally, fixation of the skin is present. Tumors range in size from 0.6–8.5 cm in greatest dimension.

Histologic Features. Tumors are well circumscribed or partially encapsulated, with pushing or locally infiltrating margins. Cellular pleomorphism and cellular atypia are uniformly present and are more prevalent than in sebaceous adenomas. Tumor cells may be arranged in multiple large foci or in sheets and have hyperchromatic nuclei surrounded by abundant clear to eosinophilic cytoplasm (Fig. 3-26 A). Areas of cellular necrosis and fibrosis are commonly found. Perineural invasion has been observed in more than 20% of tumors. Vascular invasion is extremely unusual. Rare oncocytes and foreign body giant cells with histiocytes may be observed.

Treatment. It varies from local excision and parotidectomy to preoperative and postoperative radiotherapy, with or without chemotherapy. Patient survival ranged from 8 months to 13 years (mean is 4.5 years).

Papillary Cystadenocarcinoma

(Cystadenocarcinoma, malignant papillary cystadenoma, mucus-producing adenopapillary [nonepidermoid] carcinoma, low-grade papillary adenocarcinoma of palate, papillary adenocarcinoma)

Cystadenocarcinoma is the malignant counterpart of cystadenoma. It is a rare malignant epithelial tumor characterized histologically by prominent cystic and, frequently, papillary growth but lacking features that characterize cystic variants of several more common salivary gland neoplasms.

Clinical Features. Cystadenocarcinoma is considered to be a low-grade neoplasm. Most of the cases, about 65%, occurred in the major salivary glands (primarily in the parotid). Among the reported cases men and women are found to be affected equally and the average age at presentation is about 59 years. Patients present with a slowly growing asymptomatic mass. Clinically, this neoplasm is rarely associated with pain or facial paralysis.

Histologic Features. A cystic growth pattern must dominate the histologic appearance for the diagnosis to be considered (Fig. 3-26 B). These cystic spaces vary in size between tumors as well as within the same tumor. These neoplasms may appear circumscribed or reveal haphazard growth throughout the gland. The lumina often are filled with mucus and hemorrhage

Cystic neoplasm showing irregular cysts with great variation in size and frequent intraluminal papillary process. Invasion into the parotid parenchyma is noticed (upper field) *(Courtesy of Christopher DM Fletcher).*

and dystrophic calcifications are sometimes evident focally. The lining cells vary from cuboidal to tall columnar, and often a single tumor contains basaloid, oncocytic, clear, and occasionally, mucus cells that form adenomatous or nodular, solid epithelial areas. These solid areas usually occupy the space between the cystic structures. Nuclear hyperchromatism and nuclear variability are subtle, and only rare mitotic figures are present. Nucleoli may be obvious. Encapsulation is incomplete, and infiltration into either salivary gland parenchyma or fibrous or adipose tissue is seen. The tumor may infiltrate either as cyst like structures or as solid islands. Although the vast majority of cystadenocarcinomas are low-grade lesions, moderate/intermediate-grade tumors do exist.

Treatment and Prognosis. No information is currently available that pertains specifically to the prognosis of the salivary gland cystadenocarcinomas. Currently the treatment principles for low-grade cystadenocarcinomas are similar to the principles applied for other low-grade salivary gland adenocarcinomas. These include consideration of the site, the clinical extent of the disease and the histologic grade prior to institution of therapy. Radical neck dissection should be preserved only to deal with obvious metastases.

Mucinous Adenocarcinoma

Mucinous adenocarcinoma is a rare malignant neoplasm characterized by large amount of extracellular epithelial mucin that contains cords, nests, and solitary epithelial cells. The incidence is unknown. Limited data indicate that most, if not all, occur in the major salivary glands with the submandibular gland as the predominant site. These tumors may be associated with dull pain and tenderness. This neoplasm may be considered to be low-grade.

Clinical Features. Clinically, these lesions are soft, spongy masses that may be thought to be cysts.

Histologic Features. The gross specimens are very mucoid, with a slimy texture and they may actually ooze mucoid material. These tumors are circumscribed but not encapsulated. Low magnification reveals islands and cords of tumor cells that appear to be floating within pools of pale staining mucin. The pools of mucin may be divided into irregular lobules by fibrous connective tissue septa that course through the tumor, which is unencapsulated. The tumor cells are moderately large, cuboidal, and polygonal cells with eosinophilic to amphophilic cytoplasm. The nuclei are vesicular, and scattered mitotic figures may be found. The tumor islands are surrounded by pale-staining mucoid substance. The mucoid substance stains with mucicarmine, periodic acid-Schiff, and alcian blue at pH 2.0. Mucicarmine stain also reveals that many tumor cells contain intracytoplasmic mucin.

Treatment and Prognosis. Complete excision with the care to avoid seeding the surgical site would seem to be a satisfactory mode of treatment for these salivary gland tumors.

Oncocytic Carcinoma
(Oncocytic adenocarcinoma)

Oncocytic carcinoma is a rare, predominantly oncocytic neoplasm whose malignant nature is reflected both by its abnormal morphologic features and infiltrative growth. Bauer and Bauer reported the first case in 1953. Although focal oncocytic features are seen in a wide variety of salivary neoplasms, both benign and malignant oncocytic neoplasms are extremely rare.

Clinical Features. Oncocytic carcinoma may be considered to be a high-grade carcinoma. Most cases occur in the parotid gland but recent reports have described tumors that involved the submandibular gland and minor glands of the palate, nasal cavity, and ethmoid and maxillary sinuses. The average age of patients in one series was 63 years. Patients usually develop parotid masses that cause pain or paralysis. The skin overlying the gland is occasionally discolored or wrinkled.

Histologic Features. All types of benign or malignant salivary gland tumors may have foci of oncocytic cells, but the oncocytic component usually contains such a small portion that it is unlikely to be confused with oncocytic carcinoma. Tumors with a significant oncocytic component include Warthin's tumor, oncocytoma, and oncocytic carcinoma. They are characterized by oncocytes with marked cellular atypia, frequent mitosis, destruction of adjacent structures, perineural or vascular invasion, and distant or regional lymph node metastasis. Histochemical or electron microscopic confirmation of the oncocytic (mitochondrial) nature of the cytoplasm is necessary because cytoplasmic accumulation of smooth endoplasmic reticulum, lysosomes, or secretory granules may have a similar appearance.

Treatment and Prognosis. Oncocytic carcinoma is considered to be a high-grade neoplasm and aggressive initial surgery seems to have a significantly better overall prognosis. Radiation does not appear to favorably alter the biologic behavior of this tumor. Prophylactic neck dissection may be indicated for tumors that are larger than 2 cm in diameter.

Salivary Duct Carcinoma
(Salivary duct adenocarcinoma)

Salivary duct carcinoma is a rare, typically high-grade malignant epithelial neoplasm composed of structures that resemble expanded salivary gland ducts. A low-grade variant exists. Incidence rates vary depending upon the study cited. In the AFIP files, salivary duct carcinomas represent only 0.2% of all epithelial salivary gland neoplasms. More than 85% of cases involve the parotid gland and approximately 75% of patients are men. The peak incidence is reported to be in the seventh and eighth decades of life.

Clinical Features. Parotid swelling is the most common sign. Facial nerve dysfunction or paralysis occurs in over one-fourth of patients and may be the initial manifestation. The high-grade variant of this neoplasm is one of the most aggressive types of salivary gland carcinomas and is typified

by local invasion, lymphatic and hematogenous spread with poor prognosis.

Histologic Features. The infiltrative tumor elements are typically composed of clusters of tumor cells that may have small lumina or cribriform arrangements, but solid, irregularly shaped tumor cell aggregates are frequently present. The neoplastic epithelial cells are cuboidal and polygonal with a moderate amount of eosinophilic cytoplasm and are accompanied by a dense fibrous connective tissue stroma that may be hyalinized in some areas. Invasion of the nerves and blood vessels is frequent in addition to infiltration of salivary gland lobules and extra-salivary gland tissues, such as fat, muscle, and bone. Mucicarmine and Alcian blue stains are generally negative, except, perhaps, for a small amount of luminal staining. Immunohistochemical and ultrastructural studies have identified ductal cells but no myoepithelial cells.

Treatment and Prognosis. Salivary duct carcinoma is a high-grade malignancy that must be treated aggressively. Complete local excision with radical neck dissection and postoperative radiation therapy seems to offer the maximum benefit for the patient.

Adenocarcinoma

Adenocarcinomas of the salivary glands are rare but aggressive tumors.

Clinical Features. They tend to be present in patients over 40 years of age and occur with nearly equal frequency in men and women. About half of these tumors present in the parotid glands, the minor salivary glands, particularly the palate, lip and tongue are the next most commonly affected sites. Clinical presentation again most often involves an enlarging mass. Adenocarcinoma is different from other salivary gland neoplasms in that as many as 25% of patients will complain of pain or facial weakness at presentation.

Histologic Features. Gross pathology reveals a firm mass with irregular borders and infiltration into surrounding tissue. It is generally a solid tumor without any cystic spaces. These malignancies can demonstrate a wide range of growth patterns, and for this reason, can be somewhat difficult to classify. However, all adenocarcinomas have in common the formation of glandular structures and they are described as grades I, II or III based upon the degree of cellular differentiation. Grade I lesions have well formed ductal structures while grade III lesions have a more solid growth pattern with few glandular characteristics (Figs. 3-27, 3-28).

Treatment and Prognosis. Because these are more aggressive tumors, treatment for adenocarcinoma is aggressive. Complete local excision is the mainstay of therapy. In the parotid this may include facial nerve sacrifice. In the minor salivary glands, a portion of the maxilla or mandible may have to be resected with the tumor. Postoperative radiation therapy does seem to be of some benefit. Lymph node metastasis is not uncommon and in patients with palpable neck disease

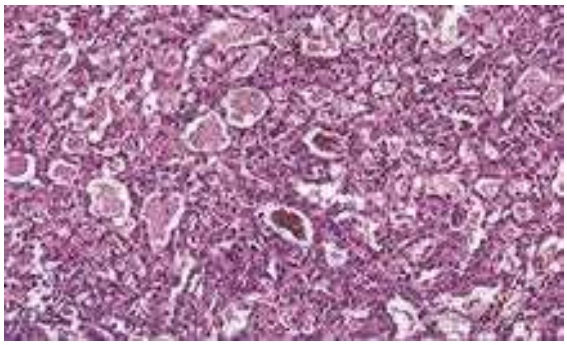

Figure 3-27. Adenocarcinoma.
Low-grade adenocarcinoma composed of a morphologically uniform population of cells showing formation of many ductal structures. Mitotic figures are rare which is typical for this group of tumors.

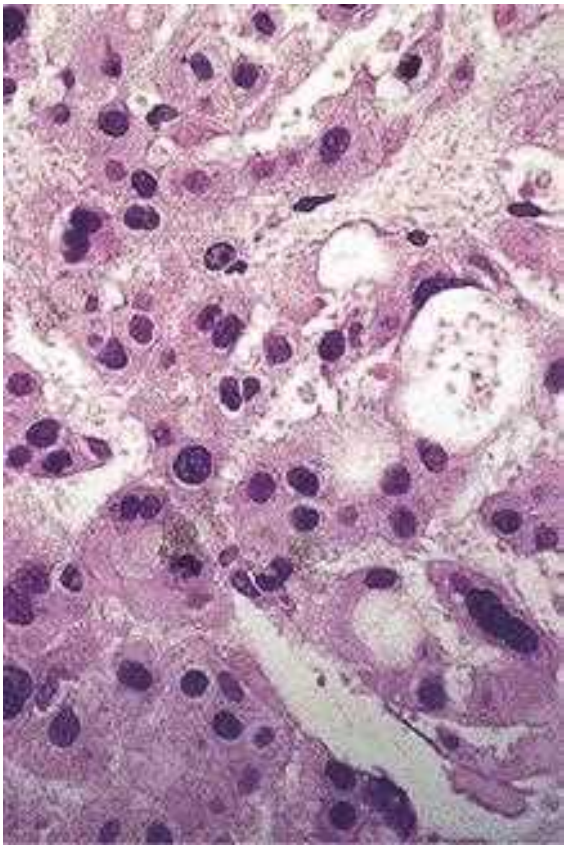

Figure 3-28. Adenocarcinoma.
High power view showing nuclear atypia.

neck dissection is warranted. Local recurrence rates vary in the literature but have been cited as high as 51%.

Malignant Myoepithelioma
(Myoepithelial carcinoma)

Ellis GL (1991) defined myoepithelial carcinoma as a malignant epithelial neoplasm whose tumor cells demonstrate cytologic differentiation towards myoepithelial cells and lack ductal

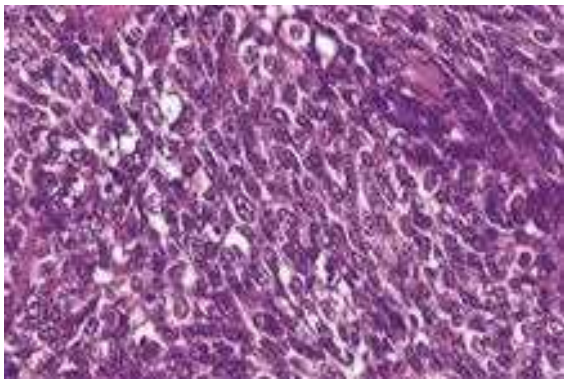

Figure 3-29. Malignant myoepithelioma.
Low magnification of malignant myoepithelioma shows sheets of tumor cells with round to ovoid nuclei and indistinct cytoplasm. Mitotic figures are evident in this field.

or acinar differentiation. Myoepithelial carcinoma is a rare, malignant salivary gland neoplasm in which the tumor cells almost exclusively manifest myoepithelial differentiation. This neoplasm represents the malignant counterpart of benign myoepithelioma. A majority of the tumors occur in the parotid gland. The mean age of patients is reported to be 55 years.

Clinical Features. The majority of patients present with the primary complaint of a painless mass. This is an intermediate- to high-grade carcinoma. Histologic grade does not appear to correlate well with clinical behavior; tumors with a low-grade histologic appearance may behave aggressively.

Histologic Features. The cytologic features of individual cells and the general morphologic features resemble tumor cells in benign myoepithelioma and the myoepithelial cells of mixed tumor. The tumor cells may be spindle shaped or plasmacytoid cells (Fig. 3-29). The cell types are often intermixed but usually one or the other cell type predominates. The tumors may be quite cellular and more suggestive of sarcoma than carcinoma. The stroma in other areas of the tumors may be more conspicuous and myxoid. These tumors are distinguished from benign myoepithelial neoplasms by their infiltrative, destructive growth. They usually demonstrate increased mitotic activity and cellular pleomorphism. Some tumor cell should be immunoreactive for cytokeratin, S100 protein, smooth muscle actin, and occasionally, glial fibrillary acidic protein.

Treatment. Wide surgical excision seems to be preferred.

Carcinoma in Pleomorphic Adenoma
(Malignant mixed tumor)

Malignant mixed tumors include three distinct clinicopathologic entities: carcinoma ex pleomorphic adenoma, carcinosarcoma, and metastasizing mixed tumor. Carcinoma ex pleomorphic adenoma constitutes the vast majority of cases, whereas carcinosarcoma (true malignant mixed tumor) and metastasizing mixed tumor are extremely rare.

Carcinoma ex Pleomorphic Adenoma (*Carcinoma ex mixed tumor*). Carcinoma ex pleomorphic adenoma is the most common of the three salivary neoplasms that are broadly referred to as malignant mixed tumors. It occurs when a carcinoma develops from the epithelial component of a preexisting pleomorphic adenoma. Diagnosis requires the identification of benign tumor in the tissue sample. The incidence or relative frequency of this tumor may vary considerably depending on the study cited. A review of material at the AFIP showed carcinoma ex pleomorphic adenoma to comprise 8.8% of all mixed tumors and 4.6% of all malignant salivary gland tumors, ranking it as the sixth most common malignant salivary gland tumor after mucoepidermoid carcinoma; adenocarcinoma; acinic cell carcinoma; polymorphous low-grade adenocarcinoma; and adenoid cystic carcinoma.

Clinical Features. The neoplasm occurs primarily in the major salivary glands. It occurs most often in the parotid, followed by the submandibular gland and palate. It presents in the sixth to eighth decade of life with patients averaging 10 years older than those with pleomorphic adenomas. Presentation is usually a painless mass but some patients will report recent rapid enlargement of a long-standing nodule. Approximately one-third of patients may experience facial paralysis.

Histologic Features. Gross pathology of carcinoma ex pleomorphic adenoma often shows a poorly circumscribed, infiltrative, hard mass. Microscopically malignant appearing cells are present adjacent to a typical appearing pleomorphic adenoma. The malignant portion of the tumor can take the form of any epithelial malignancy except acinic cell (Fig. 3-30). Most commonly this will be in the form of an undifferentiated carcinoma (30%) or adenocarcinoma (25%). This tumor tends to be more aggressive than other salivary malignancies and about 25% of patients will have lymph node metastasis on presentation.

Treatment and Prognosis. Treatment includes radical surgical resection, often in conjunction with neck dissection, and postoperative radiation therapy. Prognosis appears to be related to the local extent of disease and the histologic type of the carcinoma component.

Carcinosarcoma (*True malignant mixed tumor*). Carcinosarcoma is a rare malignant salivary gland neoplasm that

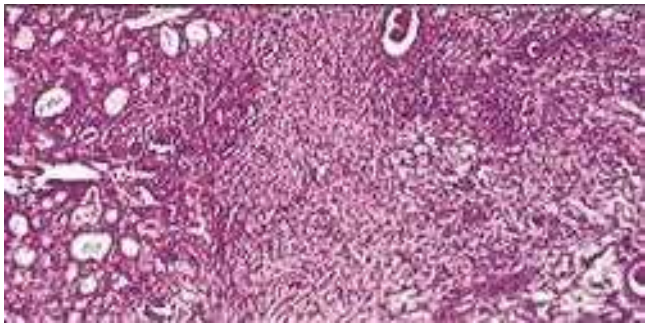

Figure 3-30. Malignant pleomorphic adenoma.
Demonstrates irregular foci of carcinoma composed of glandular structures with focal necrosis set in a mild desmoplastic background.

contains both carcinoma and sarcoma components. In a carcinosarcoma, the metastatic lesions contain both the stromal and epithelial elements. Some carcinosarcomas develop de novo while others develop in association with benign mixed tumor.

This neoplasm is rare in occurrence; there are only eight cases in the AFIP case files. Only 11 cases were recorded at MD Anderson over a 32-year period. The majority of tumors occur in the major salivary glands. The parotid is the most frequent site of occurrence. Average age at presentation is about 60 years and men and women appear to be equally affected. Clinically, swelling, pain, nerve palsy, and ulceration have been frequent findings.

Histologic Features. Microscopically, these tumors have both sarcomatous and carcinomatous elements. In the majority, the sarcoma is the dominating component and chondrosarcoma is the most common cell type. The carcinoma element is usually an undifferentiated or high-grade ductal adenocarcinoma.

Treatment and Prognosis. This is also an aggressive tumor. In the largest series reported (12 cases), the average survival period was 3.6 years and it is not uncommon for patients to have distant metastasis on presentation. Currently, recommended treatment includes radical surgery, neck dissection for palpable nodes and postoperative radiotherapy. Although efficacy has yet to be proven, chemotherapy is likely to have a role in the treatment of this disease given the high rate of distant metastasis.

Metastasizing Mixed Tumor. Metastasizing mixed tumor is a very rare histologically benign salivary gland neoplasm. The metastasizing mixed tumor refers to an otherwise benign acting pleomorphic adenoma that develops metastatic deposit. There is often a long interval between the diagnosis of the primary tumor and the metastases. The histologic features are within the spectrum of features that typify pleomorphic adenoma. The majority occur in the major salivary glands. The primary neoplasm is typically a single, well-defined mass. Recurrences, which may be multiple, have been reported to occur up to 26 years after excision of the primary neoplasm.

Squamous Cell Carcinoma

Primary squamous cell carcinoma is a malignant epithelial neoplasm of the major salivary glands that is composed of squamous (epidermoid) cells (Fig. 3-31). This diagnosis is not made in minor salivary glands because distinction from the more common mucosal squamous cell carcinoma is not possible. Primary squamous cell carcinoma of the salivary glands is quite rare, accounting for about 1.6% of salivary gland neoplasms. In order to make this diagnosis, high-grade mucoepidermoid carcinoma, metastatic squamous cell carcinoma to the gland or intraglandular nodes and direct extension of a squamous cell carcinoma must first be excluded.

Clinical Features. The reported frequency of this tumor among all major salivary gland tumors has varied from 0.9–4.7%. There is a 2 : 1 male-to-female ratio of occurrence and patients are usually over age 60. This neoplasm occurs in the parotid gland almost nine times more often than in the submandibular gland. This tumor is graded in a way similar to the extra salivary lesions according to the degree of differentiation (low, intermediate, and high). Previous exposure to ionizing radiation appears to increase the risk for developing this neoplasm. The median time between irradiation and diagnosis of the neoplasm is approximately 15.5 years. These tumors present as firm enlarging masses that are not uncommonly fixed to surrounding tissue and associated with pain or facial weakness.

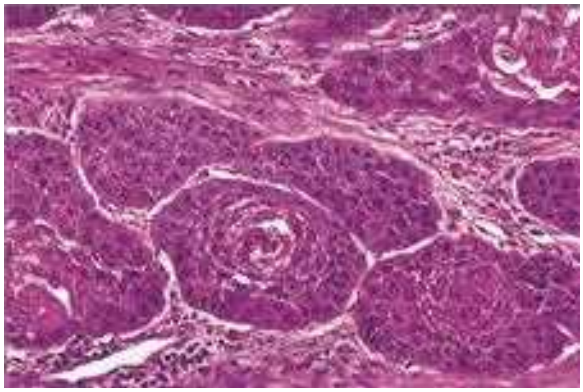

Figure 3-31. Squamous cell carcinoma.
Primary squamous cell carcinoma of salivary gland showing neoplastic squamous cells, metaplastic in origin, with varying degrees of nuclear atypia.

Histologic Features. The gross and microscopic appearance is similar to squamous cell carcinoma of other primary sites and varies from well-differentiated to poorly differentiated. Salivary gland squamous cell carcinoma displays aggressive behavior with rapid growth and early spread to regional lymph nodes (Fig. 3-32).

Treatment and Prognosis. Treatment consists of surgical resection, neck dissection and postoperative radiation. The prognosis for this neoplasm is poor. In a 30-year retrospective analysis of 50 cases of squamous cell carcinoma of the salivary glands, survival rates at five and 10 years were 24% and 18%, respectively.

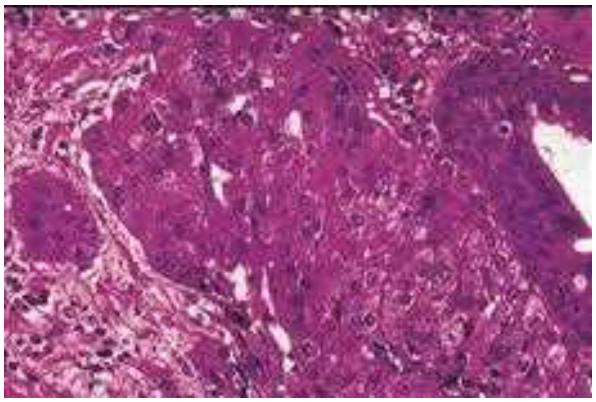

Figure 3-32. Primary squamous cell carcinoma of salivary gland (high power view).

Small Cell Carcinoma

Small cell carcinoma of the salivary gland was first described in 1972. Small cell carcinomas arising in salivary glands are extremely rare, high-grade malignant tumors and are subclassified into neuroendocrine and ductal types.

Histologic Features. Microscopically, the tumor cells have oval, hyperchromatic nuclei and scant amount of cytoplasm and are organized in sheets, strands, and nests. Small cell carcinoma of major salivary glands is a highly aggressive tumor, although the prognosis may be better than that for extra-salivary neoplasms. Studies also suggest that most salivary gland small cell carcinomas exhibit neuroendocrine differentiation. Neuroendocrine carcinomas are more frequently found in the minor salivary glands and have a better survival rate compared with small cell carcinomas of the lung. The undifferentiated counterpart of this neoplasm is the small cell undifferentiated carcinoma.

Treatment and Prognosis. The treatment of choice is wide surgical excision, possibly with radiation and/or chemotherapy. The prognosis for patients with small cell carcinomas arising in the major or minor salivary glands is better than that for patients with small cell carcinomas of the lung or larynx.

UNDIFFERENTIATED CARCINOMA

Undifferentiated carcinomas of salivary glands are a group of uncommon malignant epithelial neoplasms that lack the specific morphologic features of other types of salivary gland carcinomas. These carcinomas are histologically similar to undifferentiated carcinomas that arise in other organs and tissues. Accordingly, metastatic carcinoma is a primary concern in the differential diagnosis of these neoplasms. This group includes the following three tumors:

1. Small cell undifferentiated carcinoma
2. Large cell undifferentiated carcinoma
3. Lymphoepithelial carcinoma.

Small Cell Undifferentiated Carcinoma

(Extrapulmonary oat cell carcinoma)

Small cell undifferentiated carcinoma is a rare, primary malignant tumor that, with conventional light microscopy, is composed of undifferentiated cells, and with ultrastructural or immunohistochemical studies, does not demonstrate neuroendocrine differentiation. This is the undifferentiated counterpart of anaplastic small cell carcinoma.

Large Cell Undifferentiated Carcinoma

Large cell undifferentiated carcinoma is a tumor in which features of acinar, ductal, epidermoid, or myoepithelial differentiation are absent under light microscopy, although, occasionally, poorly formed duct like structures are found. Rapid growth of a parotid swelling is a common clinical presentation. This is a high-grade neoplasm that frequently metastasizes and has a poor prognosis.

Lymphoepithelial Carcinoma

(Undifferentiated carcinoma with lymphoid stroma, carcinoma ex lymphoepithelial lesion)

Lymphoephithelial carcinoma is an undifferentiated tumor that is associated with a dense lymphoid stroma. There is an exceptionally high incidence of this tumor in the Eskimo and Inuit populations. This neoplasm has been associated with Epstein-Barr virus infection. Over 80% occur in the parotid gland. In addition to the presence of a parotid or submandibular mass, pain is a frequent symptom, and facial nerve palsy occurs in up to 20% of patients. Over 40% of patients have metastases to cervical lymph nodes at initial presentation, and 20% develop distant metastases within three years following therapy.

Treatment and Prognosis. The treatment consists of surgery alone or of surgery in combination with radiotherapy. Very little data is available concerning the behavior of these rare tumors.

Salivary Adenocarcinoma, NOS

Adenocarcinoma, NOS, (not otherwise Specified) is a salivary gland carcinoma that shows glandular or ductal differentiation but lacks the prominence of any of the morphologic features that characterize the other, more specific carcinoma types. The diagnosis of adenocarcinoma, NOS, is essentially one of exclusion. In the Armed Forces Institute of Pathology (AFIP) review of cases, adenocarcinoma, NOS, was second only to mucoepidermoid carcinoma in frequency among malignant salivary gland neoplasms. Other series have reported an incidence of 4–10 % (Speight PM, Barret AW, 2002). In AFIP files, the mean patient age was 58 years. Approximately 40–60% of tumors occurred in the major and minor salivary glands, respectively. Among the major salivary gland tumors, 90% occurred in the parotid gland. Adenocarcinoma, NOS is graded in a similar way to extrasalivary lesions according to the degree of differentiation. Tumor grades include low grade, intermediate grade, and high grade categories (Ellis GL, Auclair PL, 1996).

Patients with tumors in the major salivary glands typically present with solitary, painless masses. Two retrospective studies indicate that survival is better for patients with tumors of the oral cavity than for those with tumors of the parotid and submandibular glands (Spiro RH, Huvos AG, Strong EW 1982, Matsuba HM, Mauney M et al, 1988). These studies differ regarding the prognostic significance of tumor grade.

OTHER CARCINOMAS

Adenosquamous Carcinoma

Adenosquamous carcinoma of the salivary gland is a controversial neoplasm that is not included in many classifications of salivary gland tumors. This is a malignant epithelial neoplasm that has histomorphologic features of both adenocarcinoma and squamous cell carcinoma.

Sebaceous Lymphadenocarcinoma

Sebaceous lymphadenocarcinoma is the malignant counterpart of sebaceous lymphadenoma and represents carcinoma arising in sebaceous lymphadenoma. These tumors appear to be low-grade malignant tumors that have the ability to recur locally. Lymph node or distant metastases may develop late in the clinical course of these tumors.

NONEPITHELIAL TUMORS

Mesenchymal Neoplasms

Mesenchymal neoplasms account for 1.9–5% of all neoplasms that occur within the major salivary glands. These classifications pertain to major salivary gland tumors. Because the minor salivary glands are small and embedded within fibrous connective tissue, fat, and skeletal muscle, it is impossible to determine the origin of a mesenchymal neoplasm from stroma. The types of benign mesenchymal salivary gland neoplasms include hemangioma, lipoma, and lymphangioma. Malignant mesenchymal salivary gland neoplasms include malignant schwannoma, hemangiopericytoma, malignant fibrous histiocytoma, rhabdomyosarcoma, and fibrosarcoma, among others; in the major salivary glands, these neoplasms represent approximately 0.5% of all benign and malignant salivary gland tumors and approximately 1.5% of all malignant tumors. It is important to establish a primary salivary gland origin for these tumors by excluding the possibilities of metastasis and direct extension from other sites. In addition, the diagnosis of salivary gland carcinosarcoma should be excluded. Primary salivary gland sarcomas behave like their soft tissue counterpart in which prognosis is related to sarcoma type, histologic grade, tumor size, and stage.

MALIGNANT LYMPHOMAS

Lymphomas of the major salivary glands are characteristically of the non-Hodgkin's type. In AFIP review of case files, non-Hodgkin's lymphoma accounted for 16.3% of all malignant tumors that occurred in the major salivary glands; disease in the parotid gland accounted for about 80% of all cases.

Patients with benign lymphoepithelial lesion (Mikulicz's disease), a manifestation of the autoimmune disease, Sjogren's syndrome, are at an increased risk for development of non-Hodgkin's lymphoma (Fig. 3-33).

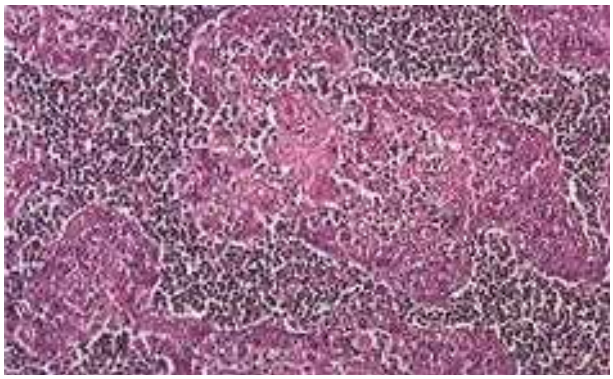

Figure 3-33. Malignant lymphoma—mucosa associated lymphoid tissue (MALT) type.
Note the myoepithelial islands suspended in a background of lymphoid tissue. The lymphoid element is neoplastic with varying degrees of malignancy.

Secondary Tumors

Malignant neoplasms whose origins lie outside the salivary glands may involve the major salivary glands by:

1. Direct invasion from cancers that lie adjacent to the salivary glands
2. Hematogenous metastases from distant primary tumors
3. Lymphatic metastases to lymph nodes within the salivary gland.

Direct invasion of nonsalivary gland tumors into the major salivary glands is principally from squamous cell and basal cell carcinomas of the overlying skin.

TUMOR LIKE LESIONS

Sialadenosis

Sialadenosis is the name given to nonneoplastic, noninflammatory enlargement of salivary glands, particularly the parotid gland. The enlargement is usually bilateral and may manifest recurrence or pain, or both. The condition is almost always found in association with systemic disorders; this association forms the basis for classification of sialadenosis.

Clinical Features. Characterized mainly by the presence of chronic, afebrile salivary gland enlargement, usually of the parotid glands. The enlargement is described as slowly evolving, indolent, undulating, and recurrent. Persons in the later decades of life (4th decade or beyond) are most afflicted. Decreased salivary secretion occurs, and sialochemistry generally demonstrates increased levels of potassium and decreased levels of sodium. Hypertrophy of acinar cells crowds and compresses the finer terminal ducts, thereby yielding the sialographic *'leafless tree'* pattern (Table 3-7).

Histologic Features. The parotid swelling is due to acinar enlargement. The diameter of the acinar cell increases two to three times that of normal. The nuclei tend to be basally situated, and the cytoplasm tends to be packed with granules. Inflammatory cells are absent but individual fat cells may be seen in the interstitial tissue. Batsakis (1988) suggests that long standing uncorrected autonomic neuropathy, such as occurs in alcoholism or diabetes mellitus eventually leads to acinar atrophy and replacement with fat.

Treatment. Treatment is generally unsatisfactory and depends on correcting the underlying cause. Subtotal parotidectomy may be considered as a last resort.

Table 3-7: Classification of sialadenosis

Pancreatogenic (exocrine) sialadenosis
Nephrogenic sialadenosis
Dysproteinemic sialadenosis
Malnutritional sialadenosis
Mucoviscidosis
Drug-induced sialadenosis

Oncocytosis

Oncocytosis is a metaplastic, sometimes hyperplastic, developmental or reactive process that is characterized by focal replacement of normal glandular tissue with enlarged eosinophilic epithelial cells with granular cytoplasm. These swollen epithelial cells were first described by Shafer (1897) and later the term 'onkocyte' was applied by Hamperl (1931) (cited by Ellis GL and Auclair PL, 1991). Oncocytosis is seen with greater frequency in older people and is considered a sequela of aging. The majority of cases occur in the parotid but it may be found in any major or minor gland. The histologic distinction between oncocytosis and oncocytoma, which is the benign neoplasm of oncocytes, may occasionally be difficult.

Histologic Features. Oncocytosis may present as scattered foci of enlarged, eosinophilic epithelial cells or a solitary focus of metaplastic oncocytes. The cells may retain an acinar arrangement and form sheets, trabeculae, or duct like structures surrounded by fine collagen septa. The cytologic features consist of large, eosinophilic, polyhedral epithelial cells with fine granular cytoplasm and a centrally placed pyknotic nucleus (Fig. 3-34). Oncocytes occasionally show transition to clear cells as a result of intracytoplasmic glycogen.

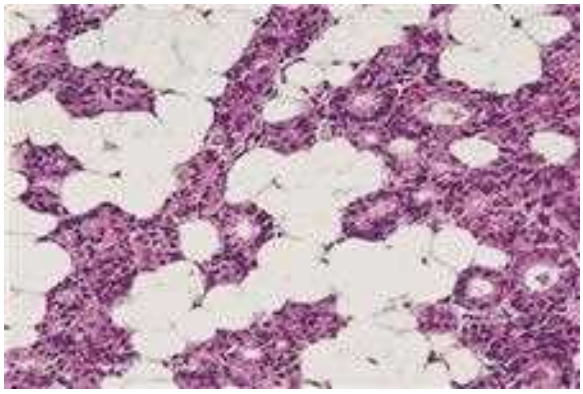

Figure 3-34. Oncocytic hyperplasia.
The granular oncocytes admixed with empty fat cells.

Ultrastructural findings are characterized by cytoplasm that is packed with large, pleomorphic mitochondria containing filamentous, tubular, and vesicular cristae. The oncocytes have been considered a product of degenerative changes.

Necrotizing Sialometaplasia
(Salivary gland infarction)

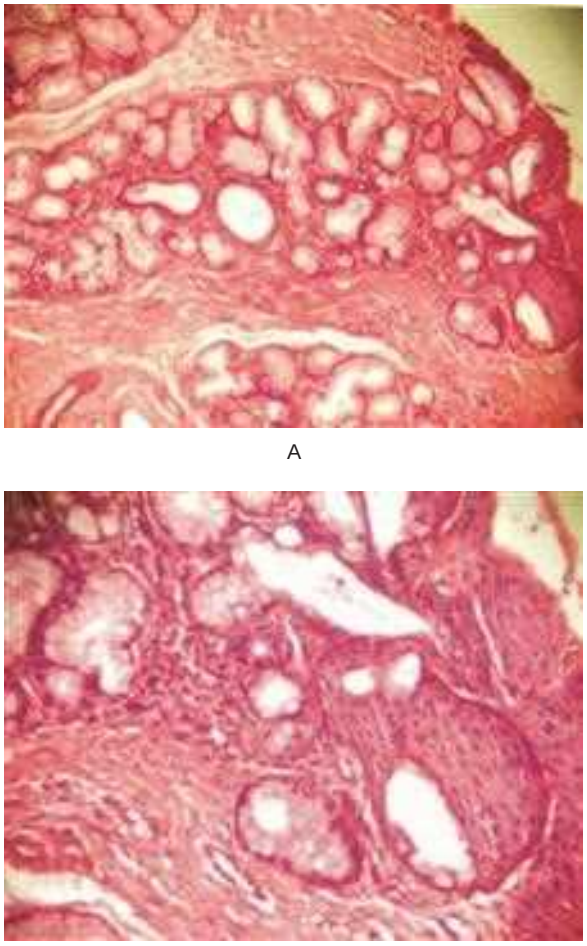
Necrotizing sialometaplasia (NS) is a non-neoplastic inflammatory condition of the salivary glands. In 1973, Abrams et al, first reported this condition. The clinical and histopathologic features of NS often simulate those of malignancies such as squamous cell carcinoma or mucoepidermoid carcinoma.

Etiology. Most cases of NS appear to arise spontaneously, whereas others are associated with a history of trauma, radiation therapy, or surgery. In most cases of NS, the etiology is believed to be related to vascular ischemia. The association of adjacent neoplasia that results in ischemic necrosis of the glandular elements and the histologic features of NS supports this pathogenic mechanism. Tobacco use is suggested as a possible etiologic risk factor for NS.

Clinical Features. NS is generally reported to involve the minor salivary glands of the oral cavity, particularly those of the palate. Reports of this entity in the minor glands of the retromolar pad area, buccal mucosa, tongue, incisive canal, and labial mucosa have also been reported. In addition, NS is recognized in the parotid and submandibular salivary glands, minor mucous glands in the lung, nasal cavity, larynx, trachea, nasopharynx, and maxillary sinus. Similar lesions are identified in the breast; the condition is referred to as post-traumatic lobular metaplasia of the breast. Lesions in the skin are referred to as syringometaplasia. The male-to-female ratio is approximately 2 : 1. The average age of patients with NS is 47.9 years, with a range of 17–80 years.

The lesions of NS often are painless; less frequently, they cause pain and numbness. NS manifests as a swelling with or without ulceration in anatomic sites that have mucous or serous glandular tissue. The typical clinical presentation of NS is that of a crateriform ulcer of the palate that simulates a malignant process. These ulcerated lesions are 1–3 cm and are usually unilateral, but bilateral synchronous lesions and metachronous lesions can occur. Some lesions of NS may present as a submucosal swelling, without ulceration of the overlying mucosa. An intact surface mucosa may be noted in an evolving lesion at the time of diagnosis, although most cases are accompanied by mucosal ulceration. Erosion of the palatal bone may occur in either ulcerated or nonulcerated lesions. Examination of a biopsy specimen is usually required to establish the correct diagnosis and to exclude a malignant or infectious process or an inflammatory condition such as Wegener granulomatosis. Extranodal lymphoma also may be considered in the clinical differential diagnosis of a palatal swelling or ulceration.

Histologic Features. The microscopic features of NS include coagulative necrosis of glandular acini and squamous metaplasia of its ducts. Mucin pooling is present, and an



A

B

Figure 3-35. Sialometaplasia.
Squamous metaplasia of salivary ducts. Lobular architecture of the glands is intact.

associated inflammatory infiltrate consists of macrophages, neutrophils, and less commonly, lymphocytes, plasma cells, and eosinophils (Fig. 3-35).

Pseudoepitheliomatous hyperplasia of the overlying mucosa can also be present, but the cytologic features of the epithelial atypia are usually absent. Occasionally, isolated mucous cells may be entrapped within the squamous islands; these cells should not be confused with those of mucoepidermoid carcinoma. The microscopic differential diagnosis for NS includes mucoepidermoid carcinoma and squamous cell carcinoma. Some believe that subacute necrotizing sialadenitis is yet another entity that occurs within the spectrum of NS; it should be distinguished from NS.

Treatment and Prognosis. NS resolves spontaneously. No treatment is necessary. Surgical care consists of incisional biopsy for diagnostic purposes. Periodic evaluation of the affected site is recommended until spontaneous resolution occurs. The prognosis for NS is excellent. Spontaneous resolution usually occurs within weeks. The average healing time for NS of the minor salivary glands of the hard and soft palates is approximately five weeks. The size of the lesion and whether or not bony perforation has occurred are clinical parameters that may influence the healing time.

Benign Lymphoepithelial Lesion

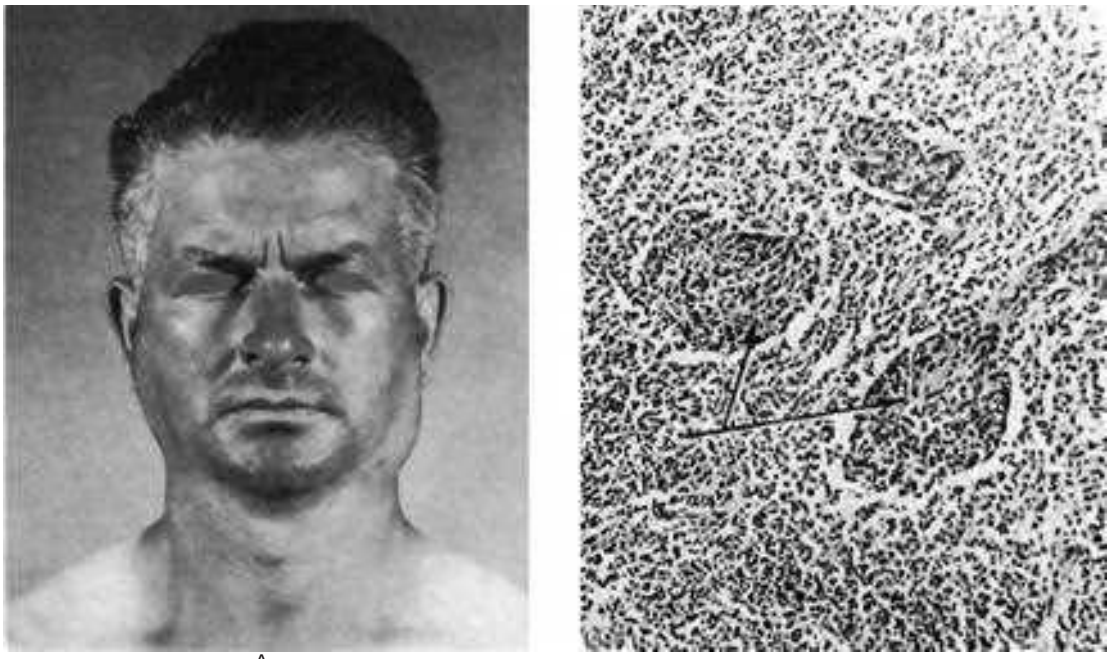
(Mikulicz syndrome, dacryosialoadenopathia, Mikulicz-Radecki syndrome, Mikulicz-Sjögren syndrome, von Mikulicz syndrome)

Mikulicz disease is a chronic condition characterized by the abnormal enlargement of the salivary and lacrimal glands. The tonsils and other glands in the soft tissue of the face and neck may also be involved. In 1888 Johann Mikulicz, a German surgeon first reported a case of chronic bilateral lacrimal gland enlargement associated with enlargement of the salivary glands. Subsequently many cases of bilateral salivary or lacrimal gland enlargement were reported as Mikulicz disease. But as most of these cases were caused by tuberculosis, sarcoidosis or lymphoma, this led to confusion regarding the terminology related to Mikulicz disease. Hence it was proposed that the term Mikulicz disease should be used if the cause is unknown and the Mikulicz syndrome be reserved for cases if the enlargement is associated with a known disease. People who have Mikulicz disease are at heightened risk for developing lymphomas.

Etiology. The exact cause of Mikulicz disease is not known, although it is suspected to be an autoimmune disorder. The symptoms of Mikulicz disease may occur due to the excessive accumulation of lymphocytes into the involved glands.

Clinical Features. Mikulicz disease affects more females than males and most often presents during the middle adult years. It often occurs in combination with Sjögren syndrome. Mikulicz disease is characterized by the sudden onset of xerostomia that may lead to difficulty in swallowing and result in tooth decay. Other symptoms include enlarged lacrimal glands, leading to absent or decreased tears; painless swellings (tumefactions) of the salivary glands (parotid, submaxillary) are noticed. The symptoms of Mikulicz disease are very similar to those of Sjögren syndrome and some researchers suspect that they may be the same disorder. Some people with Mikulicz disease may experience recurring fevers. The fever may be accompanied by dry eyes, diminished lacrimation, and uveitis. Lacrimal gland enlargement, parotid gland enlargement, dry mouth and dry eyes are the classic signs.

Histologic Features. The disease is characterized by an orderly lymphocytic infiltration of the salivary gland tissue, destroying or replacing the acini, with the persistence of islands of epithelial cells which probably represent residua of gland ducts (Fig. 3-36 B). Although the lymphoid element is usually diffuse, actual germinal centers are occasionally present. The epithelium may consist of ducts showing cellular proliferation and loss of polarity, or as the disease persists, solid nests or clumps of poorly defined epithelial cells which Morgan and Castleman termed 'epimyoepithelial islands'. These sometimes seem to form a syncytium. It has been suggested that such islands arise as a result of proliferation



A B

Figure 3-36. Benign lymphoepithelial lesion (Mikulicz's disease).
(A) There is enlargement of the parotid, submaxillary and lacrimal glands. **(B)** The photomicrograph illustrates the diffuse lymphocytic infiltrate and the typical epimyoepithelial islands *(Courtesy of Dr Frank Vellios).*

of both ductal cells and peripheral myoepithelial cells. A characteristic change also found in advanced lesions is the deposition of eosinophilic, hyaline material in the epithelial islands.

Great care must be taken in differentiating between the benign lymphoepithelial tumor and a malignant lymphoma involving the salivary glands. In the latter disease, epimyoepithelial islands are not present, the lymphoid element is atypical, and there is infiltration of the interlobular septa by lymphoid tissue. The epithelial islands, on the other hand, may be mistaken for metastatic carcinoma. Other histologically similar lesions which must be considered in the differential diagnosis are chronic sialadenitis, papillary cystadenoma lymphomatosum and uveoparotitis.

Treatment and Prognosis. Biopsy of one of the swollen glands is key to the diagnosis of Mikulicz disease. An ultrasonographic examination of the area may help to rule out other reasons for gland swelling. Treatment of this disorder is symptomatic. Artificial tears may be used to maintain moisture in the eyes, and artificial saliva may be used to treat oral symptoms. Some individuals with Mikulicz disease may be instructed to follow a soft moist diet. This may help to reduce the pain caused by chewing and swallowing.

Sjögren's Syndrome
(Sicca syndrome, Gougerot-Sjögren syndrome)

Sjögren's syndrome is a condition originally described by Henrik Sjögren in 1933, as a triad consisting of keratoconjunctivitis sicca, xerostomia and rheumatoid arthritis. Subsequently, it has been found that some patients present only with dry eyes and dry mouth (sicca complex or **primary Sjögren's syndrome**), while others also develop systemic lupus erythematosus, polyarteritis nodosa, polymyositis or scleroderma, as well as rheumatoid arthritis (**secondary Sjögren's syndrome**). As Sjögren pointed out, cases of xerostomia and arthritis without keratoconjunctivitis sicca have been observed.

Etiology. Various causes of this disease have been suggested: genetic, hormonal, infectious and immunologic, among others. It may well be that a combination of factors, both extrinsic and intrinsic, play a role in the etiology of this condition. Most authorities consider an altered immunologic response to be the main intrinsic factor which is responsible for the disease. Laboratory findings support the autoimmune etiologic role (q.v.). Bertram has reported that 75% of a series of 35 patients with Sjögren's syndrome had in their sera antisalivary duct antibody. Similar antibody was found in the sera of 24% of a group of 29 patients with systemic lupus erythematosus, a documented autoimmune disease. In addition, the sicca complex and Sjogren's syndrome have been found to be associated with the HLA system, specifically HLA-DR3 and HLA-B8 which are associated with primary form of the disease and HLA-DRw52 seen to be associated with both the forms of Sjögren's syndrome. Cytomegalovirus, paramyxovirus and Epstein-Barr virus have all been implicated in the pathogenesis of this condition but have not been proven conclusively.

Clinical Features. This disease occurs predominantly in women over 40 years of age, although children or young adults may be affected. The female: male ratio is approximately

10 : 1. The typical features of the disease are dryness of the mouth and eyes as a result of hypofunction of the salivary and lacrimal glands. This often results in painful, burning sensations of the oral mucosa. In addition, various secretory glands of the nose, larynx, pharynx and tracheobronchial tree (buccopharyngolaryngitis sicca), as well as of the vagina, are involved with this dryness. Schall and his associates have evaluated the degree of xerostomia by means of sequential salivary scintigraphy. Chisholm and Mason have quantified saliva production in patients with the sicca complex and Sjögren's syndrome. Reduced salivary flow was noted in both groups. Sialochemistry studies by Ben-Aryeh and coworkers have demonstrated significantly elevated levels of IgA, potassium and sodium in the saliva of patients with the sicca complex. Moutsopoulos has reported that 80% of patients with primary Sjögren's syndrome have parotid enlargement in contrast to only 14% with secondary Sjögren's syndrome. Lymphadenopathy is more than twice as common in the primary form of the disease.

Rheumatoid arthritis, as mentioned, is an integral part of secondary Sjögren's syndrome. It has been shown that patients with Sjögren's syndrome with rheumatoid arthritis have certain different clinical manifestations than patients with sicca complex, despite similar histologic findings and some laboratory findings. In this regard, patients without rheumatoid arthritis, that is, sicca complex or primary Sjögren's syndrome, more frequently manifest parotid gland enlargement, lymphadenopathy, purpura, Raynaud's phenomenon, kidney involvement and myositis.

Histologic Features. Three types of histologic alterations in the major salivary glands have been described. In one case, there may be intense lymphocytic infiltration of the gland replacing all acinar structures although the lobular architecture is preserved. In another, there may be proliferation of ductal epithelium and myoepithelium to form 'epimyoepithelial islands'. Both of these histologic changes are identical with those occurring in the benign lymphoepithelial lesion in Mikulicz's disease. The third alteration may be simply an atrophy of the glands sequential to the lymphocytic infiltration.

Interestingly, Bertram and Hjoting-Hansen have reported that 85% of a group of patients with Sjögren's syndrome exhibited alterations in the accessory salivary glands of the lip characteristically similar to those in the major glands; they also have suggested biopsy of the labial mucosa as an aid in establishing the diagnosis of the disease. Similar findings in accessory glands, as well as the demonstration of antisalivary duct antibody by an immunofluorescent technique, have been reported by Tarpley, Anderson and White.

Laboratory Findings. Over 75% of patients with primary Sjögren's syndrome have a polyclonal hyperglobulinemia and many develop cryoglobulins. Multiple organ- or tissue-specific antibodies are found, including antisalivary duct antibodies, rheumatoid factor and antinuclear antibodies. An increased sedimentation rate is present in 80% of these patients. Interestingly, the presence of antisalivary duct antibody is three times more common in those with secondary Sjögren's syndrome as compared to those with the sicca complex.

Radiographic Features. Sialography may be of diagnostic value in Sjögren's syndrome. Sialographs demonstrate the formation of punctate, cavitary defects which are filled with radiopaque contrast media. These filling defects have been said to produce a 'cherry blossom' or 'branchless fruit-laden tree' effect radiographically. Som and his associates have suggested that the contrast material actually extravasates through the weakened salivary gland ducts to produce the sialographic features. Poor elimination of contrast media is noted, as might be expected, with retention of the material for over a month.

Treatment and Prognosis. There is no satisfactory treatment for Sjögren's syndrome. Most patients are treated symptomatically. Keratoconjunctivitis is treated by instillation of ocular lubricants such as artificial tears containing methylcellulose, and xerostomia is treated by saliva substitutes such as those used in the treatment of person with xerostomia secondary to radiation therapy. Extensive dental caries is a complication which is quite common, and scrupulous oral hygiene and frequent fluoride application is indicated to reduce this problem. There is no specific treatment for enlargement of the salivary glands. Surgery has been employed but is generally recommended only in patients with discomfort. Although radiation therapy has been recommended in the past, its use is not advocated currently.

A major complicating factor in patients with Sjögren's syndrome is the development of pseudolymphoma and malignant lymphoma. In an extensive National Institutes of Health (NIH) study, 136 patients with Sjögren's syndrome were followed for an average period of over eight years. Nonlymphoma malignancies were no more common than would be expected, whereas lymphomas were observed in nearly 44 times the expected incidence rate. The risk of lymphoma in Sjögren's patients is 6.4 cases per 100 cases per year. Most lymphomas are non-Hodgkin's types and are B-cell in origin. Macroglobulinemia of Waldenstrom also has been noted to develop in these patients.

The relation between the benign lymphoepithelial lesion, Mikulicz's disease and Sjögren's syndrome is possibly a very close one. Mikulicz's disease, but not Mikulicz's syndrome, is probably identical with the lymphoepithelial lesion. This entity shares several features in common with Sjögren's syndrome. Both diseases are manifested, often but not invariably, by a swelling of the major salivary glands and lacrimal glands, singly or in pairs. In both diseases the patient has xerostomia, which probably is related to the displacement and destruction of acinar tissue. Finally, both diseases occur chiefly in middle-aged or elderly women.

It is likely that the benign lymphoepithelial lesion is a mild form of Sjögren's syndrome, but it should not be inferred that lymphoepithelial lesions will eventually terminate in Sjögren's

disease. More aptly, the two diseases may be considered two forms of the same disease with a probably common etiology.

SALIVARY GLAND CYSTS

Most cystic lesions of the major salivary glands are cystic neoplasms. Benign cyst is much less common and accounts for approximately 2–5% of parotid gland lesions. They are rare in the other major salivary glands. Benign cyst (sialocyst) of the parotid gland can be conveniently classified into the following three types: lymphoepithelial cyst, salivary duct cyst, and dysgenetic cyst. Polycystic (dysgenetic) disease of the parotid gland is considered a developmental malformation of the ductal system.

Lymphoepithelial Cysts

(Refer Chapter 1 Developmental Desturbances of Oral and Paraoral Structures)

Salivary Duct Cyst

Salivary duct cyst may be acquired or congenital. The majority; however, are acquired and most of these are probably secondary to obstruction. Some authors, therefore, prefer the term retention cyst to designate these lesions. Still others prefer the term simple cyst.

Clinical Features. Salivary duct cysts of the parotid gland are unilateral painless swellings with no involvement of facial nerve and no fixation to the overlying skin. The majority of the affected patients are over 40 years of age. The cysts range in size from 0.8–10.0 cm with an average size of approximately 1–3 cm.

Histologic Features. Typically, these unilocular cysts are lined by single or multilayered cuboidal or columnar epithelium. Occasional mucus containing goblet cells and areas of oncocytic differentiation may be seen. It may be completely or partially lined by squamous epithelium. A sparse to moderate lymphocytic infiltration is present in the cyst wall.

Treatment. Simple surgical resection is curative.

Chronic Sclerosing Sialadenitis of Submandibular Gland

(Küttner tumor)

Kuttner tumor or chronic sclerosing sialadenitis is a benign inflammatory condition of the submandibular gland that mimics a malignant neoplasm clinically because of presentation as a hard mass. This entity is poorly documented in the surgical pathology and cytology literature.

Histologic Features. Histologic examination of the excised submandibular glands revealed preserved lobular architecture, thickening of interlobular septa by sclerotic tissue, dense lymphoplasmacytic infiltrate, preservation of ducts with periductal fibrosis, and variable loss of acini. Fine-needle aspiration cytologic findings were characterized by scattered tubular ductal structures often enveloped by collagen bundles or lymphoplasmacytic infiltrate, isolated fragments of fibrous stroma, a background rich in lymphoid cells, and paucity or absence of acini.

Treatment and Prognosis. The treatment of sialadenitis includes appropriate antibiotic therapy and rehydration of the patient to stimulate salivary flow. Surgical drainage may be needed if there is abscess formation.

Cystic Lymphoid Hyperplasia in AIDS

Cystic lesions of the parotid gland have been reported in patients at risk for acquired immunodeficiency syndrome (AIDS). The cysts in many of these cases have features of lymphoepithelial cysts but differ from those described before the AIDS epidemic in that they are more frequently multiple and bilateral. In addition to the cysts, the parotid gland in many of the patients at risk of AIDS exhibits features suggestive of benign lymphoepithelial lesions. Such lesions, without associated cysts, may also occur in patients at risk of AIDS. The parotid lymphoid tissue in some of these cystic and noncystic lesions may exhibit features seen in the lymph nodes of patients with AIDS-related complex with persistent generalized lymphadenopathy. Transformation to malignant lymphoma may occur.

CHAPTER 4

Cysts and Tumors of Odontogenic Origin

■ T"TCLGPFTCP

CHAPTER OUTLINE

Tumors derived from the odontogenic tissues constitute an unusually diverse group of lesions. This multiformity reflects the complex development of the dental structures, since these tumors all originate through some aberration from the normal pattern of odontogenesis. An understanding of the pathogenesis of the odontogenic tumors is predicated upon an understanding of the histogenesis of the tooth.

Certain of the lesions discussed in this chapter represent only minor alterations in odontogenesis and not true neoplasms. The odontogenic cysts are included because they too represent an aberration at some stage of odontogenesis, and in fact, may be intimately associated with the development of certain of the odontogenic tumors. All of the various lesions are grouped here because of their common origin from a uniquely specialized group of tissues, and their classification is based upon this origin from the various germ layers.

Odontogenic Cysts

Cysts of the jaws can be classified as:

- Odontogenic (arising from tooth-forming tissues)
- Nonodontogenic (developmental or fissural).

The odontogenic cysts are derived from epithelium associated with the development of the dental apparatus. The type of epithelium can vary with most lesions having stratified squamous but some developmental or fissural cysts in the maxilla may have respiratory epithelium.

Several types of odontogenic cysts may occur, dependent chiefly upon the stage of odontogenesis during which they originate. Various investigators have attempted to devise a classification and system of nomenclature of the lesions. Some of these classifications have not been entirely satisfactory because they generally failed to recognize the mode of origin and development of the cysts and did not unite the views of the oral surgeon, the radiologist and the pathologist.

The following classification of odontogenic cysts (Table 4-1) is based on etiology and tissue of origin.

Dentigerous Cyst
(Follicular cyst)

Dentigenous cyst can be defined as an odontogenic cyst that surrounds the crown of an impacted tooth; caused by fluid accumulation between the reduced enamel epithelium and the enamel surface, resulting in a cyst in which the crown is located within the lumen. This is one of the most common types of developmental odontogenic cyst, estimated to be about 20% of all jaw cysts. It is estimated that about 10% of impacted teeth have formed a dentigerous cyst. Their frequency in the general population has been estimated at 1.44 cyst for every 100 unerupted teeth. The dentigerous cyst nearly always involves or is associated with the crown of a normal permanent tooth. Seldom is a deciduous tooth involved.

Clinical Features. This cyst is always associated initially with the crown of an impacted, embedded or unerupted tooth (Fig. 4-1). A dentigerous cyst may also be found enclosing a complex compound odontoma or involving a supernumerary tooth. The most common sites of this cyst are the mandibular and maxillary third molar and maxillary cuspid areas, since these are the most commonly impacted

Table 4-1: Classification of odontogenic cysts

Classification by etiology
Developmental: Unknown origin but are not the result of an inflammatory reaction
Dentigerous cyst Eruption cyst Odontogenic keratocyst Gingival cyst of newborn Gingival cyst of adult Lateral periodontal cyst Calcifying odontogenic cyst Glandular odontogenic cyst
Inflammatory: Result of inflammation
Periapical cyst Residual cyst Paradental cyst
Classification by tissue of origin
Derived from rests of Malassez
Periapical cyst Residual cyst
Derived from reduced enamel epithelium
Dentigerous cyst Eruption cyst
Derived from dental lamina (rests of Serres)
Odontogenic keratocyst Gingival cyst of newborn Gingival cyst of adult Lateral periodontal cyst Glandular odontogenic cyst
Unclassified
Paradental cyst Calcifying odontogenic cyst

Figure 4-1. Dentigerous cyst.
The cyst wall is attached to the cervical region of the associated unerupted tooth. The crown of the tooth projects into the cyst cavity and its roots exhibit hypercementosis.

teeth. Most lesions present in second and third decades, with slight male predilection (M:F–3:2). Most dentigerous cysts are solitary. Bilateral and multiple cysts are usually found in association with a number of syndromes including cleidocranial dysplasia and Maroteaux–Lamy syndrome. In the absence of these syndromes, bilateral dentigerous cysts are rare. The dentigerous cyst is potentially capable of becoming an aggressive lesion. Expansion of bone with subsequent facial asymmetry, extreme displacement of teeth, severe root resorption of adjacent teeth and pain are all possible sequelae brought about by continued enlargement of the cyst. Cystic involvement of an unerupted mandibular third molar may result in a 'hollowing-out' of the entire ramus extending up to the coronoid process and condyle as well as in expansion of the cortical plate due to the pressure exerted by the lesion. Associated with this reaction may be displacement of the third molar to such an extent that it sometimes comes to lie compressed against the inferior border of the mandible. In the case of a cyst associated with a maxillary cuspid, expansion of the anterior maxilla often occurs and may superficially resemble an acute sinusitis or cellulitis. There is usually no pain or discomfort associated with the cyst unless it becomes secondarily infected.

Radiographic Features. Radiographic examination of the jaw involved by a dentigerous cyst will reveal a radiolucent area associated in some fashion with an unerupted tooth crown (Fig. 4-2A). The impacted or otherwise unerupted tooth crown may be surrounded symmetrically by this radiolucency, although the distinction between a small dentigerous cyst and an enlarged dental follicle or follicular space is quite arbitrary, especially since the small cyst and the enlarged follicle would be histologically identical. While a normal follicular space is 3–4 mm, a dentigerous cyst can be suspected when the space is more than 5 mm. Only when the size of the radiolucency is grossly pathologic can the distinction be made with assurance.

Three radiological variations of the dentigerous cyst may be observed. In the *central* variety, the crown is enveloped symmetrically. In these instances, pressure is applied to the crown of the tooth and may push it away from its direction of eruption. In this way, mandibular third molars may be found at the lower border of the mandible or in the ascending ramus and a maxillary canine may be forced into the maxillary sinus as far as the floor of the orbit. The *lateral* type of dentigerous cyst is a radiographic appearance which results from dilatation of the follicle on one aspect of the crown. This type is commonly seen when an impacted mandibular third molar is partially erupted so that its superior aspect is exposed. The so-called *circumferential* dentigerous cyst results when the follicle expands in a manner in which the entire tooth appears to be enveloped by cyst. The dentigerous cyst is usually a smooth, unilocular lesion, but occasionally one with a multilocular appearance may occur. In actuality, the various compartments are all united by the continuous cystic membrane. Sometimes the radiolucent area is surrounded by a thin sclerotic line representing bony reaction. In cases of apparently multiple dentigerous cysts, care should be taken to rule out the possible occurrence of the odontogenic keratocyst, basal cell nevus, bifid rib syndrome (q.v.).

Histologic Features. There are no characteristic microscopic features which can be used reliably to distinguish the dentigerous cyst from the other types of odontogenic cysts.

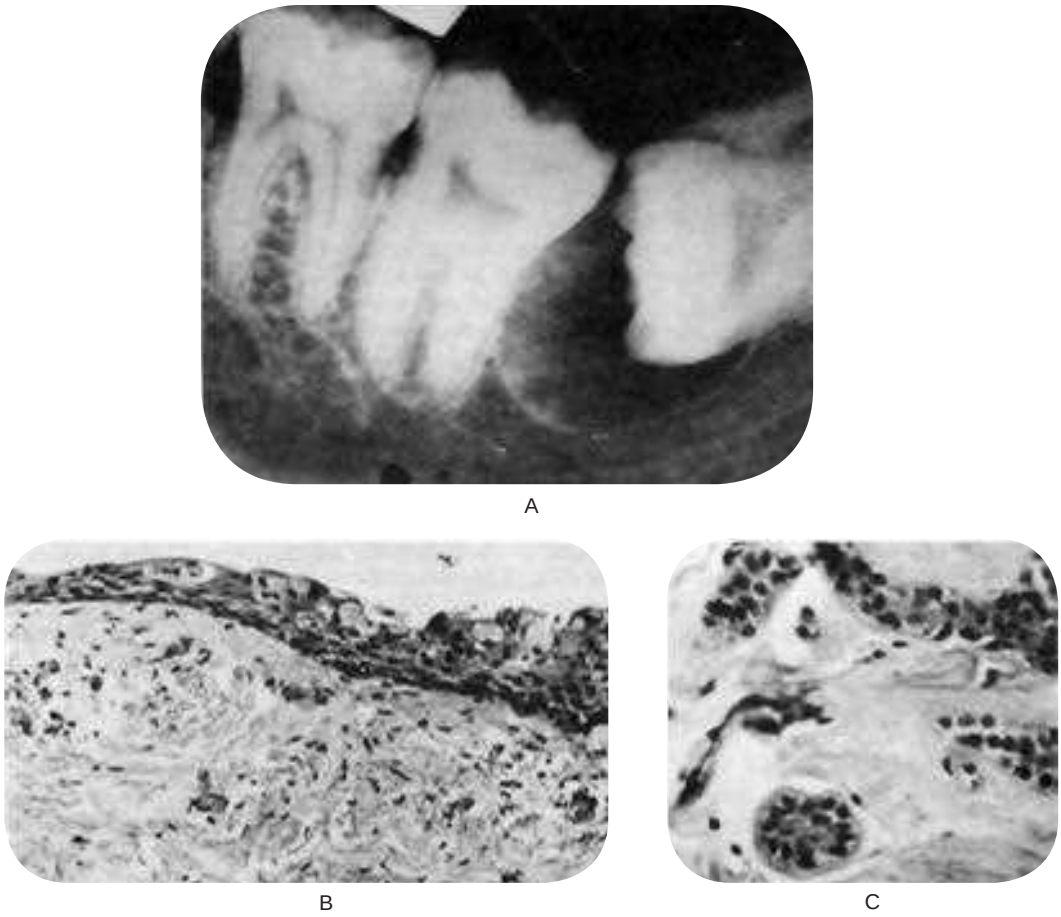

Figure 4-2. Dentigerous cyst.
The radiograph **(A)** demonstrates a large radiolucent area associated with the crown of the impacted mandibular third molar. The photomicrograph **(B)** shows this cyst to be lined by a thin layer of stratified squamous epithelium similar in appearance to the primordial cyst. Occasional mucus-containing cells are present in the epithelium. Small islands of odontogenic epithelium **(C)** are often present in the connective tissue wall.

It is usually composed of a thin connective tissue wall with a thin layer of stratified squamous epithelium lining the lumen (Fig. 4-2B). Rete peg formation is generally absent except in cases that are secondarily infected. The connective tissue wall is frequently quite thickened and composed of a very loose fibrous connective tissue or of a sparsely collagenized myxomatous tissue, each of which has been sometimes mistakenly diagnosed as either an odontogenic fibroma or an odontogenic myxoma. A hyperplastic dental follicle is not necessarily associated with inflammation. An additional feature of the connective tissue wall of both normal dental follicles and dentigerous cysts is the presence of varying numbers of islands of odontogenic epithelium (Fig. 4-2C). These are sometimes very sparse and obviously inactive, while at other times they are present in sufficient numbers to be mistaken for an ameloblastoma. While this latter odontogenic tumor can originate in this situation, care must be taken to differentiate between it and simply odontogenic epithelial rests. Inflammatory cell infiltration of the connective tissue is common although the cause for this is not always apparent. An additional finding, especially in cysts which exhibit inflammation, is the presence of Rushton bodies within the lining epithelium. These are peculiar linear, often curved, hyaline bodies with variable stainability which are of uncertain origin, questionable nature and unknown significance. Even electron microscopic studies, such as those of El-Labban, have only been of partial help in determining that the structures are probably of hematogenous origin, although it is not clear why they have such an intimate relationship to epithelium. The content of the cyst lumen is usually a thin, watery yellow fluid, occasionally blood tinged.

It was reported by Brannon in his excellent clinicopathologic study of 312 cases of odontogenic keratocysts that 8.5% of a series of 1,850 dentigerous cysts were odontogenic keratocysts (q.v.) with the characteristic histologic findings in the epithelium of a parakeratinized, corrugated surface, a remarkable uniformity of a 6- to 10-cell thickness without rete peg formation, and a polarized and palisaded basal layer of cells. This percentage of dentigerous cysts which are odontogenic keratocysts is in close agreement with the findings of Pindborg and his coworkers (7.1%) and Payne (8.5%).

The pluripotentialities of the epithelium in mandibular dentigerous cysts has been further emphasized by Gorlin, who described mucus-secreting cells in the lining stratified squamous epithelium, respiratory epithelial lining, sebaceous cells in the connective tissue wall, and lymphoid follicles with germinal centers.

Treatment. The treatment of the dentigerous cyst is usually dictated by the size of the lesion. Smaller lesions can be surgically removed in their entirety with little difficulty. The larger cysts which involve serious loss of bone and thin the bone dangerously are often treated by insertion of a surgical drain or marsupialization. Such a procedure is often necessary because of the potential danger of fracturing the jaw if complete surgical removal were attempted. Recurrence is relatively uncommon.

Potential Complications. Several relatively serious potential complications exist stemming from the dentigerous cyst, besides simply the possibility of recurrence following incomplete surgical removal. These include:

- The development of an ameloblastoma either from the lining epithelium or from rests of odontogenic epithelium in the wall of the cyst.
- The development of epidermoid carcinoma from the same two sources of epithelium.
- The development of a mucoepidermoid carcinoma, basically a malignant salivary gland tumor, from the lining epithelium of the dentigerous cyst which contains mucus-secreting cells, or at least cells with this potential, most commonly seen in dentigerous cysts associated with impacted mandibular third molars.

It is of great clinical significance that numerous cases of ameloblastoma have been reported developing in the wall of dentigerous cysts from the lining epithelium or associated epithelial rests (Fig. 4-3). Stanley and Diehl have reviewed a series of 641 cases of ameloblastoma and have found that at least 108 cases of this neoplasm, approximately 17%, were definitely associated with an impacted tooth and/or a follicular or dentigerous cyst. The disposition for neoplastic epithelial proliferation in the form of an ameloblastoma is far more pronounced in the dentigerous cyst than in the other odontogenic cysts. The formation of such a tumor manifests itself as a nodular thickening in the cyst wall, the mural ameloblastoma, but this is seldom obvious clinically. Therefore, it is not only good clinical practice, but also an absolute requisite that all tissue from dentigerous cysts be submitted to a qualified oral pathologist for thorough gross and microscopic examination. In reviewing the histologic changes sought by the oral pathologist which occur in the dentigerous cyst as a premonitory manifestation of ameloblastoma, Vickers and Gorlin have stressed that hyperchromatism of basal cell nuclei, palisading with polarization of basal cells and cytoplasmic vacuolization with intercellular spacing of the lining epithelium, **when observed together,** are manifestations of impending neoplasia. These findings may occur **individually** in other rather harmless conditions. The presence of sprouting or budding and protruding of epithelial islands from lining epithelium has been claimed to be evidence of neoplastic transformation, but this in itself was not considered such an indication by Vickers and Gorlin.

The development of epidermoid carcinoma from the lining epithelium of the dentigerous cyst also has been adequately

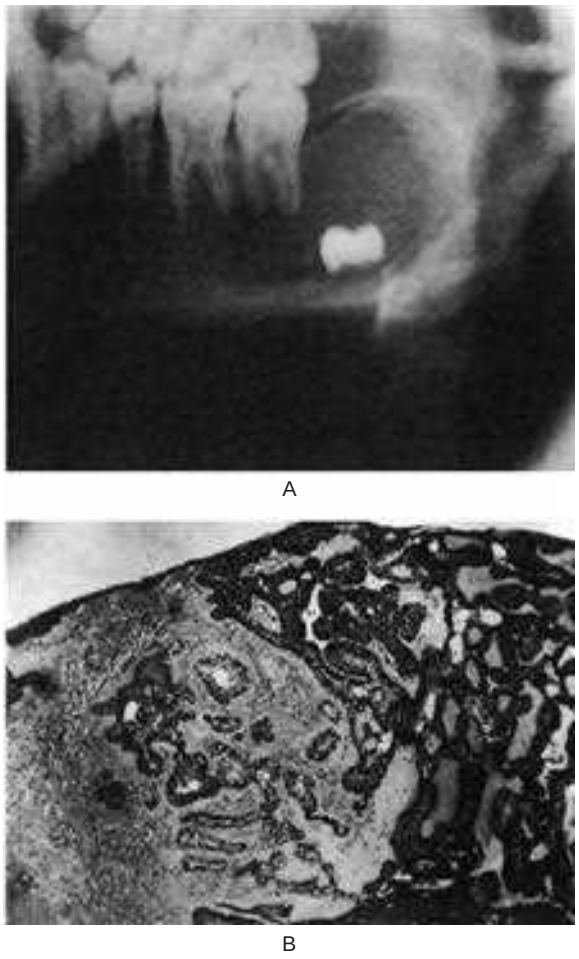

Figure 4-3. Ameloblastoma developing in wall of dentigerous cyst.

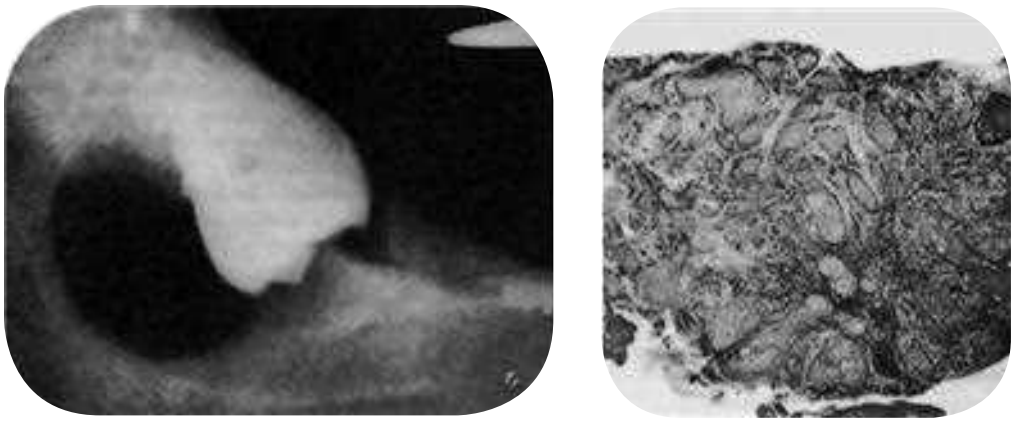
documented in the literature reviewed by Gardner, who reported eight acceptable cases among 25 cases of carcinoma developing in odontogenic cysts of all types combined. Browne and Gough have reported two additional cases of malignant transformation in dental cysts and suggested that keratin metaplasia in long-standing cyst lining appears to precede the development of the carcinomatous change, although there is little evidence that the odontogenic keratocyst is associated with malignant change more commonly than other types of odontogenic cysts. The predisposing factor and mechanism of development of this malignancy are unknown, but its occurrence appears unequivocal (Fig. 4-4).

Finally, the development of a mucoepidermoid carcinoma, a type of salivary gland tumor, is less well documented than the epidermoid carcinoma of this origin, but it also appears to be a potentiality. The inclusion of normal salivary gland tissue in the posterior portion of the body of the mandible has been reported, and undoubtedly, some central salivary gland tumors in this location originate from this source. However, cases of central mucoepidermoid carcinoma (q.v.) have been discovered in association with dentigerous cysts involving impacted mandibular third molars, and considering the frequency with which mucus-secreting cells are found



A B

Figure 4-4. Epidermoid carcinoma developing in dentigerous cyst.

in this lining epithelium indicative of the pluripotentiality of this epithelium, this very distinct possibility must always be considered. These findings comprise most of the medical rationale for removal of impacted third molars with pericoronal radiolucencies; however, impacted teeth with small pericoronal radiolucencies (suggesting the presence of normal dental follicle rather than dentigerous cyst) also may be monitored with serial radiographic examination. Any increase in the size of the lesion should prompt removal and histopathologic examination. Any lesion that appears larger than a normal dental follicle indicates removal and histopathologic examination.

Eruption Cyst

Eruption cyst is defined as an odontogenic cyst with the histologic features of a dentigerous cyst that surrounds a tooth crown that has erupted through bone but not soft tissue and is clinically visible as a soft fluctuant mass on the alveolar ridges.

An eruption cyst or 'eruption hematoma' is in fact a dentigerous cyst occurring in the soft tissues (Shear, 1992). Whereas the dentigerous cyst develops around the crown of an unerupted tooth lying in the bone, the eruption cyst occurs when a tooth is impeded in its eruption within the soft tissue overlying the bone. The pathogenesis is probably very similar to that of the dentigerous cyst. The difference is that the tooth in the case of the eruption cyst is impeded in the soft tissue of gingiva rather than in the bone. The presence of particularly dense fibrous tissue in the overlying gingiva could be responsible.

Clinical Features. Shear (1992) had recorded a 0.8% frequency. It is likely that they occur more frequent clinically and as some rupture spontaneously, these cysts go unnoticed and are not submitted for histological examination.

These cysts are found in children of different ages, and occasionally in adults if there is delayed eruption. Deciduous and permanent teeth may be involved, most frequently anterior to the first permanent molar. Clinically, the lesion appears as a circumscribed, fluctuant, often translucent swelling of the alveolar ridge over the site of the erupting tooth. When the circumcoronal cystic cavity contains blood, the swelling appears purple or deep blue; hence the term '**eruption hematoma'**. It is usually painless unless infected.

Sometimes more than one cyst may be present. There is often a brief history of about three to four weeks duration during which they enlarge to approximately 1–1.5 cm.

Radiographic Features. It may show a soft tissue shadow since the cyst is confined within it and there is usually no bone involvement.

Histologic Features. The superficial aspect is covered by the keratinized stratified squamous epithelium of the overlying gingiva. This is separated from the cyst by a strip of dense connective tissue of varying thickness which usually shows a mild chronic inflammatory cell infiltrate. Inflammatory cell infiltration is common. The follicular connective tissue is more densely cellular, less collagenous and has a basophilic hue, presumably because of a higher content of acid mucopolysaccharide in the ground substance. Odontogenic epithelial cell nests may be present in the connective tissue.

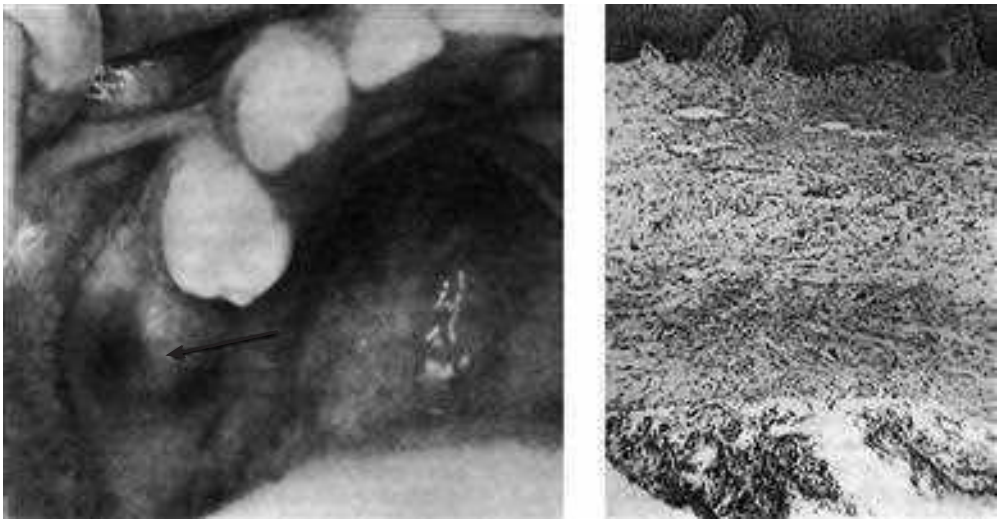
In noninflamed areas, the epithelial lining of the cysts is characteristically of reduced enamel epithelial origin, consisting of two or three cell layers of squamous epithelium with a few foci where it may be a little thicker. The adjacent corium is hyperemic and is the seat of a chronic inflammatory cell infiltrate (Fig. 4-5).

Treatment. No treatment is necessary as the cyst often ruptures spontaneously. Surgically exposing the crown of the tooth may aid the eruption process.

Odontogenic Keratocyst

A cyst derived from the remnants (rests) of the dental lamina, with a biologic behavior similar to a benign neoplasm, with a distinctive lining of six to 10 cells in thickness, and that exhibits a basal cell layer of palisaded cells and a surface of corrugated parakeratin.

This is the most interesting of jaw cysts. The term 'odontogenic keratocyst' was first used by Philipsen in 1956, while Pindborg and



A B

Figure 4-5. Eruption cyst.
The cyst is lined by a thin layer of stratified squamous epithelium in which there are scattered inflammatory cells. Eruption cyst often shows marked secondary inflammatory changes from masticatory trauma.

Hansen in 1963 described the essential features of this type of cyst. It is named keratocyst because the cyst epithelium produces so much keratin that it fills the cyst lumen. Furthermore, flattening of the basement membrane and palisading of the basal epithelial cells, reminiscent of odontogenic epithelium, are characteristics of odontogenic keratocyst.

They are unique odontogenic lesions that have the potential to behave aggressively, that can recur, and can be associated with the nevoid basal cell carcinoma syndrome. Toller (1967) suggested that OKCs might be regarded as benign cystic neoplasms. Whether they are developmental or neoplastic continues to be debated.

Studies indicate that a significant number of OKCs show clonal loss of heterozygosity of common tumor suppressor genes. The finding of clonal deletion mutations of genomic DNA in these cysts supports the hypothesis that they are neoplastic rather than developmental in origin. The odontogenic keratocyst is regarded as a distinctive entity because of its characteristic histology, proliferation kinetics, and behavior. Therefore, although keratinization may be present in many other types of cysts, the specific histologic pattern of the odontogenic keratocyst separates it from all others.

Differences in cytokeratin, epithelial membrane antigen (EMA) and carcinoembryonic antigen (CEA) immunoreactivity between the parakeratinized OKC and the orthokeratinized variety have been demonstrated and the suggestion made that the latter having a considerably less aggressive behavior is different entity and should bear a different name **orthokeratinized odontogenic cyst** (Shear M, 2002).

There is general agreement that the origin of the odontogenic keratocyst comes from dental lamina remnants in the mandible and maxilla. However, the origin of this cyst from the extension of basal cells of the overlying oral epithelium has also been suggested.

Reclassification of the Odontogenic Keratocyst to Tumor: Keratocystic Odontogenic Tumor (KOT)

In 1967, Toller suggested that the OKC may best be regarded as a benign neoplasm rather than a conventional cyst based on its clinical behavior. The WHO has reclassified the lesion as a tumor based on several factors, that formed the basis of this decision.

- ***Behavior:*** The KOT is locally destructive and recurrence rate is very high.
- ***Histopathology:*** The basal epithelial layer of KOT shows proliferation and budding into the underlying connective tissue in the form of daughter cysts and mitotic figures are frequently found in the suprabasal layers of the lesional epithelium.
- ***Genetics:*** PTCH (patched), a tumor suppressor gene involved in both syndrome associated and sporadic KOTs, occurs on chromosome 9q22.3 – q31. Normally, PTCH forms a receptor complex with the oncogene SMO (smoothened) for the SHH (sonic hedgehog) ligand. PTCH binding to SMO inhibits growth signal transduction. SHH binding to PTCH releases this inhibition. If normal functioning of PTCH is lost, the proliferation-stimulation effects of SMO are permitted to predominate.

Evidence has shown that the pathogenesis of syndrome associated and sporadic KOTs involves a 'two hit mechanism', with allelic loss at 9q22. The 'two hit mechanism' refers to the process by which a tumor suppressor gene is inactivated. The first hit is a mutation in one allele, which, although it can be dominantly inherited, has no phenotypic effect. The second hit refers to loss of the other allele and is known as 'loss of heterozygosity' (LOH). In KOTs, this leads to the dysregulation of the oncoproteins cyclin D1 and p53. LOH

in the 9q22.3–q31 region has been reported for many epithelial tumors, including basal cell carcinomas, squamous cell carcinomas, and transitional cell carcinomas; and LOH is by definition a feature of tumorigenic tissue.

Clinical Features. The largest and most detailed series of cases of odontogenic keratocyst has been published by Brannon, and his data are probably most representative of this lesion. The cyst may occur at any age, from the very young to the very elderly, although Brannon found it to be exceedingly rare under the age of 10 years, there being only two such patients in his series of 283 persons. The peak incidence is in the second and third decades of life, with a gradual decline thereafter. The data of Browne (104 patients) and of Forssell (119 patients) are virtually identical. In all series, there is a predilection for occurrence in males, ranging from 1.44:1 (Brannon), 1.46:1 (Browne) to 1.79:1 (Forssell).

The mandible is invariably affected more frequently than the maxilla: in the series of Brannon, 65% versus 35%, in the series of Browne, 79% versus 21%, and in that of Forssell, 78% versus 22%. In the mandible, the majority of the cysts occur in the ramus-third molar area, followed by the first and second molar area and then the anterior mandible. In the maxilla, the most common site is the third molar area followed by the cuspid region.

Multiple odontogenic keratocysts occur with some frequency. Lesions found in children are often reflective of multiple odontogenic keratocysts as a component of the nevoid basal cell carcinoma syndrome. However, at other times, these multiple cysts are independent of the syndrome. A rather remarkable parallelism between the odontogenic keratocyst and the ameloblastoma with respect to mean age of occurrence, predilection for site of occurrence, radiographic findings and recurrence rate has also been pointed out by Browne.

There are no characteristic clinical manifestations of the keratocyst, although about 50% of the patients in Brannon's series were symptomatic prior to seeking treatment. Among the more common features are pain, soft-tissue swelling and expansion of bone, drainage and various neurologic manifestations such as paresthesia of the lip or teeth. The maxillary OKC tends to be secondarily infected with greater frequency than the mandibular ones, due to its vicinity to the maxillary sinus.

Radiographic Features. Radiographically most OKCs are unilocular, presenting a well-defined peripheral rim. Scalloping of the border is also a frequent finding and this represents variations in the growth pattern of the cyst. Multilocular radiolucent OKC is also observed, generally representing a central cavity having satellite cysts. When it is multilocular and especially if located in the third mandibular molar area, it may be confused radiographically with an ameloblastoma. Occasionally OKC may mimic a dentigerous cyst and contain the crown of a retained tooth within its lumen. The final diagnosis of any cystic cavity within the jaw bones will be achieved only after biopsy of the surgical specimen. Multilocularity (20%) is often present and tends to be seen more frequently in larger lesions. Most lesions, however, are unilocular, with as many as 40% noted adjacent to the crown of an unerupted tooth (dentigerous cyst position). Approximately 30% of maxillary and 50% of mandibular lesions produce buccal expansion. Mandibular lingual enlargement is occasionally seen. Proximity to the roots of adjacent normal teeth sometimes causes resorption of these roots, although displacement is more common. Sometimes these cysts displace the neurovascular bundle.

Histologic Features. The odontogenic keratocyst wall is usually rather thin unless there has been superimposed inflammation. The lining epithelium is highly characteristic, and is composed of:

- A parakeratinized surface which is typically corrugated, rippled or wrinkled.
- A remarkable uniformity of thickness of the epithelium, usually ranging from 6 to 10 cells thick.
- A prominent palisaded, polarized basal layer of cells often described as having a 'picket fence' or 'tombstone' appearance.

Histologically, these cysts are formed with a stratified squamous epithelium that produces orthokeratin (10%), parakeratin (83%), or both types of keratin (7%). No rete ridges are present; therefore, the epithelium often sloughs from the connective tissue (94% of the time). The epithelium is thin, and mitotic activity is frequent; therefore, OKC grows in a neoplastic fashion and not in response to internal pressure. In the presence of an intense inflammatory process, the adjacent epithelium loses its keratinized surface, may thicken and develop rete processes or may ulcerate.

The connective tissue wall often shows small islands of epithelium similar to the lining epithelium; some of these islands may be small cysts. In at least some cases, the apparent islands of epithelium and small satellite or 'daughter' cysts actually represent the ends of folds of the lining epithelium of the main cystic cavity which have been cut in cross-section; the linings of these cysts are very commonly folded. Forssell and his associates have studied this problem using serial sections of cysts and found microcysts in the wall in 20% and epithelial islands in 50% of their cases. In 35% of the cases, apparent microcysts were found to be part of the main cyst by the serial sections while pseudo islands of epithelium were found in 75% of the cases.

The lumen of the keratocyst may be filled with a thin straw colored fluid or with a thicker creamy material. Sometimes the lumen contains a great deal of keratin, while at other times it has little. Cholesterol, as well as hyaline bodies at the sites of inflammation, may also be present. The electrophoretic measurement of fluid from these cysts has been reported by Toller to show that it contains a very low content of soluble protein compared with the patient's own serum (Fig. 4-6).

Dysplastic and neoplastic transformation of the lining epithelium in the odontogenic keratocyst is an uncommon occurrence but has been reported. Of the 312 keratocysts studied by Brannon, only two exhibited cellular atypia. Occasional other cases have also been described in the literature. Areen and his associates have recently reported a case of epidermoid carcinoma developing in an odontogenic keratocyst, and in reviewing the literature, have emphasized the necessity for careful microscopic examination of all such cysts.

Figure 4-7. Odontogenic keratocyst.
(A) The epithelial lining is uniformly thin, generally ranging from 8–10 cell layers thick. The basal layer exhibits a characteristic palisaded pattern with polarized and intensely stained nuclei of uniform diameter. The luminal epithelial cells are parakeratinized and produce an uneven or corrugated profile. **(B)** Odontogenic keratocyst stained using proliferating cell nuclear antigen (PCNA) antibodies (x 10).

The variant of OKC that produces only orthokeratin acts somewhat differently than other OKCs. These almost always are found in a dentigerous association, usually around the mandibular third molar, and they are much less aggressive. They do not have a hyperchromatic basal layer; in fact, the basal layer is flattened. They are not associated with basal cell nevus syndrome (orthokeratinized odontogenic cyst).

Finally, the highly characteristic nature of the parakeratinized lining epithelium and its relationship to the high recurrence rate have been emphasized by a report dealing with orthokeratinized odontogenic cysts and their recurrence rate. Wright investigated 59 cases of orthokeratinized odontogenic cysts and found that they showed a predilection for occurrence in males, most commonly in the second to fifth decades. These cysts were located predominantly in the posterior mandible, where they most typically appeared as dentigerous cysts. The thin, uniform lining epithelium was covered with orthokeratin and showed a prominent granular layer and a cuboidal to flattened basal layer. Follow-up of 24 of these patients revealed only one case of recurrence. This difference in biologic behavior would further underscore the necessity for very strict application of the definition of the term odontogenic keratocyst in diagnosis of the lesion (Fig. 4-7).

Treatment and Prognosis. The odontogenic keratocyst should be surgically excised. However, clinical experience has shown that complete eradication of the cyst may be difficult because the wall of the cyst is very thin and friable and may easily fragment. In addition, perforation of cortical bone, particularly in lesions involving the ramus, is common and this complicates total removal.

The most important feature of the odontogenic keratocyst is its extraordinary recurrence rate. This has been reported as being between 13 and 60%. A review of 763 cases of odontogenic keratocysts in 13 different reported series of cases has shown the average recurrence rate to be 26%, with the majority occurring within five years of the surgical procedure. Forssell, Forssell and Kahnberg (1988) observed that recurrences were more frequent (63%) with cysts in patients with the nevoid basal cell carcinoma syndrome than with cysts in patients without the syndrome (37%). Keratocysts enucleated in one piece recurred significantly less often than cysts enucleated in several pieces, and the recurrence rate in cases with a clinically observable infection, a fistula or with a perforated bony wall was higher. The size of the cyst did not seem to influence its prognosis after surgery, but those whose radiographic appearance was multilocular had a higher recurrence rate than those with a unilocular appearance.

Browne found no significant differences in recurrence rate following three basic methods of treating the lesions:

- Marsupialization

- Enucleation and primary closure
- Enucleation and packing open.

Furthermore, recurrence does not appear related to the presence of satellite cysts. On this basis, Browne concluded that recurrence of the keratocyst is due to the nature of the lesion itself, i.e. the presence of additional remnants of dental lamina from which a cyst may develop, and is not related to its method of treatment. Since recurrence may be long delayed in this lesion, follow-up of any case of odontogenic keratocyst with annual radiographs is essential for at least five years after surgery. It is also essential that patients with an odontogenic keratocyst, especially if multiple, be evaluated medically to rule out the possibility of the jaw cyst-basal cell nevus-bifid rib syndrome (q.v.).

Jaw Cyst-Basal Cell Nevus, Bifid Rib Syndrome

(Basal cell nevus syndrome, hereditary cutaneomandibular polyoncosis, Gorlin and Goltz syndrome)

This syndrome, first described by Binkley and Johnson in 1951, has been thoroughly reviewed by Gorlin and his coworkers. A hereditary condition, it is transmitted as an autosomal dominant trait, with high penetrance and variable expressivity. It is caused by mutations in patched **(PTCH)**, a tumor suppressor gene that has been mapped to chromosome **9q22.3–q31**.

Clinical Features. The syndrome is very complex and includes a great variety of possible abnormalities. These may be briefly summarized as follows:

- **Cutaneous anomalies,** including basal cell carcinoma, other benign dermal cysts and tumors, palmar pitting, palmar and plantar keratosis and dermal calcinosis.
- **Dental and osseous anomalies,** including odontogenic keratocysts (often multiple), mild mandibular prognathism, rib anomalies (often bifid), vertebral anomalies and brachymetacarpalism (Fig. 4-8).
- **Ophthalmologic abnormalities,** including hypertelorism with wide nasal bridge, dystopia canthorum, congenital blindness and internal strabismus.
- **Neurologic anomalies,** including mental retardation, dural calcification, agenesis of corpus callosum, congenital hydrocephalus and occurrence of medulloblastomas with greater than normal frequency.
- **Sexual abnormalities,** including hypogonadism in males and ovarian tumors.

Some of these patients have shown a lack of response to parathormone as judged by the lack of phosphate diuresis which, coupled with shortened fourth metacarpals in some patients, has suggested that there may be some relationship to pseudohypoparathyroidism.

Oral Manifestations. The odontogenic keratocysts are indistinguishable from those previously described by that term which are not associated with this syndrome (Fig. 4-8). Because they often develop early in life, deformity and displacement of developing teeth may occur. However, they may not develop until middle age even though the basal cell skin tumors have occurred early in life.

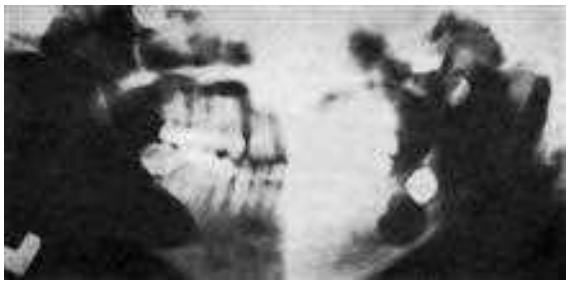

Figure 4-8. Odontogenic keratocysts in the basal cell nevus syndrome.

Treatment and Prognosis. Several cases of ameloblastoma have developed in cysts of this syndrome, thus emphasizing the importance of surgical removal of the cysts and their histologic examination. Whenever a diagnosis of odontogenic keratocyst is received by the dentist, he must be certain to rule out the presence of this syndrome because of the many associated problems which these patients ultimately will face.

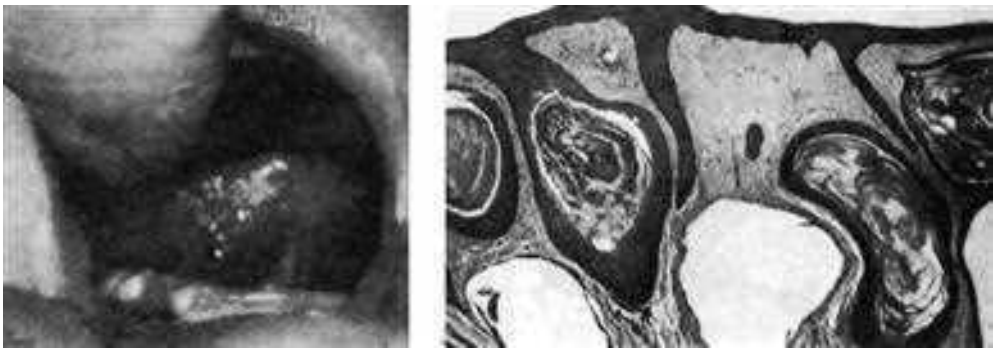
Dental Lamina Cyst of Newborn

(Gingival cyst of newborn, Epstein's pearls, Bohn's nodules)

Dental lamina cyst of the newborn are multiple, occasionally solitary, superficial raised nodules on edentulous alveolar ridges of infants that resolve without treatment; derived from rests of the dental lamina and consisting of keratin-producing epithelial lining. **Bohn's nodules** and **Epstein's pearls** are two similar lesions with which gingival cysts sometimes may be confused; however, the location and etiology of these lesions are somewhat different. As originally described, Epstein's pearls are cystic, keratin-filled nodules found along the midpalatine raphe, probably derived from entrapped epithelial remnants along the line of fusion (q.v.). Bohn's nodules are keratin-filled cysts scattered over the palate, most numerous along the junction of the hard and soft palate and apparently derived from palatal salivary gland structures (q.v.). Discussions of these various types of cysts in the newborn have been published by Fromm and by Cataldo and Berkman.

In studying sections of the maxillae and mandibles of 17 infants, Kreshover reported finding 65 examples of gingival cysts (38 multiple and 27 single). These cysts were localized in the corium below the surface epithelium. Those in the anterior portion of the jaws were usually displaced lingually with respect to the deciduous incisors and cuspids. Those in the posterior portion of the jaw were found occlusal to the crown of the molars. Kreshover stated that in all instances the cystic lesions were seen to arise from cells of the dental lamina. The etiology of these cysts has been thoroughly discussed by Maher and Swindle.

Clinical Features. Occasionally these dental lamina cysts in infants become sufficiently large to be clinically obvious as small discrete white swellings of the alveolar ridge, sometimes appearing blanched as though from internal pressure (Fig. 4-9A). These probably correspond to those structures described in the older literature as the 'predeciduous dentition'. These lesions appear to be asymptomatic and do not seem to produce discomfort in the infants.



A B

Figure 4-9. Gingival cyst of the newborn.
(Courtesy of Dr Ralph E McDonald and Dr Alfred Fromm).

Histologic Features. These are true cysts with a thin epithelial lining which lacks rete processes and show a lumen usually filled with desquamated keratin, occasionally containing inflammatory cells (Fig. 4-9B). Interestingly, dystrophic calcification and hyaline bodies of Rushton (q.v.), commonly found in dentigerous cysts, are also sometimes found in this lesion.

Treatment. No treatment is required inasmuch as these lesions almost invariably will disappear by opening onto the surface of the mucosa or through disruption by erupting teeth.

Gingival Cyst of Adult

A small developmental odontogenic cyst of the gingival soft tissue derived from the rests of the dental lamina, containing a lining of embryonic epithelium of cuboidal cells and distinctive focal thickenings similar to the lateral periodontal cyst.

The gingival cyst of the adult is an uncommon cyst of gingival soft tissue, occurring in either the free or attached gingiva.

The etiology and pathogenesis of this lesion have been reviewed by Ritchey and Orban, who suggested possible sources of cystic formation as:

- Heterotopic glandular tissue.
- Degenerative changes in a proliferating epithelial peg.
- Remnants of the dental lamina, enamel organ or epithelial islands of the periodontal membrane.
- Traumatic implantation of epithelium.

Of these possibilities, only the last two appear valid, and on this basis there do appear to be two recognizable forms of gingival cyst:

- That arising from cystic transformation of dental lamina or the 'glands' or rests of Serres.
- That arising from traumatic implantation of surface epithelium (and, therefore, not truly an odontogenic cyst).

The origin of the gingival cyst of the adult has been evaluated by Wysocki and his colleagues, who concluded that it does arise from postfunctional rests of dental lamina and thus represents the extraosseous counterpart of the lateral periodontal cyst, with which it shares a common histogenesis. Buchner and Hansen have reported essentially the same conclusions. The similarities between the lateral periodontal cyst and the gingival cyst of the adult in clinical behavior, morphologic appearance, anatomic site of occurrence and age predilection are too striking to be coincidental.

The vast majority of these gingival cysts appear to originate in the fashion described from dental lamina, including a soft tissue counterpart of the multilocular botryoid odontogenic cyst. However, an implantation type of cyst can occur lined by a more mature keratinizing stratified squamous epithelium lining derived from surface mucosal epithelium. Finally, as suggested by Buchner and Hansen, there is some evidence that a dental lamina cyst of the newborn may persist into adulthood, as judged by the finding of cysts packed with orthokeratin that appear identical to those in the newborn.

Clinical Features. The gingival cyst may occur at any age but is most common in adults. In the review of the literature by Reeve and Levy, the majority of patients were over 40 years of age. The mean age in the 33 cases reported by Buchner and Hansen was 48 years and that of the 10 cases reported by Wysocki and his associates was 51 years. The location of the lesion closely follows that of the lateral periodontal cyst. Thus, all except one cyst in the series of Wysocki and his coworkers were in the mandibular bicuspid-cuspid incisor area, the one exception being in the maxillary lateral incisor area. The locations in the series of Buchner and Hansen were virtually identical except that they had several cases also in the maxillary arch from cuspid to first molar.

This lesion presents generally as a small, well-circumscribed, painless swelling of the gingiva, sometimes closely resembling a superficial mucocele (Fig. 4-10). The lesion is of the same color as the adjacent normal mucosa and seldom measures over 1 cm in diameter, generally much less. Although this cyst may occur in either the free or attached gingiva, some gingival cysts occur in the gingival papilla itself.

Radiographic Features. The gingival cyst is a soft tissue lesion and does not generally manifest itself on the dental radiograph. If it enlarges to sufficient size, it may cause superficial erosion of the cortical plate of bone, but this is still generally not visible on the radiograph. If a circumscribed,

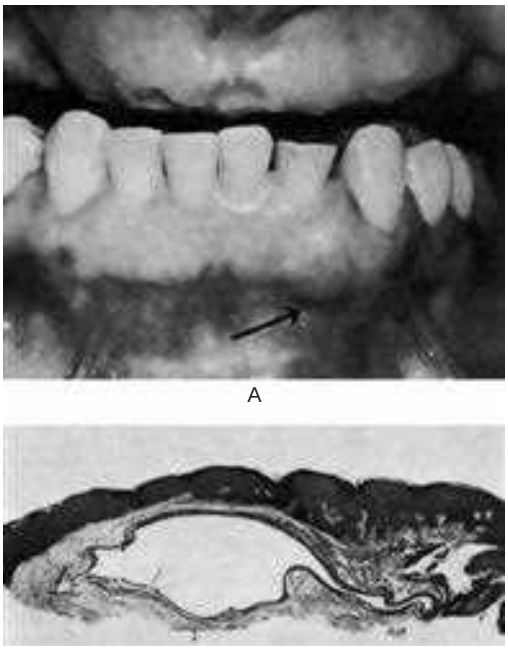


Figure 4-10. Gingival cyst of the adult.

radiolucent cystic lesion of alveolar bone with some swelling of the soft tissue is present, the cyst probably represents a lateral periodontal cyst rather than a gingival cyst.

Histologic Features. The gingival cyst of the adult is a true cyst, since it is a pathologic epithelium lined cavity which usually contains fluid (Fig. 4-10 B). The lining epithelium is generally identical to that found in the lateral periodontal cyst, with the occasional exceptions noted above. The epithelium ranges in thickness from simply one flattened cell to several cells, a thin stratified squamous epithelium. Glycogen-rich clear cells may be present, especially in the focal thickenings or plaques of the lining. Dental lamina rests may also be found in the connective tissue wall and these are commonly composed of the same type of glycogen-rich clear cells. As noted earlier, these lesions may be unicystic or polycystic. Since the cyst lies free in the connective tissue of the gingiva, it may or may not exhibit an associated inflammatory reaction.

In cases of the traumatic or implantation type of gingival cyst, calcification or even ectopic ossification on rare occasions may be associated with the cystic lesion, reminiscent of the ossification occurring after experimental implantation of bladder epithelium into subcutaneous tissues.

Treatment. Local surgical excision of the lesion in adults is usually recommended, and the lesions do not tend to recur. A neoplastic potential has never been reported.

Lateral Periodontal Cyst

A slow growing, nonexpansile developmental odontogenic cyst derived from one or more rests of the dental lamina, containing an embryonic lining of one to three cuboidal cells and distinctive focal thickenings (plaques).

The lateral periodontal cyst, as the name implies, occurs on a lateral periodontal location and it is of developmental origin arising from cystic degeneration of clear cells of the dental lamina. In order to establish the proper diagnosis, an inflammatory origin as well as exclusion of a possible odontogenic keratocyst must be ruled out clinically and histologically.

The lateral periodontal cyst is an uncommon but well-recognized type of developmental odontogenic cyst. The various theories concerning the etiology and pathogenesis of the lesion have been reviewed by Standish and Shafer. These cysts appear to arise in intimate association with the lateral root surface of an erupted tooth, with a predilection for the mandibular bicuspid area. The possibilities which have been offered to explain their origin and mode of development include:

- Origin initially as a dentigerous cyst developing along the lateral surface of the crown, and as the tooth erupts, the cyst assumes a position in approximation to the lateral surface of the root.
- Origin from proliferation of rests of Malassez in the periodontal ligament although the stimulus for this proliferation is unknown.
- Origin simply as a primordial cyst of a supernumerary tooth germ, since the predilection for occurrence of the lateral periodontal cyst in the mandibular bicuspid area corresponds well with the known high incidence of supernumerary teeth in this same region.
- Origin from proliferation and cystic transformation of rests of dental lamina, which are in a postfunctional state and therefore have only a limited growth potential that is in accordance with the usual small size of these cysts.

This latter theory, including the suggestion that the lateral periodontal cyst and the gingival cyst of the adult (q.v.) share this common histogenesis from postfunctional dental lamina rests and that these two cysts represent basically the central or intraosseous and peripheral or extraosseous manifestations of the same lesion, has been discussed in detail by Wysocki and his colleagues. At present, it seems the most appropriate one. They have also pointed out the important fact that in many reports of the lateral periodontal cyst in the previous literature, the term has been used to designate any cyst that may be positioned against the lateral root surface of a tooth (e.g. lateral radicular cyst related to pulp infection, odontogenic keratocyst, etc.). This positional use of the term should be avoided and the designation applied only to that specific developmental lesion with characteristic features.

An unusual form of cyst was reported in 1973 by Weathers and Waldron under the term **botryoid odontogenic cyst.** They described two cases of cysts which had a multilocular pattern apparent radiographically, histologically and even clinically at the time of surgical removal. Additional experience with this cyst, as indicated by Wysocki and his associates, now strongly suggests that this is simply a polycystic variant of the lateral periodontal cyst developing through cystic transformation of multiple islands of dental lamina rests. The epithelial lining in the two cysts is identical, as are its clinical features, including age of predilection and sites of occurrence.

In addition, a multilocular extraosseous form analogous to the gingival cyst of the adult also occurs.

Clinical Features. The lateral periodontal cyst occurs chiefly in adults, according to the series of 39 cases reported by Wysocki and his associates in which there was a mean age of 50 years and an age range of 22–85 years. In this series, there was a predilection for occurrence in males over females, 67: 28 with 5% unknown. The location of the lesion was extremely limited in this study: 67% of cases were in the mandibular bicuspid/cuspid/incisor area, while 33% were in the maxillary lateral incisor area. Lesions were found at no other sites and this has also been the experience of most other investigators. No rational explanation has been offered for this localization.

The majority of cases have presented no clinical signs or symptoms and have been discovered during routine radiographic examination of the teeth. Occasionally, when the cyst is located on the labial surface of the root, there may be a slight mass obvious, although the overlying mucosa is normal. Unless otherwise affected, the associated tooth is vital. If the cyst becomes infected, it may resemble a lateral periodontal abscess and even seek to establish drainage.

Radiographic Features. The periapical radiograph discloses the lateral periodontal cyst as a radiolucent area in apposition to the lateral surface of a tooth root (Fig. 4-11A–D). The lesion is usually small, seldom over 1 cm in diameter, and may or may not be well circumscribed. In most cases the border is definitive and is even surrounded sometimes by a thin layer of sclerotic bone. The botryoid odontogenic cyst appears similar except that its polycystic nature is often evident through its multilocular pattern on the radiograph (Fig. 4-12).

Histologic Features. Histologically, the lateral periodontal cyst is a distinct type of developmental cyst characterized by a thin, nonkeratinized epithelium usually one to five cell layers thick, which resembles the reduced enamel epithelium. Cuboidal or even columnar cells may be found composing the lining. Many of the lining cells have a clear, vacuolated, glycogen-rich cytoplasm (Fig. 4-13). This lining is incomplete and easily sloughs away. Focal thickened plaques of proliferating lining cells often project into the lumen in areas. These are especially prominent in the botryoid odontogenic cyst (Fig. 4-13). Rests of dental lamina are sometimes found in the connective tissue wall and these similarly are frequently composed of glycogen-rich clear cells. These also appear to be more common in the botryoid-type cyst. Papillary infoldings of the lateral periodontal cyst wall are sometimes seen and inflammatory cells may be present, but this is a secondary reaction. The histologic characteristics of these cysts have been detailed by Wysocki and his colleagues as well as by Shear and Pindborg. The connective tissue subjacent to the epithelium exhibits a zone of hyalinization, consisting of a thick fibrous noninflamed cyst wall. A different histologic appearance has been described for this cyst with the name of **botryoid**

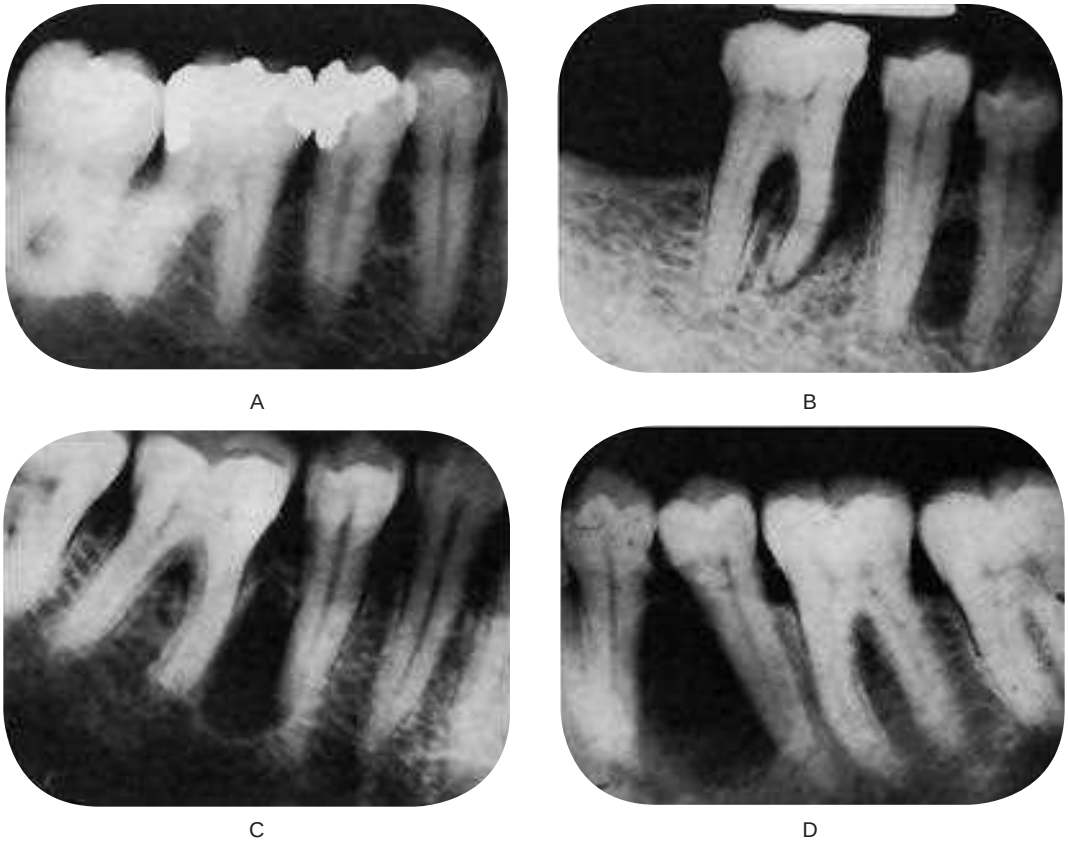

Figure 4-11. Lateral periodontal cysts.
A cyst lies in the periodontal tissues proximal to the roots of premolar and molar teeth. The pulp of the associated teeth appear normal.

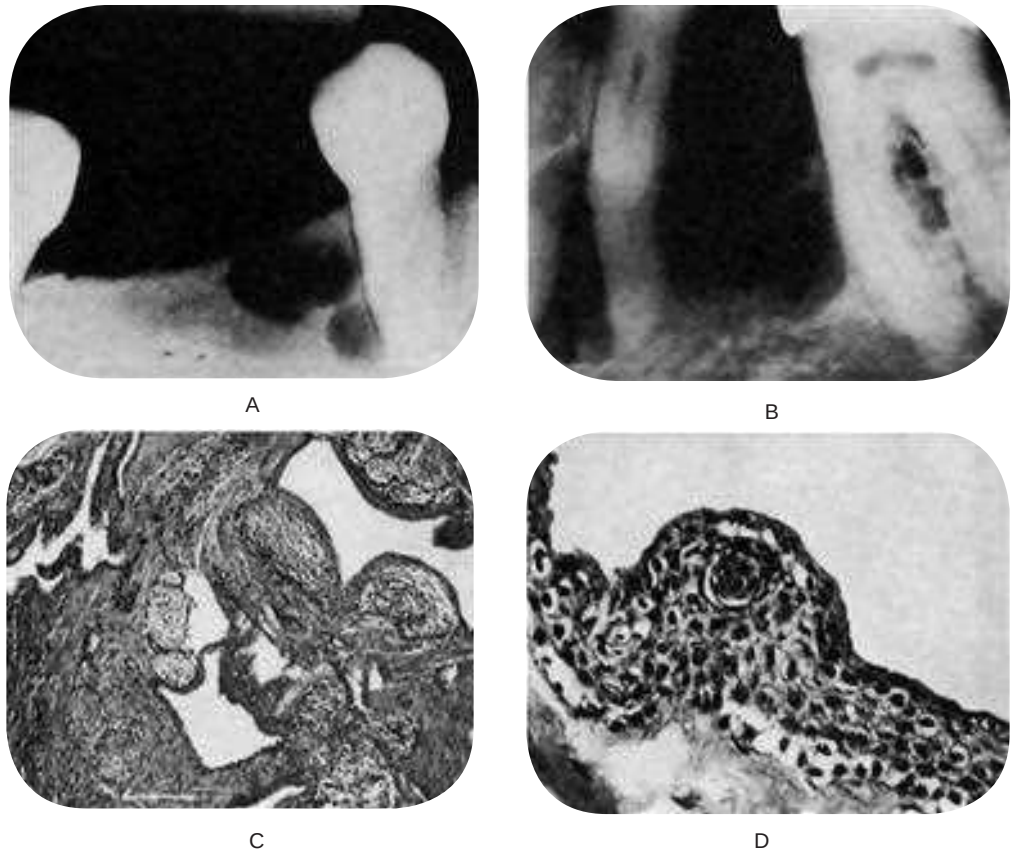

Figure 4-12. Botryoid odontogenic cysts.
The multilocular appearance **(A, B)** is indicative of their polycystic nature. The lining epithelium **(C, D)** of the numerous small cysts is thin and shows focal areas of thickening.

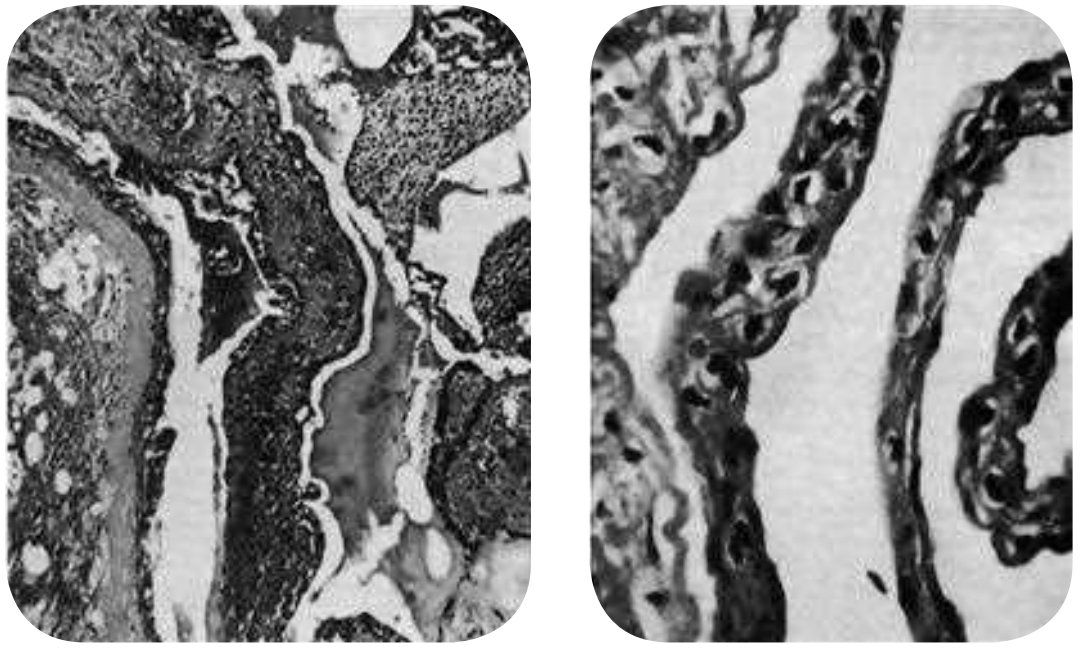

Figure 4-13. Lateral periodontal cysts.

odontogenic cyst. This name reflects the gross similarity of the cystic cavities to that of a cluster of grapes.

Treatment and Prognosis. Provided that the lesion is unilocular on radiographic examination the lateral periodontal cyst is treated by surgical enucleation. Attempts should be made to avoid sacrificing the associated tooth, but this may not always be possible. The botryoid variety, a lesion that is radiographically or histologically multilocular, has an increased risk of recurrence or persistence and patients treated for a botryoid odontogenic cyst should be followed periodically. It is especially important that the diagnosis be established because of the similarity in appearance between this cyst and other more serious lesions such as an early ameloblastoma.

Calcifying Odontogenic Cyst

(Keratinizing and/or calcifying epithelial odontogenic cyst, Gorlin cyst, cystic keratinizing tumor)

A rare, well-circumscribed, solid or cystic lesion derived from odontogenic epithelium that resembles follicular ameloblastoma but contains 'ghost cells' and spherical calcifications.

The so-called calcifying odontogenic cyst (COC) represents a heterogeneous group of lesions that exhibit a variety of clinicopathologic and behavioral features. Because of this diversity, there has been confusion and disagreement on the terminology and classification of these lesions. The term calcifying odontogenic cyst includes both non-neoplastic cyst and true neoplasms. **The 1992 WHO classification includes this cyst and all its variants in the category of odontogenic tumors.**

It has become obvious that it is not one lesion but really two—a cystic lesion and a solid neoplastic lesion. A third malignant counterpart of the neoplastic lesion may be added. The calcifying odontogenic cyst may present as an intraosseous cystic lesion or in association with an odontoma. On rare occasions, it may present as a peripheral (gingival) lesion. The neoplasm, more aptly termed a **dentinogenic ghost cell tumor**, is a rare lesion that may occur in bone or in the gingival soft tissue (for detailed description refer section on odontogenic tumors).

Glandular Odontogenic Cyst

(Sialo-odontogenic cyst, mucoepidermoid odontogenic cyst)

An unusually large solitary or multilocular odontogenic cyst probably derived from the rests of dental lamina, consisting of a stratified squamous epithelium containing numerous mucus-secreting cells.

The glandular odontogenic cyst (GOC), also known as **sialo-odontogenic cyst** has many similarities to the lateral periodontal cyst of which it is considered a variant by some authors. Glandular odontogenic cyst occurs in the same location as the lateral periodontal cyst but as a rule it has a multilocular radiolucent appearance. The name of the cyst is not yet established. The term most descriptive of the lesion is probably **mucoepidermoid odontogenic cyst** because of the presence of both secretory elements and stratified squamous epithelium (Sadeghi et al, 1991). The use of this name might, however, lead to confusion with the mucoepidermoid carcinoma, and is therefore unlikely to find favor (Shear, 1992).

Padayachee and van Wyk, 1987, indicated that the typical features of the cyst are that it is intrabony and multilocular radiographically; that it can recur if not adequately excised; that it is multicystic, with the cystic spaces lined by a nonkeratinized epithelium similar to reduced enamel epithelium, with epithelial thickenings or plaques; that mucous and cylindrical cells form an integral part of the epithelial component; and that mucinous material within the cystic spaces is a prominent feature. Gardner et al, (1988) who favored the name 'glandular odontogenic cyst' suggested that its histological features and biological behavior are sufficient for it to be regarded as an entity.

Clinical Features. The glandular odontogenic cyst occurs over a wide age range. A slight male predilection was reported. The common site affected was anterior mandible. The lesions showed slow progressive growth, were painless and locally destructive. The mandible seems to be affected more commonly (87.2%) than the maxilla. The age ranges from 10–90 years with the mean of 49.5 years.

Radiographic Features. The lesions appear well defined with a multilocular pattern but without specific diagnostic features.

Histologic Features. Histologically, glandular odontogenic cyst is lined in parts by a nonkeratinized stratified epithelium of varying thickness (Fig. 4-14). The epithelium has a glandular or pseudoglandular structure, with goblet mucous producing cells as well as intraepithelial crypts or microcysts containing mucus. These microcysts may open onto the surface of the epithelium giving a papillary or corrugated appearance. Some cells may also be ciliated. Occasionally the epithelium is thinner, similar to reduced enamel epithelium. Epithelial thickenings or plaques may be present either in this thin epithelium or in the stratified epithelium. Interface between epithelium and connective tissue is flat. The diagnosis of

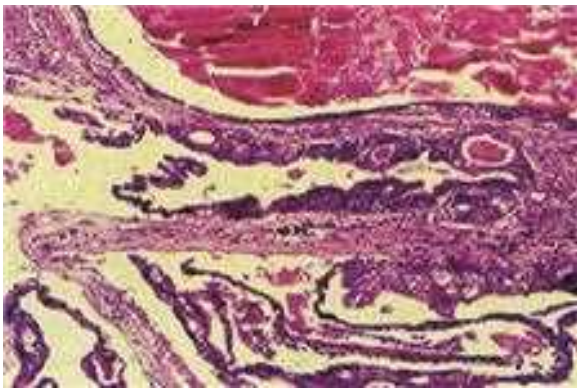

Figure 4-14. Sialo-odontogenic cyst.
Nonkeratinized stratified epithelium of varying thickness; cuboidal or columnar ciliated surface lining with goblet cells; polycystic with secretory and epithelial elements; microcysts may form duct like structures and are filled with a PAS-positive material surrounded by fibrous capsule.

glandular odontogenic cyst should be considered when observing a lateral periodontal multilocular radiolucency. The diagnosis is essentially microscopic.

Treatment. The treatment should be conservative but with a careful dissection of the margins in order to avoid recurrences. Patient should be followed-up periodically in order to assess early recurrences.

INFLAMMATORY CYSTS

Periapical Cyst

(Radicular cyst, apical periodontal cyst, root end cyst)

The periapical (radicular) cyst is the most common odontogenic cyst. The usual etiology is an infected tooth, leading to necrosis of the pulp. Toxins exit at the apex of the tooth, leading to periapical inflammation. This inflammation stimulates the epithelial rests of Malassez, which are found in the apical periodontal ligament, resulting in the formation of a periapical granuloma that may be infected or sterile. Eventually, this epithelium undergoes necrosis caused by a lack of blood supply, and the granuloma becomes a cyst (periapical cyst). The lesions are not usually clinically detectable when small but most often are discovered as an incidental findings on radiographic survey.

Pathogenesis. This cyst is classified as inflammatory, because in the majority of cases it is a consequence to pulpal necrosis following caries, with an associated periapical inflammatory response. Other causes include any event that may result in pulpal necrosis such as tooth fracture and improper restorations, among others. The first line of defense to pulpal necrosis in the periapical area is the formation of a granuloma. A granuloma is a highly vascularized tissue containing a profuse infiltrate of immunologically competent cells, i.e. lymphocytes, macrophages and plasma cells.

The epithelial rests of Malassez, which are pluripotential in nature can differentiate into any type of epithelium, under the proper stimuli. These rests play a central role in the formation of radicular cysts. In the midst of the rich vascular area provided by the periapical granuloma, the rests of Malassez proliferate and eventually form a large mass of cells. With continuous growth, the inner cells of the mass are deprived of nourishment and they undergo liquefaction necrosis. This leads to the formation of a cavity which is located in the center of the granuloma, giving rise to a radicular cyst.

Islands of squamous epithelium which have developed from odontogenic rests of Malassez can also be found in a periapical granuloma without cystic transformation. Endodontists refer to these granulomas as **'bay cyst'**.

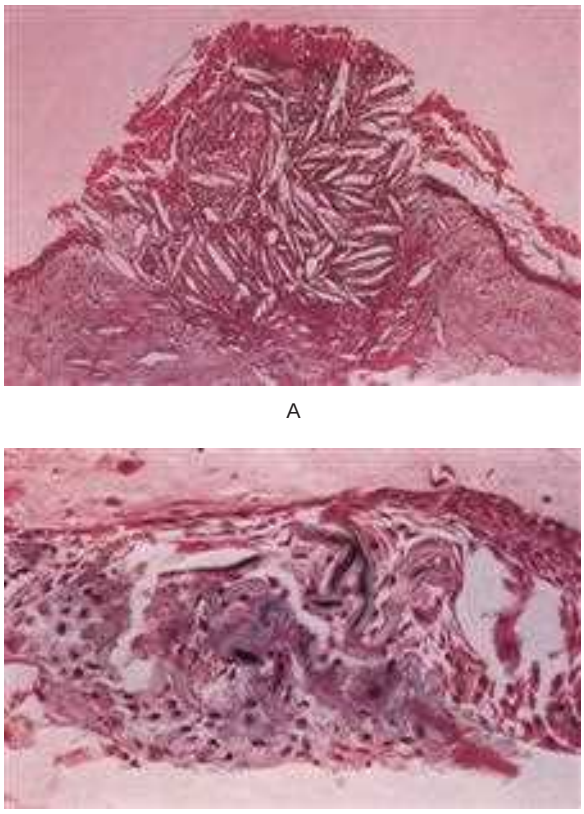
Clinical Features. Around 60% of all jaw cysts are radicular or residual cysts. Radicular cysts can occur in the periapical area of any teeth, at any age but are seldom seen associated with the primary dentition. The majority of cases of apical periodontal cysts are asymptomatic. The tooth is seldom painful or even sensitive to percussion. This type of cyst is only infrequently of such a size that it destroys much bone, and even more rarely does it produce expansion of the cortical plates. The apical periodontal cyst is a lesion that represents a chronic inflammatory process and develops only over a prolonged period of time. In some cases, such a cyst of long standing may undergo an acute exacerbation of the inflammatory process and develop rapidly into an abscess (periapical abscess) that may then proceed to a cellulitis or form a draining fistula. The cause of such a sudden flare up is not known, but it may be a result of loss of local or generalized tissue resistance.

Radiographic Features. The radiographic image of the radicular cyst is a peri- or para-apical, round or oval radiolucency of variable size which is generally well delineated and most likely with a marked radiopaque rim. Other lesions, such as granulomas, neoplasms of various origin and some diseases of bone can also present a similar radiolucent periapical appearance. Therefore, a periapical radiolucency cannot be automatically assumed to be a cyst. Several studies have indicated that it is not possible to rely on the radiographic size of a periapical radiolucency to establish the diagnosis of either cyst or granuloma unless the lesion is larger than 2 cm in diameter. Rarely radicular cysts will induce resorption of the root of the affected tooth.

Histologic Features. Microscopically a radicular cyst is limited by a mature collagenous connective tissue wall. Abundant fibroblasts can be identified within the cystic wall. The wall generally presents an inflammatory infiltrate of variable degree. Lymphocytes are generally the most prominent cells in the infiltrate and are characterized by their darkly stained nucleus, which occupies most of the cytoplasm. Plasma cells are also abundant in cysts' walls and mostly seen in long standing (chronic) cysts. They are characterized by an eccentric nucleus with a cartwheel arrangement of the nuclear chromatin. Plasma cells are considered repertoire of immunoglobulins. Other histological findings within the cystic wall are: erythrocytes and areas of hemorrhage, occasional spicules of dystrophic bone, multinucleated giant cells and cholesterol crystals (Fig. 4-15A).

The cavity of a radicular cyst is generally lined by stratified squamous epithelium. These cysts can be lined by respiratory epithelium, especially if they are in the vicinity of the maxillary sinus. The epithelial lining, many times, is discontinuous, frequently missing over areas of intense inflammation. Rarely radicular cysts may be lined by mucus producing epithelium in either maxillary or mandibular locations. The mucous epithelium is the result of metaplastic transformation of the epithelial rests of Malassez which are pluripotential. In rare instances, carcinoma has been reported developing from the lining epithelium of odontogenic cysts, including the radicular cyst. These have been reviewed by Gardner (1969).

An interesting and peculiar structure, originally described by Rushton and subsequently reported by Molyneux, Medak and Weinmann and Shear, is the hyaline body or Rushton body, often found in great numbers in the epithelium of apical, periodontal or residual cysts (Fig. 4-15 B). These hyaline bodies are tiny linear or arc-shaped bodies, generally associated with the lining epithelium, that appear amorphous



A

B

Figure 4-15. Radicular cyst.
(A) The cyst cavity is filled with an eosinophilic coagulum containing slit-like spaces which contain cholesterol. These cholesterols may form mucosal nodules; the epithelial lining becomes discontinued where such nodules have formed. **(B)** Hyaline bodies. Another feature that may be seen within the epithelial linings of radicular cyst is the peculiarly shaped structures which are eosinophilic, and typically, are described as lady's hairpin shaped *(Courtesy of Dr K W Lee)*.

in structure, eosinophilic in reaction and brittle in nature, since they evidence fracture in some cases. Their frequency of occurrence in cyst linings ranges between 2.6 and 9.5% of cysts, according to a review by Allison. The etiology, pathogenesis, and significance of these structures are unknown. The lumen of the cyst usually contains a fluid with a low concentration of protein that stains palely eosinophilic. Occasionally the lumen may contain a great deal of cholesterol, and in rare instances, limited amounts of keratin are present.

Treatment. The treatment of the radicular cyst consists of extraction of the involved teeth and careful curettage of the periapical tissue. Under some conditions, root canal therapy may be carried out with apicoectomy of the cystic lesion. The cyst does not recur if surgical removal is thorough. If the cystic sac is badly fragmented, leaving epithelial remnants, or if a periapical granuloma is incompletely removed with epithelial rests remaining, a residual cyst may develop in this area months or even years later. If untreated, the radicular cyst slowly increases in size at the expense of the surrounding bone. The bone undergoes resorption, but seldom is there a remarkable expansion of the cortical plates, as is frequently seen in the case of the dentigerous cyst.

Residual Cyst

Residual cyst is a term of convenience because no teeth are left by which to identify the lesion. Most commonly, these actually are retained periapical cysts from teeth that have been removed. The histology of the lining is a nondescript stratified squamous epithelium.

Theoretically, it could develop in a dental granuloma that is left after an extraction. The residual cyst may be found in any of the tooth bearing areas of the mandible or maxilla. Morphologically, the residual cyst may present as a fairly well defined radiolucency that can vary in size from a few mm to several cm. Clinically, these cysts are usually found on routine radiographic examination of patients. They may have been present for many months or years and only become symptomatic upon secondarily infected (Figs 4-16 A, B, and C). Usually, residual cysts do not expand bone. Treatment is surgical curettage (refer periapical cyst).

Paradental Cyst

A cyst of uncertain origin found primarily on the distal or facial aspect of a vital mandibular third molar, consisting of intensely inflamed connective tissue and epithelial lining.

The paradental cyst is an inflammatory cyst which develops on the lateral surface of a tooth root. Some authors refer to this cyst as an inflammatory periodontal cyst or collateral cyst. This cyst is of rare occurrence and must be radiographically differentiated from the lateral periodontal cyst. It is treated by surgical ablation and does not have a tendency to recur.

It seems clear that the paradental cyst is of inflammatory origin and that it arises from odontogenic epithelium. Craig (1976) has suggested that either the cell rests of Malassez or the reduced enamel epithelium might provide the cell of origin. He favored the latter source, arguing that in his study the rests of Malassez always appeared inactive and that if the Malassez rests were responsible the lesions should be equally distributed around the root surface. His serial sections indicated that the development of paradental cyst may follow hyperplasia and cystic change in reduced enamel epithelium. He suggested that the presence of an extension of reduced enamel epithelium over the enamel projections might be the source, and could explain the frequent buccal location of the cyst.

Pathogenesis. There is no unanimity with regard to pathogenesis. Ackerman, Cohen and Altini (1987) like Craig (1976), favored origin from reduced enamel epithelium but suggested that cyst formation occurs as a result of unilateral expansion of the dental follicle secondary to inflammatory destruction of periodontium and the alveolar bone. Fowler and Brannon (1989) suggested that it may be a variant of the dentigerous cyst or derived from an occluded periodontal pocket. Vedtofte and Praetorius (1989) were satisfied that the cyst was of inflammatory origin, initiated by a pericoronitis at the time of tooth eruption and considered rests of Malassez and reduced enamel epithelium the most likely source of the cyst epithelium.

Clinical Features. In the sample of 2,616 jaw cysts reported by Shear (1992), there were 65 paradental cysts classified over a 32-year period (2.5%). The series of 50 cases reported by

Histopathological features of **(A)**, residual cyst using H & E stain (x 10), **(B)** of residual cyst using PCNA antibody stain (x 10), and **(C)** of residual cyst using PCNA antibody stain (x 40).

Ackerman, Cohen and Altini (1987) represented the 3% of a sample of 1,852 odontogenic cysts observed over a 20-year period. Virtually all the cases in the study by Ackermann, Cohen and Altini occurred between the ages of 10 and 39 with two-thirds of their sample in the third decade; the same as in Craig's material (cited by Shear, 1992). There was a considerable preponderance of males reported by Ackermann, Cohen and Altini and by Fowler and Brannon but of Vedtofte and Praetorius. There was an equal gender distribution. Ackermann, Cohen and Altini found most of their cyst located distally and distobuccally to the third molar. All the papers emphasized that the involved teeth were vital. Bilateral examples occurred in a number of instances.

Radiographic Features. All authors reported a variable radiographic picture but there are some features which appeared consistently and which seem to be useful in contributing to the diagnosis. These are the non widening of the periodontal ligament space and that the lesion was superimposed on the buccal root face. When there was a distal as well as a buccal radiolucency, the distal element was separate from the distinct distal follicular space (Shear, 1992).

Histologic Features. Histologically, the cysts were lined by a hyperplastic nonkeratinized stratified squamous epithelium. An intense inflammatory cell infiltrate is present associated with the hyperplastic epithelium and in the fibrous capsule adjacent to the epithelium. Histologically the paradental cyst cannot be differentiated from a radicular cyst.

Treatment. Enucleation and extraction of associated molar.

TUMORS OF ODONTOGENIC ORIGIN

Odontogenic tumors represent a spectrum of lesions ranging from malignant (rare) and benign neoplasms to dental hamartomas, all arising from odontogenic residues, i.e. odontogenic epithelia and/or ectomesenchyme with variable amounts of dental hard tissues formed generally in the same sequence as in normal tooth development.

Occasionally an odontogenic tumor develops from a preexisting developmental cyst (e.g. adenomatoid odontogenic tumor from a dentigerous cyst) or dental primordium (e.g. ameloblastomas often take the place of lower third molars). In many instances the exact tissue of origin (histogenesis) of an odontogenic tumor may only be inferred from its site and structure.

Classification of Odontogenic Tumors. The WHO classification (1992) divides odontogenic tumors into benign and malignant, with major subdivisions in each category (White, 2004) (Table 4-2). The subdivisions for the benign neoplasms are based on types of odontogenic tissue involved in the process and include:

- Odontogenic epithelium without odontogenic ectomesenchyme.
- Odontogenic epithelium with odontogenic ectomesenchyme, with or without dental hard tissue formation.
- Odontogenic ectomesenchyme with or without included odontogenic epithelium.

The classic example of odontogenic tumor viz. ameloblastoma is an archetype of a neoplasm where the neoplastic component is epithelial only without contribution from the ectomesenchyme. In the second category, some of the neoplasms are pure epithelial tumors but are capable of inducing dysplastic enamel and dentin formation. Examples include adenomatoid odontogenic tumor, calcifying odontogenic cyst, and odontoameloblastoma. Other tumors in the category exhibit neoplastic cells of both odontogenic epithelium and

Table 4-2: Odontogenic tumors (modified WHO classification)

A. Benign
- I. Odontogenic epithelium without odontogenic ectomesenchyme
  1. Ameloblastoma
  2. Squamous odontogenic tumor
  3. Calcifying epithelial odontogenic tumor (Pindborg tumor)
  4. Adenomatoid odontogenic tumor*
- II. Odontogenic epithelium with odontogenic ectomesenchyme with or without hard tissue formation
  1. Ameloblastic fibroma
  2. Ameloblastic fibrodentinoma
  3. Ameloblastic fibro-odontoma
  4. Odontoameloblastoma
  5. Calcifying odontogenic cyst
  6. Complex odontoma
  7. Compound odontoma
- III. Odontogenic ectomesenchyme with or without included odontogenic epithelium
  1. Odontogenic fibroma
  2. Myxoma (myxofibroma)
  3. Cementoblastoma (benign cementoblastoma, true cementoma)

B. Malignant
- I. Odontogenic carcinomas
  1. Malignant ameloblastoma
  2. Primary intraosseous carcinoma
  3. Clear cell odontogenic carcinoma**
  4. Ghost cell odontogenic carcinoma
- II. Odontogenic sarcomas
  1. Ameloblastic fibrosarcoma
  2. Ameloblastic fibrodentinosarcoma
  3. Ameloblastic fibro-odontosarcoma

** Originally classified under II, but in a new revision of the WHO classification it will be classified under I.*

*** Originally classified as a benign tumor under I (clear cell odontogenic tumor), but it is now recognized as a malignant tumor (clear cell odontogenic carcinoma) and classified accordingly.*

ectomesenchyme and include ameloblastic fibroma and ameloblastic fibro-odontoma (mixed odontogenic tumors). Yet other entities represent hamartomatous proliferations of both tissues, including compound and complex odontomas. In the third category, odontogenic ectomesenchyme with or without included odontogenic epithelium, the neoplastic cells appears to be of connective tissue origin. Neoplasms include odontogenic fibroma and odontogenic myxoma. Any epithelial component is not considered to be neoplastic.

Ameloblastic carcinoma and odontogenic sarcomas are examples of odontogenic neoplasms which contain a malignant epithelial and connective tissue component as part of the tumor. Calcifying odontogenic cyst has been placed in the odontogenic tumors classification by the WHO because some variants consist of a solid tumor with ameloblastoma like areas, dentinoid, and ghost cells. This form has been designated as dentinogenic ghost cell tumor or odontogenic ghost cell tumor. Benign cementoblastoma has currently been delinked from the WHO classification of odontogenic tumors and is described along with benign osteoblastoma.

Ameloblastoma

(Adamantinoma, adamantoblastoma, multilocular cyst)

The ameloblastoma is a true neoplasm of enamel organ type tissue which does not undergo differentiation to the point of enamel formation. It has been described very aptly by Robinson as being a tumor that is 'usually unicentric, nonfunctional, intermittent in growth, anatomically benign and clinically persistent'.

The term 'ameloblastoma' as applied to this particular tumor was suggested by Churchill in 1934 to replace the term 'adamantinoma', coined by Malassez in 1885, since the latter term implies the formation of hard tissue, and no such material is present in this lesion. The first neoplasm of this nature reported in the scientific literature is credited to Broca in 1868, although Guzack reported a tumor of the jaw in 1826 which may be the first recorded instance of an ameloblastoma. In any event, the first thorough description of an ameloblastoma is that of Falkson in 1879.

It is the second most common odontogenic neoplasm, and only odontoma outnumbers it in reported frequency of occurrence. Excluding odontoma, the incidence of ameloblastoma is at least equal to the incidence of all the other odontogenic neoplasms combined. However G Sriram and Shetty RP based on an Indian institutional study on 250 odontogenic tumors reported ameloblastoma to be the most common (61.5%) odontoplasmic neoplasm in India. Its incidence, combined with its clinical behavior, makes ameloblastoma the most significant odontogenic neoplasm of concern to oral and maxillofacial surgeons.

Pathogenesis. The earlier workers noted the resemblance between the odontogenic apparatus and the ameloblastoma and suggested that the neoplasm was derived from a portion of this apparatus or from cells potentially capable of forming dental tissue. Malassez described small collections of epithelial cells adjacent to the roots of teeth in the periodontal ligament and suggested that the 'adamantine epithelioma' was produced by a proliferation of these cell rests.

Most authorities consider the ameloblastoma to be of varied origin, although the stimulus initiating the process is unknown. Thus the tumor conceivably may be derived from:

- Cell rests of the enamel organ, either remnants of the dental lamina or remnants of Hertwig's sheath, the epithelial rests of Malassez.
- Epithelium of odontogenic cysts, particularly the dentigerous cyst, and odontomas.
- Disturbances of the developing enamel organ.
- Basal cells of the surface epithelium of the jaws.
- Heterotopic epithelium in other parts of the body, especially the pituitary gland.

Presently, it is thought that it is likely the result of alterations or mutations in the genetic material of cells that embryologically preprogrammed for tooth development. Environmental factors and individual patient variables (e.g. general health status, nutritional status) also likely have a role in modulating the incidence of the disease. This theory is demonstrated by the finding that the average age of occurrence of ameloblastoma in industrialized nations is 10–15 years greater than that seen in developing countries (Kessler HP et al, 2003).

Cahn in 1933 reported a case of ameloblastoma originating in the wall of a dentigerous cyst, and numerous cases have subsequently been recognized as developing in this fashion.

It should be reiterated that Stanley and Diehl, in reviewing 641 cases of ameloblastoma, found that 108 of these tumors, approximately 17%, were definitely associated with an impacted tooth and/or a follicular (dentigerous) cyst. They also noted a marked reduction in the prevalence of such cases after the age of 30, presumably because of the loss of the ameloblastomatous potential of the odontogenic epithelium in impacted tooth follicles and follicular cysts as patients age. Such a significant finding emphasizes the dangerous potential of the dentigerous cyst and the need for careful microscopic examination of every such lesion. This is discussed in greater detail in the section on the dentigerous cyst. Since a dentigerous cyst may develop in association with an odontoma, as well as with an impacted tooth, it is suggested that these too be examined by the pathologist. There is apparently little tendency for the development of the ameloblastoma in the ordinary apical periodontal or radicular cyst.

Clinical Features. A wide age range of occurrence of the tumor from 10 years through 90 years has been reported. The average age at diagnosis is in the range of 33–39 years, and most cases cluster between ages 20 and 60 years. Only about 10% of cases are reported to arise in children, and less than one third of those occur in children younger than 10 years. No significant sex predilection has been reported. There is conflicting evidence on the incidence rates in different races. Although some reports claim an increased incidence of ameloblastoma in black individuals, a large study identifies Asians as the population with the greatest number of affected patients. Because sizeable numbers of cases are reported in every racial group, race does not seem to be a significant defining demographic characteristic of the disease (Reichart PA et al, 1995).

Ameloblastoma occurs in all areas of the jaws, but the mandible is the most commonly affected area (more than 80% of all cases). Within the mandible, the molar angle-ramus area is involved three times more commonly than are the premolar and anterior regions combined. Statistics on the location of maxillary ameloblastomas are more variable and more difficult to interpret. Some studies report a low incidence in the anterior maxilla, whereas other studies suggest that the incidence in the anterior maxilla is roughly equivalent to the incidence in the maxillary molar region. When comparing large studies, it appears that maxillary tumors tend to occur in slightly older patients than do mandibular lesions. The incidence of occurrence of ameloblastoma in different sites within the jaws has been shown to vary among racial groups. Asians seem to have fewer tumors involving the ramus than do whites or blacks, whereas blacks have an increased frequency of tumors in the anterior mandible compared with the other two groups (Kessler HP et al, 2003).

Peripheral (extraosseous) ameloblastoma. This is a tumor which histologically resembles the typical central or intraosseous ameloblastoma but which occurs in the soft tissue outside and overlying the alveolar bone. In addition, a number of cases of lesions in a similar location and with similar histologic features have been reported under the term 'basal cell carcinoma of the gingiva'. Many investigators consider these the same basic lesion, including Gardner, who has reviewed the literature, adding seven additional unpublished cases for a total of 21 examples of peripheral ameloblastoma. Occasional other cases have since been reported, such as those of Greer and Hammond and of Gould and his colleagues.

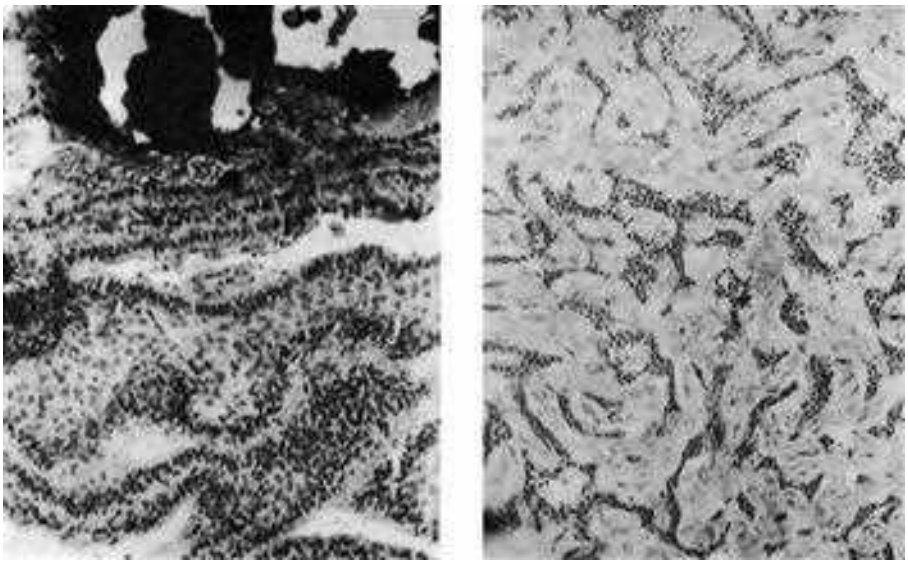
This tumor appears to originate from either surface epithelium or remnants of dental lamina. In some instances, the tumor exhibits one or more areas of continuity with the surface epithelium, while in other cases, even with serial sectioning, no evidence of continuity between the two can be found.

The ages of the patients in the 21 cases reviewed by Gardner ranged between 23 and 82 years, with 10 patients between 30 and 50 years of age. There was a slight predilection for occurrence in males, 13 cases to 8 cases in females. There was an approximately 2 : 1 ratio of occurrence in the mandible over the maxilla. The lesions, all of which appeared as nodules on the gingiva, varied in size from 3 mm to 2 cm in diameter. In only two cases was radiographically evident superficial erosion of bone present.

The peripheral ameloblastoma histologically may exhibit the same pattern seen in the intraosseous ameloblastoma. However, while some lesions appeared to be of the follicular type, the vast majority were acanthomatous, at least in areas. Greer and Hammond have studied the ultrastructural characteristics of their case and found the electron microscopic appearance to be similar to that of the intraosseous ameloblastoma and the cutaneous basal cell carcinoma. In a similar ultrastructural study, Gould and his associates found that the features of their tumor was characteristic of origin from either surface epithelium or odontogenic remnants, thereby precluding definitive conclusions regarding site of origin. In terms of differential diagnosis, one must always consider the possibility of the peripheral odontogenic fibroma, which is also a peripheral lesion of the gingiva with variable amounts of odontogenic epithelium. The distinction on the basis of the connective tissue parenchyma of the odontogenic fibroma is usually not difficult, although cases with features of both lesions may occur, such as that reported by Sciubba and Zola.

One of the most important aspects of the peripheral ameloblastoma, emphasizing the need for its careful identification as a peripheral lesion and separation from the intraosseous counterpart, is the difference in clinical behavior. The peripheral lesion is relatively innocuous, lacks the persistent invasiveness of the intraosseous lesion and has very limited tendency for recurrence. For this reason, it may be excised locally, although follow-up examination is always good practice.

Pituitary ameloblastoma (craniopharyngioma, Rathke's pouch tumor). This is a neoplasm involving the central nervous system which grows as a pseudoencapsulated mass, usually in the suprasellar area but occasionally in the intrasellar area, and often destroys the pituitary gland. The peak incidence is reported to be between 13 and 23 years of age. According to Zulch, the pituitary ameloblastoma is the most common tumor of childhood and adolescence. In his series of 6,000 CNS tumors, it constituted 2.5% of the total in all patients regardless of age.



A B

Figure 4-17. Ameloblastoma like tumors in other locations.
(A) Craniopharyngioma showing typical ameloblastoma like formation with calcification. **(B)** Adamantinoma of tibia *(Courtesy of Dr William G Sprague and Dr David C Dahlin).*

It is generally thought to originate from the unobliterated portions of the fetal craniopharyngeal duct, which itself is derived from Rathke's pouch. This pouch is a recess arising as a result of invagination of a portion of the stomodeal ectoderm, and the pituitary gland forms by fusion of this pouch with a process of the forebrain. Epithelial remnants of this craniopharyngeal duct are extremely common in the adult. These cell rests have a certain pluripotential and on occasion may give rise to tumors histologically similar to the ameloblastoma of the jaw.

Microscopic features of the craniopharyngioma, not generally found in the ameloblastoma, include the almost universal occurrence of irregular calcified masses as well as occasional foci of metaplastic bone or cartilage (Fig. 4-17 A). In addition, many investigators have noted the similarity between the craniopharyngioma and the calcifying odontogenic cyst because of the presence in the pituitary lesion of islands and nests of 'ghost' cells, as well as the calcifications and the fact that cyst formation is common. Several cases of craniopharyngioma with tooth formation have also been reported, such as that of Seemayer and his associates.

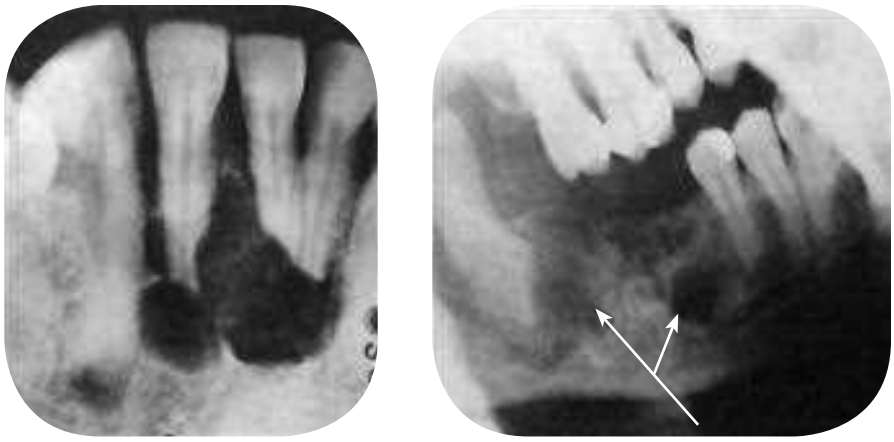
There is great variability in the rate of growth of the pituitary ameloblastoma. Depending upon its exact location, there may be a gamut of clinical features eventually manifested, such as evidence of endocrine disturbance, drowsiness or even toxic symptoms. The treatment of this neoplasm is a neurosurgical problem.

Adamantinoma of long bones. This tumor has been discussed by Baker, Dockerty and Coventry, who reviewed the literature and concluded that the true nature of the lesion is still unknown. The tumor, which bears a superficial microscopic resemblance to the ameloblastoma of the jaws, has occurred in the tibia in approximately 90% of the slightly over 100 reported cases, but also has been recorded in the ulna, femur and fibula (Fig. 4-17B). Changus and his coworkers suggested that the lesion is actually a malignant angioblastoma, and this view is supported by Huvos and Marcove in their investigation of 14 cases. In contrast, Unni and his coworkers studied 29 cases, with ultrastructural microscopy of three of the tumors, and concluded that this provided evidence that the islands of tumor cells were epithelial in origin. Thus, although the histogenetic origin of this tumor is unknown, most authorities agree that it is not related to the ameloblastoma of the jaws, even though they support retention of the term 'adamantinoma' because of its acceptance through usage and for lack of a better name.

Radiographic Features. The ameloblastoma has been described classically as a multilocular cyst like lesion of the jaw. This is especially true in advanced cases of ameloblastoma. Here, the tumor exhibits a compartmented appearance with septa of bone extending into the radiolucent tumor mass (Fig. 4-18A). In many cases, however, the lesion is a unilocular one and presents no characteristic or pathognomonic features (Figs. 4-18B, 4-19). The periphery of the lesion on the radiograph is usually smooth, although this regularity may not be borne out at the time of operation. In the advanced lesion producing jaw expansion, thinning of the cortical plate may be seen on the radiograph (Figs. 4-20, 4-21).

The term 'cystic ameloblastoma' is frequently used in referring to certain of these neoplasms. It is important to note that there is no correlation between the term thus used clinically and the appearance of the tumor on the radiograph. The radiographic film does nothing more than indicate the relative presence or absence of calcified tissue, and a variety of lesions may manifest themselves in manner similar to that of the ameloblastoma.

Histologic Features. Six histopathologic subtypes of ameloblastoma are recognized: follicular, acanthomatous, granular



A B

Figure 4-18. Ameloblastoma.
(A) The typical loculations which often occur are clearly seen. **(B)** This lateral jaw radiograph reveals an early lesion with no loculations, but with several focal areas of bone destruction.

Figure 4-21. Ameloblastoma of the mandible.

cell, basal cell, desmoplastic, and plexiform. Most tumors show a predominance of one pattern, but few lesions are found to be composed purely of one histopathologic subtype. Mixtures of the different patterns commonly are observed. Lesions tend to be subclassified according to the predominant pattern that is present. The literature-based retrospective study by Reichart et al (1995) showed that the histologic subtype may have prognostic implications for recurrence. According to their study, the follicular type of ameloblastoma had the highest rate of recurrence at 29.5%. In contradistinction, the acanthomatous type of ameloblastoma showed only a 4.5% recurrence rate. The plexiform subtype was intermediate between the two extremes and showed a 16.7% recurrence rate. Studies have verified that desmoplastic ameloblastoma shows a tendency to recur, and the rate of recurrence is reported within the range of the other histologic subtypes of ameloblastoma.

A moderately to densely collagenized connective tissue characteristically constitute the stroma. The epithelial component of the neoplasm proliferates in what seems to be disconnected islands, strands, and cords within the collagenized fibrous connective tissue stroma. A prominent budding growth pattern often is seen, with small, rounded extensions of epithelium projecting from larger islands, recapitulating the various stages of enamel organ formation (Kessler HP et al 2003). The islands, strands, and cords may vary considerably in size. In high power magnification, the darkly staining periphery is composed of tall columnar cells with hyperchromatic nuclei. The nuclei tend to be round to oval in shape, and the nuclei of adjacent cells are in roughly the same location within the cytoplasm. This produces a characteristic palisading pattern. The palisaded nuclei are oriented away from the basement membrane area of the cell, and a small clear vacuole can be seen between the nucleus and the basement membrane. This peripheral layer of tall columnar cells with hyperchromasia, reverse polarity of the nuclei, and subnuclear vacuole formation mimic the normal embryologic development of the tooth bud at the stage of enamel matrix production. These classic features of ameloblastoma originally were described by Vickers and Gorlin in 1970 (criteria).

Focally in many ameloblastomas, the proliferating epithelium is seen to exert an inductive effect on the surrounding connective tissue stroma. In these areas, a zone of hyalinization of the collagen is present immediately adjacent to the epithelium. Fibroblasts are almost totally absent within the zone of hyalinization. It is theorized that the ameloblastic epithelium, in an attempt to complete its embryologic function and produce enamel matrix, signals the connective tissue to induce dentin formation; however, the fibroblastic cells in the connective tissue are unable to differentiate into odontoblasts, a required step in dentin and enamel formation. The hyalinized zone most likely represents the end result of this blockade in the normal embryologic sequence of odontogenesis (Kessler HP et al, 2003).

The ***follicular (simple) ameloblastoma*** is the most commonly encountered variant (Reichart PA et al, 1995), composed of many small discrete islands of tumor composed of a peripheral layer of cuboidal or columnar cells whose nuclei are generally well polarized. These cells strongly resemble ameloblasts or preameloblasts and these enclose a central mass of polyhedral, loosely arranged cells resembling the stellate reticulum. The terms 'solid' and 'cystic' have often been applied to the ameloblastoma and have variously referred to the clinical or histologic appearance of the tumor. Clinically, some cases exhibit tiny cysts that are grossly evident when the lesion is excised and examined carefully. In such instances, the stellate reticulum like tissue has undergone complete breakdown or cystic degeneration, and in such cases, there is often flattening of the peripheral columnar cells so that they resemble low cuboidal or even squamous cells. Cyst formation is relatively common in this follicular type of ameloblastoma.

In the ***plexiform ameloblastoma,*** the ameloblast like tumor cells are arranged in irregular masses, or more frequently, as a network of interconnecting strands of cells. Each of these masses or strands is bounded by a layer of columnar cells, and between these layers may be found stellate reticulum like cells. Sometimes double rows of columnar cells are lined up back to back. However, the stellate reticulum like tissue is much less prominent in the plexiform type than in the follicular type of ameloblastoma. Areas of cystic degeneration of stroma are also common.

In the ***acanthomatous ameloblastoma,*** the cells occupying the position of the stellate reticulum undergo squamous metaplasia, sometimes with keratin formation in the central portion of the tumor islands. This usually occurs in the follicular type of ameloblastoma. On occasion, epithelial or keratin pearls may even be observed.

In the ***granular cell ameloblastoma,*** there is marked transformation of the cytoplasm, usually of the stellate reticulum like cells, so that it takes on a very coarse, granular, eosinophilic appearance. This often extends to include the peripheral columnar or cuboidal cells as well. Ultrastructural studies, such as that of Tandler and Rossi, have shown that these cytoplasmic granules represent lysosomal aggregates with no recognizable cellular components. Hartman has reported a series of 20 cases of granular cell ameloblastoma and emphasized that this granular cell type appears to be an aggressive lesion with a marked proclivity for recurrence unless appropriate surgical measures are instituted at the first operation. In addition, several cases of this type have been reported as metastasizing. However, all other clinical features of the lesion appear similar to the other forms of ameloblastoma.

The ***basal cell type of ameloblastoma*** bears considerable resemblance to the basal cell carcinoma of the skin. It is believed that this is the rarest histologic subtype and the epithelial tumor cells are more primitive and less columnar, are generally arranged in sheets, more so than in the other tumor types (Fig. 4-22).

The ***desmoplastic ameloblastoma*****,** characteristically, is found in a dense collagen stroma that may appear hyalinized and hypocellular. The desmoplastic ameloblastoma has a greater tendency to grow in thin strands and cords of epithelium rather than in an island like pattern. The epithelial proliferation almost seems to be compressed and fragmented by the dense hyalinized

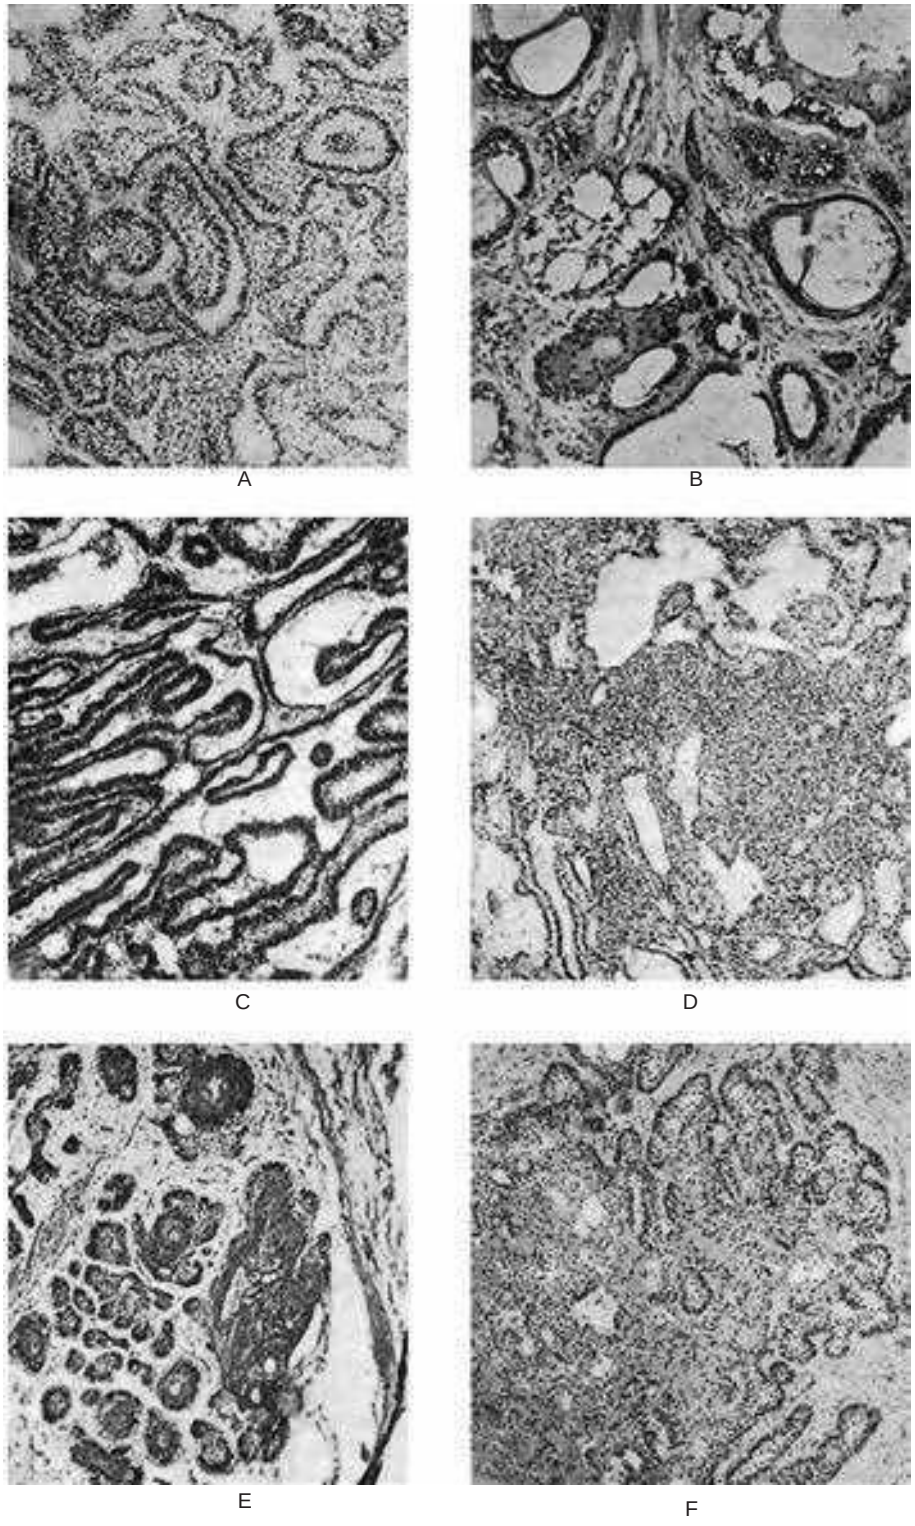

Figure 4-22. Ameloblastoma.

stroma. Central cells are often scant in the epithelial proliferation, and the cells making up the periphery of the strands and cords often are flattened or cuboidal rather than tall columnar in appearance. Reverse polarity of nuclei and subnuclear vacuole formation may be difficult to recognize (Fig. 4-23).

Most desmoplastic ameloblastomas display occasional classic islands of follicular ameloblastoma among the predominant strands and cords. Without these classic islands of ameloblastoma, the diagnosis can be difficult.

The growth pattern of the neoplasm, categorized as conventional or unicystic, is more important than the histopathologic subtype in treatment decision. The desmoplastic ameloblasloma is more important than the histopathologic subtype in treatment decision. Desmoplasia of the stromal connective tissue can be argued to be a maturation stage of the tumor, as similar dense collagenization is seem during maturation of long tumors (Sivapathamundaram et al, 2007). However, these authors failed to explain the off occurrence of these variants in the anterior jaw, unlike in conventional forms.

Unicystic ameloblastoma, the second and far less frequent growth pattern seen in the intraosseous ameloblastoma is the unicystic type. This growth pattern is seen in approximately 6% of ameloblastomas. It tends to occur in a younger population (average age in one large study, 22.1 years) compared with the patient population with conventional ameloblastomas. A high percentage of these lesions are associated with an impacted tooth, and the most commonly cited provisional diagnosis is dentigerous cyst. Cystic areas nearly always are noted grossly at the time of surgery. Recognition of this growth pattern is important, because it is well accepted that the unicystic type has a considerably better overall prognosis and a much reduced incidence of recurrence compared with conventional ameloblastoma (Li TJ et al, 1998).

The unicystic ameloblastoma is characterized by one or more of the following features:

- Lining epithelium exhibiting alterations virtually identical with those described by Vickers and Gorlin as representing early ameloblastomatous changes in the dentigerous cyst (q.v.).

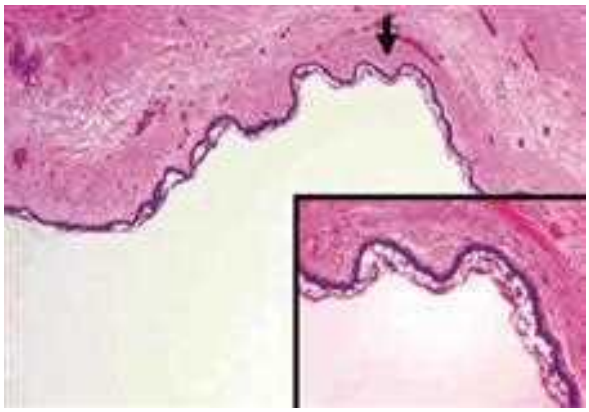

Figure 4-24. Unicystic ameloblastoma.
The ameloblastoma shows a cystic architecture with the typical ameloblastic changes confined to the cyst-lining epithelium. The arrow indicates the area enlarged in the inset at lower right (hematoxylin-eosin, original magnification x2). (Inset) Ameloblastic epithelium with hyperchromatic palisaded basal cell layer, thin layer of stellate reticulum like cells, and abrupt transition to a thin parakeratinizing luminal surface (hematoxylin-eosin, original magnification x10) *(Courtesy of Dr HP Kessler).*

- Nodules of tumor projecting intraluminally.
- Ameloblastomatous lining epithelium proliferating into the connective tissue wall.
- Islands of ameloblastoma occurring isolated in the connective tissue wall (Fig. 4-24).

The recurrence rate of this lesion is distinctly lower than that for the characteristic ameloblastoma, thus indicating a less aggressive type of lesion. The epithelium lining the cystic cavity of the neoplasm shows typical cytomorphologic features that are recognizable as ameloblastoma, with a basal cell layer composed of columnar cells displaying hyperchromatic, palisaded nuclei.

Reverse polarity of the nuclei is present, and a subnuclear vacuole is usually noted between the basement membrane and nucleus. A thin overlying layer of stellate reticulum-like cells is seen. A luminal parakeratin layer may or may not be present. When keratinization is present, an abrupt transition from the stellate reticulum-like layer is usually observed. In some instances, the ameloblastic epithelium may be proliferative, with extension of the ameloblastic epithelium into the lumen of the cystic cavity. This feature has been termed **intraluminal proliferation,** and in many instances, this growth resembles the plexiform type of ameloblastoma. Thus, some lesions have been referred to as plexiform **unicystic ameloblastoma** (Fig. 4-25).

Treatment and Prognosis. There are some differences of opinion about the preferable method of treatment of the ameloblastoma. The only unanimity centers around the fact that complete removal of the neoplasm, regardless of how it is accomplished, will result in a cure of the patient.

The types of treatment that have been used include both radical and conservative surgical excision, curettage, chemical and electrocautery, radiation therapy or a combination of surgery and radiation. The majority of workers today prefer

Figure 4-25. Ameloblastoma with mural growth.
Ameloblastic epithelium infiltrates the connective tissue of the cyst wall. The infiltrating ameloblastic epithelium remains in direct continuity with the ameloblastic epithelium lining the cystic lesion. The cyst lumen is seen at the bottom (hematoxylin-eosin, original magnification x5).

some form of surgical excision. Curettage is least desirable, since it is associated with the highest incidence of recurrence. The basic principles of treatment have been discussed in detail by Gardner and Mehlisch and his colleagues.

Frissell reviewed the reported cases in which radiation therapy was utilized and found that there was considerable variance of opinion as to its benefit. The report of Kimm, supported by study of serial biopsy, on the treatment of the ameloblastoma by radiation indicated that this neoplasm is generally highly radioresistant and that the use of this form of therapy is not warranted. Wide clinical experience has shown the truth of this finding. Regardless of the form of treatment, long-term follow-up of the patient is an absolute necessity.

Treatment decisions for ameloblastoma are based on the individual patient situation and the best judgment of the surgeon. The surgical plan should be influenced strongly by whether the lesion involves the mandible or maxilla. Maxillary lesions behave distinctly differently from mandibular lesions. The higher cancellous bone percentage in the maxilla facilitates the spread of the ameloblastoma, whereas the density of the cortical plates in the mandible tends to limit spread of the neoplasm. Regardless of which jaw is involved, once an ameloblastoma has recurred, retreatment becomes more challenging. Radical retreatment typically is performed even for suspected unicystic lesions during the initial phase of the disease.

Calcifying Epithelial Odontogenic Tumor
(Pindborg tumor)

The calcifying epithelial odontogenic tumor was first described in 1956 by the late Dr Jens J Pindborg. Pindborg tumor is now a universally recognized synonym for this neoplasm. An alternative abbreviation also commonly used is CEOT.

The Pindborg tumor is classified as an uncommon, benign, odontogenic neoplasm that is exclusively epithelial in origin. Some have suggested that the epithelial cells of the Pindborg tumor are reminiscent of the cells in the stratum intermedium layer of the enamel organ in tooth development. Some hypothesize that the Pindborg tumor arises from remnants of the primitive dental lamina found in the initial stage of odontogenesis, and these epithelial rests are the more likely true progenitor cell. The definite etiology of this neoplasm still remains enigmatic.

Clinical Features. A report by Franklin and Pindborg in 1976 shows that 113 cases of this intraosseous tumor have been described in the literature since Pindborg's original paper. As the number of reported cases continues to increase, we are rapidly improving our knowledge of this lesion.

This tumor occurs most frequently in middle-age. Of the reported cases, the mean age of occurrence at the time of diagnosis was 40 years of age in both men and women, with a range of 8–92 years. There is no significant difference in occurrence between the gender, since 49% of the cases were in men and 51% in women.

There is a predilection for occurrence of the tumor in the mandible over the maxilla by a ratio of 2 : 1, and the prevalence in the molar region is three times that in the bicuspid region, whereas in other sites in the jaws there is a relatively even distribution. If these two respects, i.e. age and site, the Pindborg tumor is very similar to the ameloblastoma.

Most patients with this lesion are asymptomatic and are aware only of a painless swelling. It is significant, however, that 52% of the reported cases have been definitely associated with an unerupted or impacted tooth.

An extraosseous calcifying epithelial odontogenic tumor is also known to occur but is quite rare, with only eight reported cases, according to the review by Wertheimer and his associates in 1977. This extraosseous lesion has had a mean age of occurrence of 35 years and an approximately equal sex distribution. With the exception of one equivocal lesion on the upper lip, all cases have occurred on the gingiva, five mandibular and two maxillary, and almost invariably in the anterior segment (Fig. 4-26). The extraosseous lesion is histologically identical with the intraosseous one.

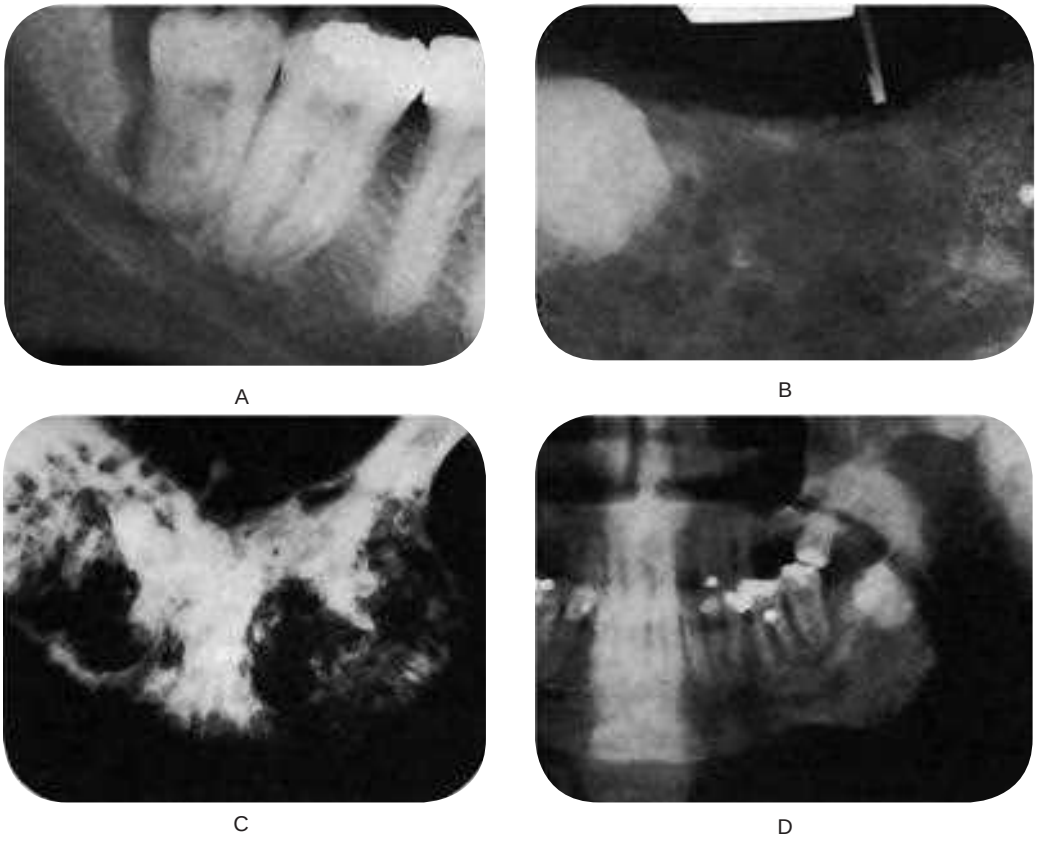

Figure 4-27. Calcifying epithelial odontogenic tumor of Pindborg.
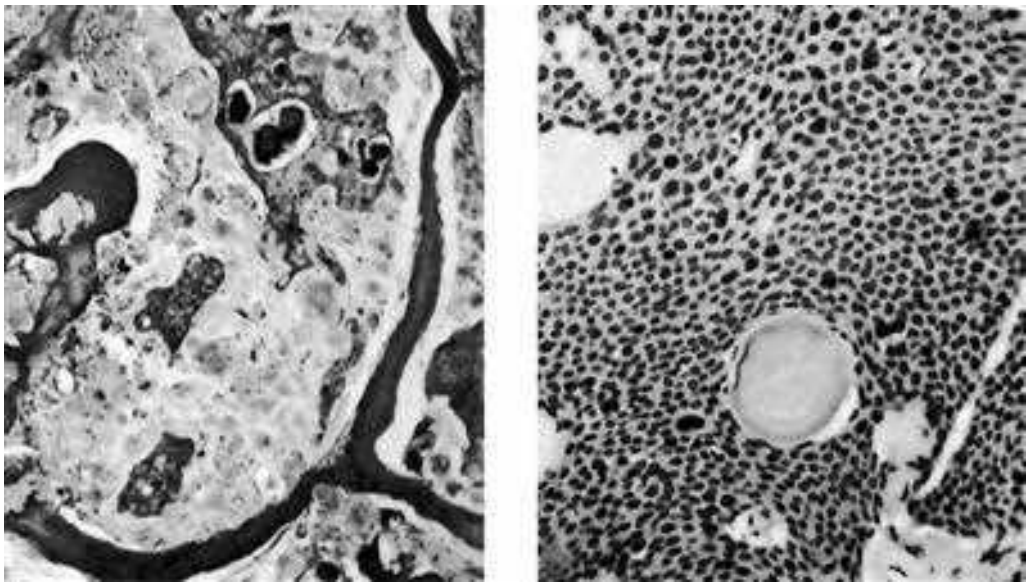
(Courtesy of Dr Charles Redish, Dr Robert Bresick, Dr Charles Hutton, and Dr Ronald Vincent).

Radiographic Features. The tumor may show considerable radiographic variation. In some cases, the lesion appears as either a diffuse or a well-circumscribed unilocular radiolucent area, while in other cases there may appear to be a combined pattern of radiolucency and radiopacity with many small, irregular bony trabeculae traversing the radiolucent area in many directions, producing a multilocular or honeycomb pattern. Scattered flecks of calcification throughout the radiolucency have given rise to the descriptive term of a 'driven snow' appearance. In some instances, the lesion is totally radiolucent and is in association with an impacted tooth, thus leading to a mistaken clinical diagnosis of dentigerous cyst (Fig. 4-27).

On CT examination, calcifying epithelial odontogenic tumor in the mandible demonstrates expansion and thinning of buccal and lingual cortical bony plates by a well-defined mass containing scattered radiopaque areas of varying size and signal intensity. MRI reveals predominantly a hypointense lesion on T1-weighted images and a mixed hyperintense lesion on T2-weighted images.

Histologic Features. The calcifying epithelial odontogenic tumor is composed of polyhedral epithelial cells, sometimes closely packed in large sheets but other times consisting chiefly of scattered small islands of cells in a bland fibrous connective tissue stroma (Fig. 4-28). Occasionally, the cells are arranged in cords or rows, mimicking adenocarcinoma. The tumor cells have a well-outlined cell border with a finely granular eosinophilic cytoplasm, and intercellular bridges are often prominent. The nuclei are frequently pleomorphic, with giant nuclei and multinucleation being quite common but mitotic figures rare. The tumor cells in some lesions are characterized by extreme morphologic variation with severe cellular abnormalities, mimicking those often seen in some highly malignant neoplasms, while other cases of the calcifying epithelial odontogenic tumor are composed of very monomorphic, innocuous-appearing tumor cells; yet, to the best of our knowledge, the biologic behavior does not differ between the two.

A well-recognized form of this neoplasm is the **clear-cell variant.** In this type, the tumor cells exhibit a clear vacuolated cytoplasm rather than an eosinophilic cytoplasm. The nucleus may remain round or oval in the center of the cells or be flattened against the cell membrane. According to Krolls and Pindborg, who have discussed these histomorphologic variations, most of the clear cells are mucicarmine negative, although a few may show a faint tinge. In some tumors, the clear cells comprise the bulk of the tumor cells while, in others, they consist of only a few scattered foci. In as much as a variety of other types of tumors, both primary (e.g. mucoepidermoid carcinoma) and metastatic (e.g. hypernephroma), may exhibit clear cells, great care must be utilized in their interpretation and diagnosis.



A B

Figure 4-28. Calcifying epithelial odontogenic tumor of Pindborg.

This tumor has been investigated under the electron microscope by many researchers including Anderson and his coworkers, who have demonstrated that the tumor cells exhibit the features commonly seen in epidermal cells such as intercellular bridges with desmosomes, intracytoplasmic tonofilaments and well-developed hemidesmosomes.

One of the characteristic microscopic features of this tumor is the presence of a homogeneous, eosinophilic substance which has been variously interpreted as amyloid, comparable glycoprotein, basal lamina, keratin or enamel matrix. In at least some instances, this appears to form intracellularly and then is extruded into the extracellular compartment as a result of cell secretion or degeneration. This homogeneous eosinophilic material may be present in large or very limited quantities. In most cases, it stains metachromatically with crystal violet, positively with Congo red, and fluoresces under ultraviolet light with thioflavin T, all in a fashion similar to amyloid (Fig. 4-29). Ultrastructural studies have shown that this amyloid-like material is composed of at least three different types of fibrils, but that they have a smaller size than the fibers of 'conventional' amyloid, although this term is a rapidly expanding one. Some forms of amyloid are now suggested to arise from light chain fragments of immunoglobulin molecules, called immunamyloid, while another form is thought to originate from cells of certain endocrine tumors (e.g. medullary carcinoma of the thyroid) which may be derived from the endocrine polypeptide cells of neural crest origin of the amine precursor uptake and decarboxylation (APUD) system, called APUD-amyloid. On the evidence available at present, the exact nature of the amyloid like substance in the CEOT cannot be definitively assessed.

Another characteristic feature of the Pindborg tumor is the presence of calcification, sometimes in large amounts, and often in the form of Liesegang rings. This calcification

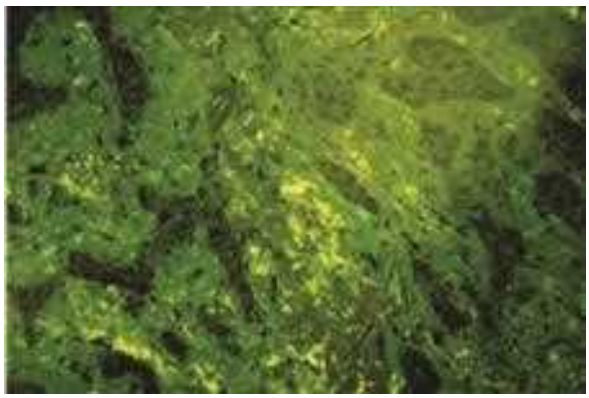


Figure 4-29. Calcifying epithelial odontogenic tumor of Pindborg.
Photomicrograph showing apple-green color birefringence of amyloid deposited in fibrous connective tissue stroma (Congo red stain under polarized light source, original magnification x20) *(Courtesy of Dr RK Goode).*

actually appears to occur in some instances in globules of the amyloid like material, many of which have coalesced and are transformed from being PAS (periodic acid-Schiff)-negative to PAS-positive during this calcification process. There does not appear to be necessarily a relationship between the amount of amyloid material formed in a given lesion and the amount of calcification occurring.

The source of the epithelial cells comprising this tumor was originally suggested by Pindborg to be the reduced enamel epithelium of the associated unerupted tooth. Today, most investigators believe that the cells originate from the stratum intermedium because of the morphologic similarity of the tumor cells to the normal cells of this layer of the odontogenic apparatus. Unfortunately, this does not explain those cases of tumor apparently occurring without an associated unerupted tooth or those extraosseous cases outside the jaw.

Treatment and Prognosis. There are a variety of alternative surgical treatment methods to successfully manage Pindborg tumors. Small, intrabony lesions with well-defined borders can be treated with enucleation or curettage followed by judicious removal of a thin layer of bone adjacent to the tumor. But some pathologists suggest that maxillary tumors should be treated more aggressively than a similar-sized lesion in the mandible.

Lesions designated recurrences, following conservative approaches like intrabony curettage, may in fact represent persistence of disease. Like ameloblastoma, small infiltrative foci of Pindborg tumor may insinuate along bony trabeculae and appear as uninvolved bone radiographically.

Recurrent or persistent tumors, which over an extended time have become larger and more extensive (greater than 4 cm), would require segmental resections such as partial or hemimandibulectomy or hemimaxillectomy.

Early intervention is advocated for the treatment of histopathologically atypical or frankly malignant calcifying epithelial odontogenic tumors before such a lesion could escape the confines of the involved mandible or maxilla. Radical resection of the affected jaw portion and any associated soft tissues with not less than 1 cm in every direction, as might be performed for any other variant of odontogenic carcinoma is adviced. Adjunctive external beam radiation therapy is advocated following determination of local spread to cervical lymph nodes and adjunctive chemotherapy may play some role in control of distant organ metastasis in some patients. Most studies of Pindborg tumor report a local recurrence rate of between 10 and 20% following conservative but complete removal of the lesion. The incidence of malignant transformation to odontogenic carcinoma ex-Pindborg tumor is so extremely low as to be considered distinctly rare; only three such cases being reported.

Adenomatoid Odontogenic Tumor

(Adenoameloblastoma, ameloblastic adenomatoid tumor)

Adenomatoid odontogenic tumor (AOT), generally considered to be an uncommon tumor, occurs mostly in association with an unerupted maxillary cuspid. Some investigators consider it as a benign neoplasm, while others have categorized it as a hamartomatous malformation due to the limited size and to the lack of recurrence of most cases (attributed perhaps to its minimal growth potential). Those who prefer to consider AOT to be a benign neoplasm believe that the limited size of most cases stems from early detection and removal of the lesion. They also point to the considerable size of some reported cases that had gone undetected or untreated for many years and resulted in facial asymmetry and distortion.

Histogenesis. Like all other odontogenic tumors, the specific stimulus that triggers proliferation of the progenitor cells of AOT is unknown. Because of its exclusive occurrence within the tooth-bearing areas of the jaws (most often associated closely with an unerupted or impacted tooth) and its cytologic resemblance to the dental lamina and components of the enamel organ, there is no disagreement that the AOT is of odontogenic origin (Rick GM, 2004).

Clinical Features. The mean age of these patients was approximately 18 years, with a range of 5–53 years. However, 73% of the patient were under 20 years of age. There is a marked predilection for occurrence of the tumor in females — 64% contrasted to 36% developing in males. The site of occurrence is greater in the maxilla (65%) than in the mandible (35%). In contrast to the ameloblastoma, this tumor occurs more frequently in the anterior part of the jaws with 76% developing anterior to the cuspid in the maxilla and mandible. Only very rarely does the lesion occur distal to the premolar area. It is of some interest that in at least 74% of the cases, the tumors were associated with an unerupted tooth, and in over two-thirds of the cases, this tooth was the maxillary or mandibular cuspid.

The vast majority of the lesions measured between 1.5 and 3.0 cm, although large lesions, exceeding 7.0 cm, have been reported. A large proportion of these tumors produced an obvious clinical swelling although they were generally asymptomatic. Five tumors reported in the literature have been extraosseous in their occurrence, according to Swinson.

Giansanti and his coworkers have pointed out that the high percentage of these lesions being associated with unerupted teeth and present as dentigerous cysts would strongly suggest that they are related to some late disturbance in odontogenesis. Since none of the associated teeth were described as morphologically defective, the disturbance must occur after odontogenesis is complete.

Adenomatoid odontogenic tumor may occur within the jaw bones or the gingiva. Peripheral lesions present as a painless, gingival colored mass that ranges from 1–1.5 cm in diameter. They are 10 times more prevalent in the maxillary gingiva than in the mandibular gingiva. The female to male ratio for the gingival lesion is 14: 1 (Philipsen HP et al, 1991).

Adenomatoid odontogenic tumor has to be clinically differentiated from central odontogenic cysts and tumors, benign fibro-osseous lesions and benign mesenchymal neoplasms. Gingival lesions cannot be differentiated clinically from gingival fibromas, peripheral cemento-ossifying fibromas, peripheral giant cell lesions, or from other peripheral odontogenic tumors, such as odontogenic fibroma, ameloblastoma, calcifying odontogenic cyst, and calcifying epithelial odontogenic tumor.

Radiographic Features. Central AOTs present as well-demarcated, almost always unilocular radiolucency that generally exhibit a smooth corticated (and sometimes sclerotic) border.

Most lesions are pericoronal or juxtacoronal but the radiolucency may extend apically beyond the cementoenamel junction on at least one side of the root. Rare, multilocular cases have been reported and a scalloped border is observed occasionally. Most cases are between 1 and 3 cm in greatest diameter. About 65% of reported cases also demonstrate faintly detectable radiopaque foci within the radiolucent lesion. Occasionally, a more obvious intralesional radiopacity may be identified, usually eccentrically positioned within the lesion. Divergence of roots and displacement of teeth occurs more frequently than root resorption. Orbital and maxillary sinus encroachment have been reported. Gingival lesions may cause slight erosion of the underlying alveolar bone cortex.

Histologic Features

Macroscopic features. Central AOTs macroscopically appears as a soft, roughly spherical mass with a distinct fibrous capsule. Upon gross sectioning, the tumor may exhibit white to tan, solid to crumbly tissue or one or more cystic spaces of varying sizes with yellowish brown fluid or semisolid material; fine, hard 'gritty' granular material; and one to several larger calcified masses. Additionally, intact specimens demonstrate the crown of an embedded tooth in the solid tumor mass or projecting into a cystic cavity.

Microscopic features. The AOT exhibits diverse histomorphologic features. The tumor is made up of a multinodular proliferation of spindle, cuboidal, and columnar cells in a variety of patterns comprising of scattered duct like structures, eosinophilic material, and calcifications in several forms; delimited by a fibrous capsule of variable thickness. Cytologic atypia is never a prominent feature.

Although not present in all tumors, the most distinctive microscopic feature of AOT is varying numbers of duct like structures with lumina of varying size that are lined by a single layer of cuboidal to columnar epithelial cells that have nuclei that frequently are polarized away from the lumen. These duct like or microcyst lumina frequently are lined by an eosinophilic rim of varying thickness (the so-called **hyaline ring**).

The stellate reticulum like spindle cells, and occasionally round or polygonal epithelial cells dominate the tissue between the cell-rich nodules. Small amounts of eosinophilic material or calcifications also may be present between these cells. Anastomosing strands of basaloid epithelial cells which resemble cell rests of the dental lamina, are arranged in a plexiform, trabecular, cribriform, or lattice like configuration. They occasionally extend between the cell-rich nodules and usually are present in the peripheral subcapsular area of most tumors. Many AOTs contain a few clusters of well defined calcifying epithelial odontogenic tumor like foci with eosinophilic polyhedral squamous epithelial cells and prominent intercellular bridges, and occasional mild nuclear pleomorphism (Fig. 4-30).

A considerable number of AOTs demonstrate cystic component. It is not clear whether this represents pooling of the mucoid stroma or if the tumor developed within or adjacent to a preexisting cyst. Although the cyst lining may occasionally resemble that seen in dentigerous cysts, it more often is similar to the basaloid cells that form the plexiform pattern that was described above. Some tumors exhibit pools of finely fibrillar eosinophilic material at the epithelial–connective tissue interface; this was immunoreactive for the basement membrane component laminin. Some AOTs contain varying amounts of dysplastic dentin, dentinoid, and osteodentin. Irregular to round calcified bodies which may exhibit areas with a concentric layered pattern (Liesegang rings) may be seen in parenchymal or stromal zones. The supporting stroma is loose, hypocellular, and fibrovascular that may show a prominent vascular component.

Treatment and Prognosis. The majority of tumors of this variety have been treated by conservative surgical excision and recurrence, if it ever occurs, is exceedingly rare.

Squamous Odontogenic Tumor
(Benign epithelial odontogenic tumor)

The squamous odontogenic tumor is a lesion which had been recognized as an apparent entity for a number of years but had not been named or reported until 1975, when Pullon and a small group of other oral pathologists combined their material and published six cases. Several additional cases have been reported since the original study, including five further cases by Goldblatt and his colleagues, who also reviewed the literature and commented further on this lesion.

The most important aspect of this lesion is its mistaken histologic identification as an acanthomatous ameloblastoma or as a well-differentiated epidermoid carcinoma. Most investigators believe that it represents a benign odontogenic neoplasm, probably arising from rests of Malassez, although a hamartomatous epithelial proliferation has also been considered.

The **histogenesis** of squamous odontogenic tumor may be varied. Rests of Malassez are the source of the epithelial proliferation for lesions that are associated with the alveolar process adjacent to the lateral root surface of the teeth, and dental lamina may be the source for lesions that developed in association with the crowns of unerupted or impacted teeth. Surface stratified squamous epithelium and rests of Serres have been cited as the sources of the extraosseous variant.

Clinical Features. The age at discovery of the 16 cases evaluated by Goldblatt and his coworkers ranged from 11 to 67 years with 10 cases being between 19 and 31 years of age. There were six males and 10 females in the series.

There is a slight male preponderance, and the mandible is commonly involved. In the maxilla, lesions centered around the incisor-cuspid area, whereas in the mandible, lesions had a predilection for the bicuspid-molar area. However, several cases exhibited multiple site involvement, including both maxillary and mandibular involvement in the same patient.

The lesions were often asymptomatic but presenting manifestations included mobility of involved teeth, pain, tenderness to percussion, and occasionally, abnormal sensations.

Radiographic Features. There are no radiographic features sufficiently characteristic to suggest the diagnosis of this condition. It presents as a semicircular or roughly triangular radiolucent area, with or without a sclerotic border, usually in association with the cervical portion of the tooth root (Fig. 4-31 A, B).

Histologic Features. The squamous odontogenic tumor is composed entirely of islands of mature squamous epithelium without a peripheral palisaded or polarized columnar layer (Fig. 4-31 C, D). This peripheral layer is usually quite flattened or at least cuboidal. The squamous cells are very uniform and exhibit no pleomorphism, nuclear hyperchromatism or mitotic activity. Occasionally, individual cell keratinization is present but no epithelial pearls. Intercellular bridges are usually seen with no difficulty. Three other variable findings are microcyst formation involving only small portions of the epithelial islands, laminar calcifications in the epithelium and globular, hyalin, eosinophilic structures within the islands, which are not amyloid. The fibrous stroma of the tumor is

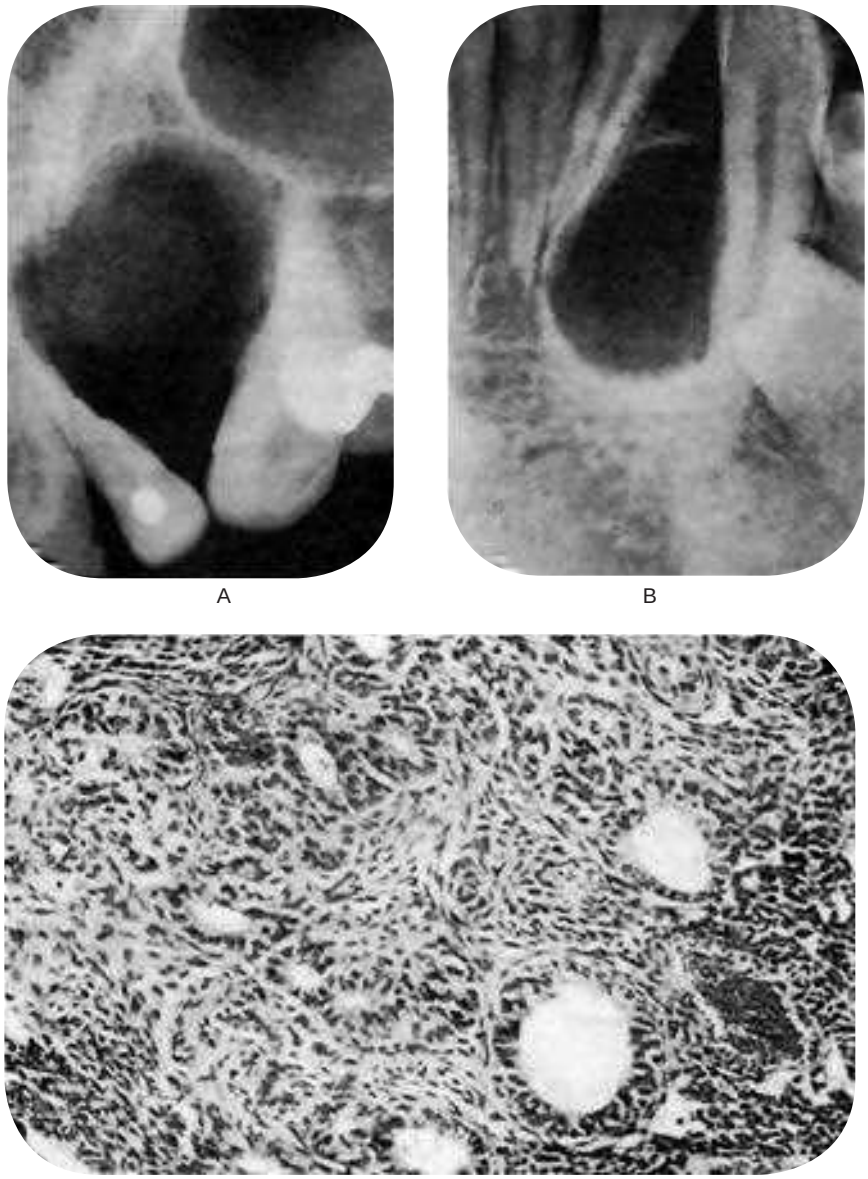

Figure 4-30. Adenomatoid odontogenic tumor.
The tumor in **(A)** radiographically resembled a globulomaxillary cyst. The tumor in **(B)** was associated with an impacted tooth and superficially resembled a dentigenous cyst. The photomicrograph **(C)** shows the typical duct like structures *(Courtesy of Dr Charles Redish and Dr Charles A Waldron).*

simply mature bundles of collagen fibers and is devoid of any peri-insular inductive effect.

Squamous odontogenic tumor like proliferations have been reported by Wright in the walls of odontogenic cysts, such as dentigerous or apical periodontal cysts. These proliferations may appear histologically nearly identical with those in the squamous odontogenic tumor, but they do not appear to cause any alteration in the usual biologic behavior of the cyst and do not appear to develop into the tumor. Care must be used, however, in differentiating between these proliferations and the tumor itself.

Although squamous odontogenic tumor exhibits a unique microscopic picture, it may be confused with other conditions, including ameloblastoma and squamous cell carcinoma. The acanthomatous and desmoplastic variants of ameloblastoma have been misdiagnosed as squamous odontogenic tumor. Both variants exhibit squamous differentiation within the tumor islands, but there is demonstrable ameloblastic change of the peripheral cells, including columnar shape, polarization of elongated nuclei away from the basement membrane, and a vacuolated or clear cytoplasm. These changes may be less evident in the desmoplastic variant but can be found on careful and thorough examination of the specimen. These changes are not seen in the squamous odontogenic tumor in which the peripheral cell layer is composed of flat to cuboidal cells. The islands and strands of desmoplastic ameloblastoma are often thin and compressed rather than rounded and broad-based, as seen in squamous odontogenic tumor.

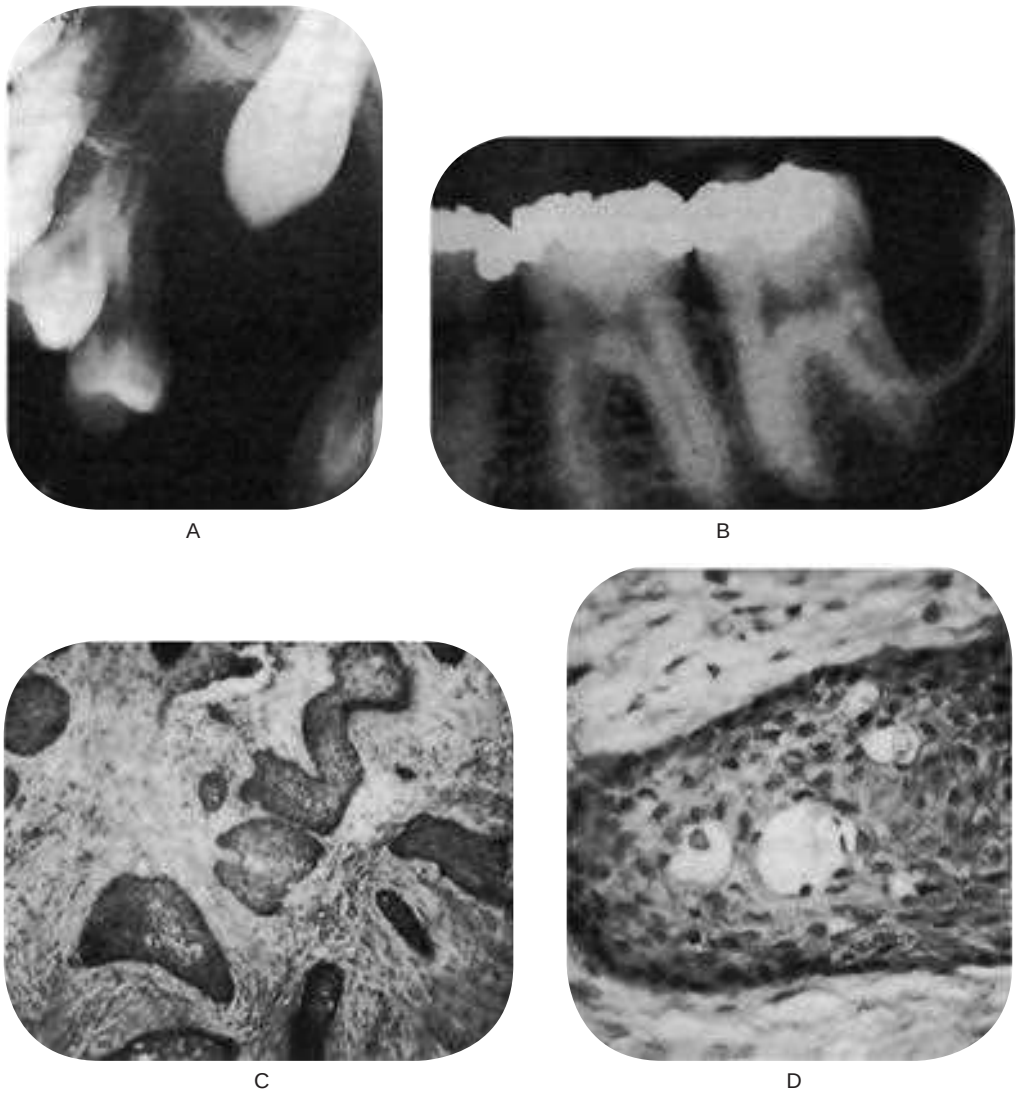

Figure 4-31. Squamous odontogenic tumor.
The radiographic appearance of the lesion **(A, B)** is nonspecific. However, the innocuous-appearing islands of squamous epithelium are quite characteristic (**C, D**) *(B, Courtesy of Dr Richard P Elzay and Dr Bennet Malbon).*

Squamous odontogenic tumor may be confused with well-differentiated squamous cell carcinoma; however, the islands in squamous odontogenic tumor are well defined, and the cells lack variation in cell size, shape and nuclear staining and mitotic figures that are characteristically seen in squamous cell carcinoma. Significant keratin formation also is not typical.

Occasionally, dentigerous and apical periodontal (radicular) cysts and periodontal granulation tissue exhibit foci of squamous odontogenic tumor like proliferation. This has been interpreted as a nonneoplastic, reactive process that is secondary to the cyst formation or inflammation. Foci of squamous odontogenic tumor within the connective tissue wall of odontogenic cysts do not seem to alter the prognosis of the primary cystic process.

Treatment. Enucleation, curettage, and local excision are treatment modalities that are most often described in case reports of squamous odontogenic tumor. Clinically aggressive lesions have been treated by en bloc excision.

ODONTOGENIC EPITHELIUM WITH ODONTOGENIC ECTOMESENCHYME WITH OR WITHOUT HARD TISSUE FORMATION

Ameloblastic Fibroma

(Soft mixed odontogenic tumor, soft mixed odontoma, fibroadamantoblastoma)

The ameloblastic fibroma is a relatively uncommon neoplasm of odontogenic origin which is characterized by the simultaneous proliferation of both epithelial and mesenchymal tissue without the formation of enamel or dentin. Thus this may be viewed as an example of a true mixed tumor.

Some investigators have suggested; however, that the ameloblastic fibroma represents an immature complex odontoma and that, if the tumor is left undisturbed, it will ultimately differentiate or mature further into a lesion known as an ameloblastic fibro-odontoma (q.v.) and then continue

maturation into a completely differentiated odontoma. In contrast, Eversole and his coworkers, in a discussion of the histogenesis of odontogenic tumors, have proposed that the mixed odontogenic tumors are solely and totally dependent upon the presence of differentiation factors which are or are not elaborated by a particular tumor. Thus, they have concluded that there is little probability of sequential differentiating events resulting in the progression of an immature entity such as the ameloblastic fibroma into a highly differentiated entity such as the complex odontoma. As Eversole and his associates discussed, and as Slootweg has emphasized, if these three lesions—the ameloblastic fibroma, the ameloblastic fibro-odontoma and the odontoma—were simply stages in a continuum, clinical data on each of the lesions should support this. For example, the ameloblastic fibroma should occur in younger patients, the odontoma in somewhat older patients and the ameloblastic fibro-odontoma in an intermediate age group. In addition, the gender predilection and distribution of all lesions should be the same. Slootweg has investigated this problem utilizing data from 55 reported cases of ameloblastic fibroma, 50 cases of ameloblastic fibro-odontoma, 77 cases of complex odontoma and 48 cases of compound odontoma. While correction had to be made for the fact that the odontogenic apparatus is active in various parts of the jaws at various ages, Slootweg concluded that the ameloblastic fibroma represents a separate specific neoplastic entity that does not develop into a more differentiated odontogenic lesion. He also concluded from his data that the ameloblastic fibro-odontoma does represent an immature complex odontoma, a hamartomatous rather than neoplastic odontogenic lesion.

Clinical Features. The ameloblastic fibroma, arising most commonly in the molar region of the mandible, is similar in location to the simple ameloblastoma. Nearly 75% of the 55 cases reviewed by Slootweg occurred in this location. There is a considerable difference, however, in the age group of patients most commonly affected. Whereas the simple ameloblastoma occurs typically in middle-aged persons, the average age of the patient at the time of discovery being approximately 33 years according to Small and Waldron, the ameloblastic fibroma occurs in much younger persons. In the review of 55 cases, Slootweg found that the average age of patients with the ameloblastic fibroma was 14.6 years, with 40% of the patients under the age of 10 years. He also reported that there was a very slight predilection for occurrence in males.

This tumor exhibits some what slower clinical growth than the simple ameloblastoma and does not tend to infiltrate between trabeculae of bone. Instead it enlarges by gradual expansion so that the periphery of the lesion often remains smooth. It will frequently cause no complaint on the part of the patient and has been discovered accidentally during radiographic examination. Pain, tenderness or mild swelling of the jaw may induce the patient to seek aid from the dentist, however.

Radiographic Features. No constant significant differences between the appearance of the simple ameloblastoma and that of the ameloblastic fibroma are found. The later is manifested as a unilocular or multilocular radiolucent lesion which has a rather smooth outline, often with a sclerotic border, and which may or may not produce evident bulging of bone (Fig. 4-32). In the study of 24 cases by Trodahl, most of the lesions were associated with unerupted teeth. In addition, he found considerable variation radiographically in the size of lesions, there being a range of 1–8.5 cm in diameter.

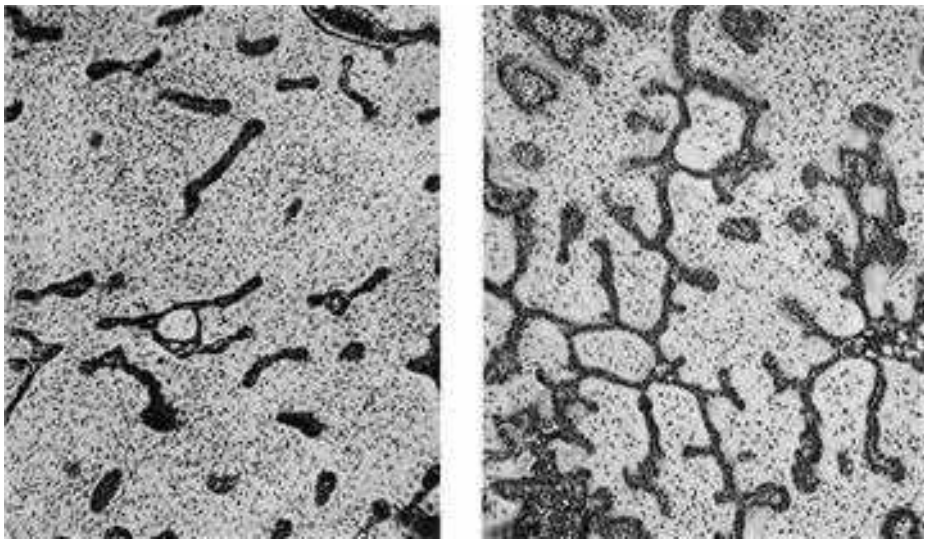
Figure 4-32. Ameloblastic fibroma.
The neoplasm was asymptomatic and was discovered during routine radiographic examination.

Histologic Features. The microscopic appearance of this odontogenic neoplasm is characteristic. The ectodermal portion consists of scattered islands of epithelial cells in a variety of patterns, including rosettes, long finger like strands, nest and cords. These epithelial cells are usually of a cuboidal or columnar type and bear close resemblance to primitive odontogenic epithelium. Mitotic activity is not common. Because the pattern of these cells is one of strands and cords, tissue resembling stellate reticulum is often not seen. However, occasional cases occur in which some of these tumor islands are found 'opening,' with the formation of stellate reticulum. The resemblance to the dental lamina is far more striking in this lesion than in the simple ameloblastoma (Fig. 4-33 A, B).

The mesenchymal component is made up of a primitive connective tissue that, in some cases, shows closely intertwining fibrils interspersed by large connective tissue cells closely resembling those of the dental papilla. There may be a paucity of blood vessels, and juxtaepithelial hyalinization of areas of the connective tissue occurs. On occasion, this may even resemble dysplastic dentin. Electron microscopic studies have suggested that this apparent hyalinization may, instead, actually represent exuberant basal lamina.

Treatment and Prognosis. The treatment of the ameloblastic fibroma has been somewhat more conservative than that of the simple ameloblastoma, since it does not appear to infiltrate bone as actively or as widely as the ameloblastoma. It also tends to separate from the bone more readily.

At one time the ameloblastic fibroma was regarded as exhibiting little tendency for recurrence, even following the



A B

Figure 4-33. Ameloblastic fibroma.
Within a stroma of primitive mesoderm there are interlacing thin strands of odontogenic epithelium, from which budding outgrowths arise. The epithelial buds have a peripherally placed row of more columnar cells and centrally placed more stellate cells.The septae of fibrous tissue may give the tumor a lobular pattern.

most conservative surgical removal. This was based on part on the review by Gorlin and his associates of 35 documented cases with only two instances of recurrence (approximately 6%). In contrast, Trodahl subsequently reported 10 recurrences in his series of 24 cases (approximately 44%). Since these two series, numerous other instances of recurrent lesions have been reported, and these have been reviewed and discussed by Zallen and his colleagues, who noted a total cumulative recurrence rate of 18.3% for this lesion. In addition, there have been a surprising number of cases reported of ameloblastic fibrosarcoma originating, at least in some instances, in a recurrent ameloblastic fibroma, as in the cases of Leider and his associates. Thus, it would seem that a somewhat more aggressive surgical removal, rather than simple curettage, should be considered for this lesion.

Ameloblastic Fibro-odontoma

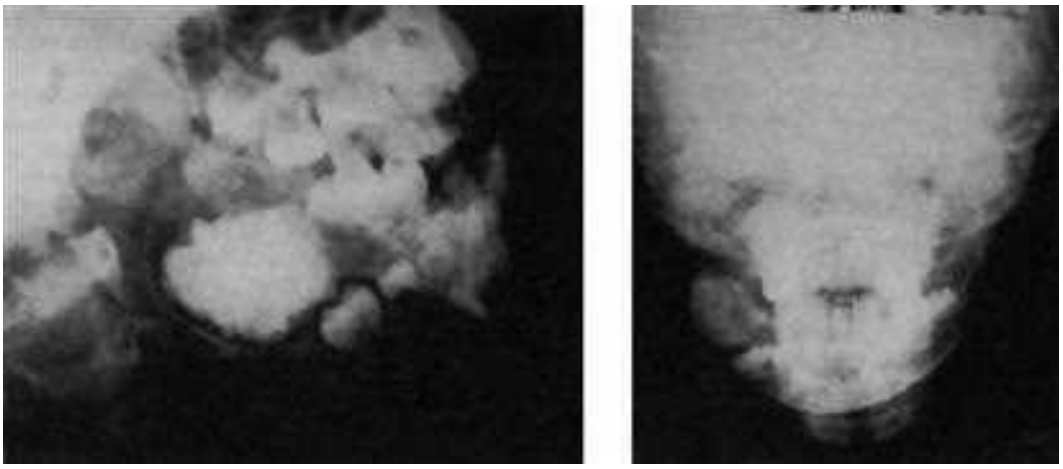
The ameloblastic fibro-odontoma (AFO) has been confused in the earlier literature with a lesion of similar nomenclature, the ameloblastic odontoma (q.v.), although a clear distinction between the two was finally drawn by Hooker in 1967 at the annual meeting of the American Academy of Oral Pathology. It has been emphasized that some investigators, furthermore, have believed that the ameloblastic fibroma (q.v.) represents an early, undifferentiated complex odontoma and that the ameloblastic fibro-odontoma is simply a further differentiated maturing odontoma. After investigating this problem, Slootweg concluded that the ameloblastic fibroma is a true neoplasm and does not differentiate into an ameloblastic fibro-odontoma. This evidence has been discussed in the section on ameloblastic fibroma. He also concluded that the ameloblastic fibro-odontoma to be discussed here did, in fact, represent an immature complex odontoma, and therefore, represented a hamartomatous rather than a neoplastic odontogenic lesion.

Clinical Features. The original report by Hooker consisted of 26 cases of ameloblastic fibro-odontoma. Of these 26 cases, there were 20 male and six female for a ratio of 3.3 : 1 in favor of the males. However, of the 50 cases reviewed by Slootweg, which did not include the 26 cases of Hooker, there were 28 males and 22 females. The age range of the cases in the series of Hooker was 0.5–39 years with the mean being 11.5 years of age. Nineteen of the 26 cases occurred under the age of 15, only two cases over the age of 20. In the Slootweg series, the mean age was 8.1 years, with 62% of the patients under the age of 10 years. Hooker's cases were evenly divided between the maxilla and mandible with 13 each. Nine of the 13 cases in the maxilla, and 10 of the 13 in the mandible occurred in the molar area. All cases were associated with an impacted tooth and three cases involved the maxillary sinus. Of Slootweg's cases, 38% were in the maxilla and 62% in the mandible, with 54% occurring in the posterior mandible.

Clinical manifestations of the lesion are often absent. The two most common presenting complaints are swelling and failure to tooth eruption.

Radiographic Features. The ameloblastic fibro-odontoma is almost invariably a well-circumscribed lesion, presenting as an expansile radiolucency generally containing either a solitary radiopaque mass or multiple small opacities representing the odontoma portion of the lesion (Fig. 4-34). Some of the lesions are relatively small when first detected, measuring not over 1–2 cm in diameter, while others may be exceedingly large, involving a considerable portion of the body of the mandible and even extending into the ramus. Occasionally, these lesions will become huge. A case was illustrated by Miller and his associates in their series that showed the calcified mass alone to measure 6 cm by 7 cm and that had produced a terrible facial deformity.

Histologic Features. The lesion consists of the same apparent type of tissue as seen in the ameloblastic fibroma.



A B

Figure 4-34. Ameloblastic fibro-odontoma.

Thus, cords, fingers, strands and rosettes of primitive odontogenic columnar or cuboidal epithelial cells, often resembling dental lamina, are found. The mesenchymal component is an embryonic fibrous connective tissue with delicate fibrils interspersed by large primitive fibroblasts, all resembling dental papilla. In addition, typical composite odontoma is found (Fig. 4-35 A, B).

Treatment and Prognosis. The ameloblastic fibro-odontoma is treated by curettage, since it does not appear to locally invade bone. There appears to be little tendency for recurrence of the ameloblastic fibro-odontoma. Tsagaris reviewed a total of 77 cases, including Hooker's 26 cases from the Armed Forced Institute of Pathology, and of 29 cases which he was able to follow up, found only one recurrence.

Odontoma

The term 'odontoma', by definition alone, refers to any tumor of odontogenic origin. Through usage, however, it has come to mean a growth in which both the epithelial and the mesenchymal cells exhibit complete differentiation, with the result that functional ameloblasts and odontoblasts form enamel and dentin. This enamel and dentin are usually laid down in an abnormal pattern because the organization of the odontogenic cells fails to reach a normal state of morphodifferentiation. Most authorities accept the view today that the odontoma represents a hamartomatous malformation rather than a neoplasm. This lesion is composed of more than one type of tissue, and for this reason, has been called a composite odontoma. In some composite odontomas the enamel and dentin are laid down in such a fashion that the structures bear considerable anatomic resemblance to normal teeth, except that they are often smaller than typical teeth. They have been termed *compound composite odontomas* when there is at least superficial anatomic similarity to normal teeth. On the other hand, when the calcified dental tissues are simply an irregular mass bearing no morphologic similarity even to rudimentary teeth, the term *complex composite odontoma* is used. The complex form of odontoma is less common than the compound type.

Etiology. The etiology of the odontoma is unknown. It has been suggested that local trauma or infection may lead

to the production of such a lesion. This is entirely possible, but it would appear more likely that in such an event hypoplasia would be the end-result, depending upon the stage of odontogenesis. There is no seeming predilection for occurrence of the odontoma in particular sites of the oral cavity; it does not appear to be associated especially with supernumerary teeth, as might be suggested were it to occur with great frequency between the maxillary central incisors or distal to the maxillary third molar.

It has been suggested by Hitchin that odontomas are either inherited or are due to a mutant gene or interference, possibly postnatal, with the genetic control of tooth development. On the other hand, Levy has reported the experimental production of this lesion in the rat by traumatic injury.

Clinical Features. The odontoma may be discovered at any age in any location of this dental arch, maxillary or mandibular. Budnick has compiled an analysis of 149 cases of odontoma (76 complex and 73 compound) from the literature (65 cases) and from the files of Emory University (84 cases). While it may be discovered at any age, from the very young to the very elderly, he found the mean age of detection to be 14.8 years, with the most prevalent age for diagnosis and treatment being the second decade of life. He also found a slight predilection for occurrence in males (59%) compared with females (41%).

Of all odontomas combined, 67% occurred in the maxilla and 33% in the mandible. The compound odontoma had a predilection, in this study, for the anterior maxilla (61%), whereas only 34% of complex odontomas occurred here. In general, complex odontomas had a predilection for the posterior jaws (59%) and lastly the premolar area (7%). Interestingly, both types of odontomas occurred more frequently on the right side of the jaw than on the left (compound, 62%; complex 68%). The odontoma usually remains small, the diameter of the mass only occasionally greatly exceeding that of a tooth. Occasionally, it does become large and may produce expansion of bone with consequent facial asymmetry. This is particularly true if a dentigerous cyst develops around the odontoma.

Most odontomas are asymptomatic, although occasionally signs and symptoms relating to their presence do occur. These generally consist of unerupted or impacted teeth, retained deciduous teeth, swelling and evidence of infection.

Radiographic Features. The radiographic appearance of the odontoma is characteristic. Since most odontomas are clinically asymptomatic and are discovered by routine radiographic examination, the dentist should be familiar with their appearance. They are often situated between the roots of teeth and appear either as an irregular mass of calcified material surrounded by a narrow radiolucent band with a smooth outer periphery (Fig. 4-36), or as a variable number of tooth like structures with the same peripheral outline. This latter type of odontoma may contain only a few structures resembling teeth, or it may contain several dozen (Fig. 4-36). Both forms of odontoma are frequently associated with unerupted teeth. It is of interest that the majority of odontomas in the anterior segments of the jaws are compound composite in type, while the majority in the posterior areas are complex composite. This latter odontoma may appear also as a calcified mass overlying the crown of an unerupted or impacted tooth. A developing odontoma may be discovered on the routine radiograph and present difficulty in diagnosis because of the lack of calcification (Fig. 4-37).

Histologic Features. The histologic appearance of the odontoma is not spectacular. One finds normal-appearing enamel or enamel matrix, dentin, pulp tissue and cementum which may or may not exhibit a normal relation to one another (Fig. 4-38). If the morphologic resemblance to teeth does exist, the structures are usually single-rooted. The connective tissue capsule around the odontoma is similar in all respects to the follicle surrounding a normal tooth.

One additional interesting feature is the presence of 'ghost' cells in odontomas. These are the same cells described in the calcifying odontogenic cyst (q.v.) and have been reported by Levy to be present in nearly 20% of a series of 43 odontomas which he investigated. This has been substantiated by Sedano and Pindborg, although they could find no significance attached to the presence of these cells regarding prognosis or treatment of the odontoma.

Treatment and Prognosis. The treatment of the odontoma is surgical removal, and there is no expectancy of recurrence. Since both the ameloblastic odontoma and the ameloblastic fibro-odontoma bear great resemblance to the common odontoma, particularly on the radiograph, it is suggested that all odontomas be sent to a qualified oral pathologist for microscopic examination.

Ameloblastic Odontoma
(Odontoameloblastoma)

The ameloblastic odontoma is an odontogenic neoplasm characterized by the simultaneous occurrence of an ameloblastoma and a composite odontoma. As judged by the reported cases reviewed by Frissell and Shafer, it is a rare clinical entity. It should not be inferred that this tumor represents two separate neoplasms growing in unison; there exists, rather, a peculiar proliferation of tissue of the odontogenic apparatus in an unrestrained pattern, including complete morphodifferentiation, as well as apposition and even calcification. The lesion is unusual in that a relatively undifferentiated neoplastic tissue is associated with a highly differentiated tissue, both of which may show recurrence after inadequate removal.

Clinical Features. So few cases of this tumor have been reported that any statistical information may not be valid. However, the ameloblastic odontoma appears to occur at any age, but more frequently in children, and is somewhat more common in the mandible than in the maxilla. It is a slowly expanding lesion of bone which produces considerable facial deformity or asymmetry if left untreated. Since it is a central lesion, considerable destruction of bone occurs. Mild pain may be a presenting complaint, as well as delayed eruption of teeth.

Radiographic Features. Central destruction of bone with expansion of the cortical plates is prominent. The character-

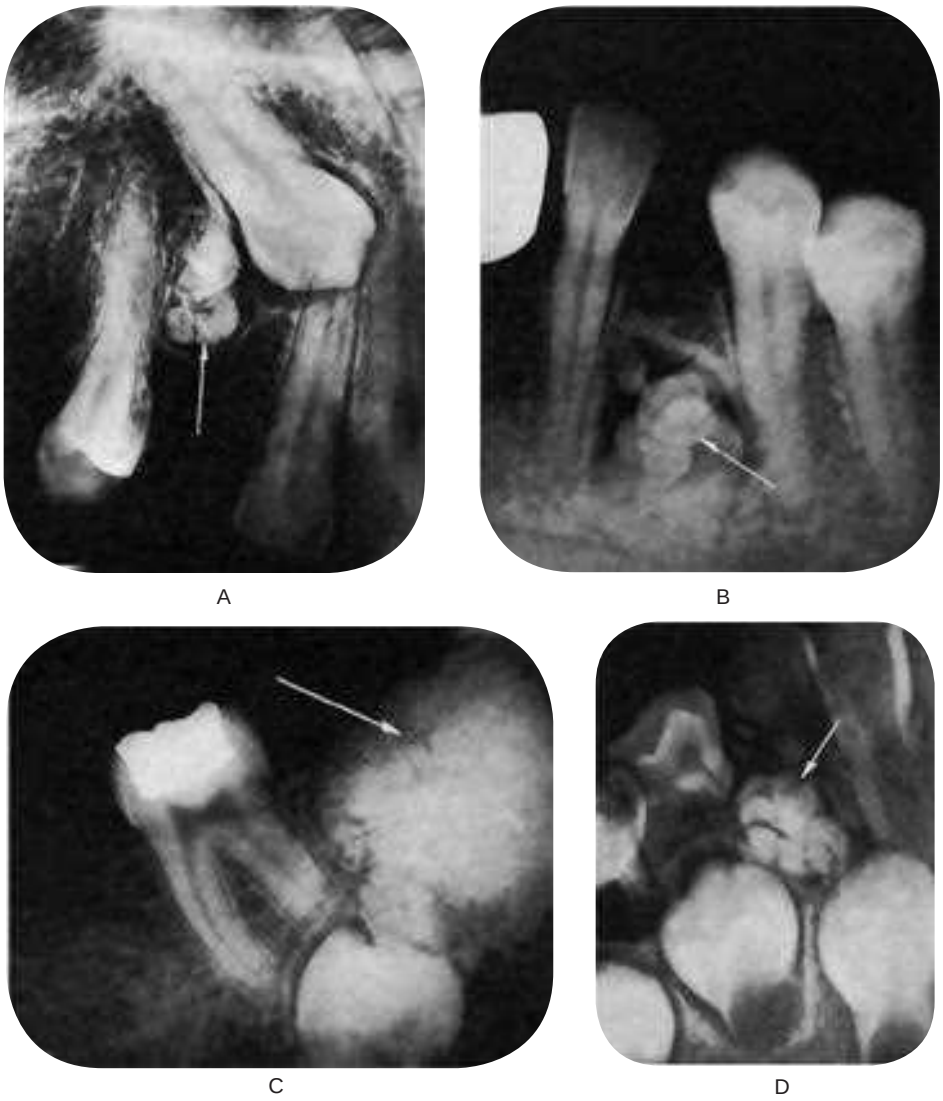

Figure 4-36. Odontoma.
Radiographs **(A)** and **(B)** illustrate two examples of compound composite odontoma, and **(C)** shows an example of a complex composite odontoma. The odontoma may also occur in young children, as seen in radiograph **(D)**. *(C, Courtesy of Dr Wilbur C Moorman).*

istic feature is the presence within the lesion proper of numerous small radiopaque masses which may or may not bear resemblance to formed, albeit miniature, teeth (Fig. 4-39 A). In other instances there is only a single, irregular radiopaque mass of calcified tissue present. Thus the radiographic appearance of the ameloblastic odontoma is identical with that of the composite odontoma of one form or another.

Histologic Features. The microscopic appearance of this tumor is both unusual and characteristic. It consists of a great variety of cells and tissue in a complex distribution, including columnar, squamous and undifferentiated epithelial cells, as well as ameloblasts, enamel and enamel matrix, dentin, osteodentin, dentinoid and osteoid material, stellate reticulum-like tissue, dental papilla, bone and cementum as well as stromal connective tissue (Fig. 4-39 B). Many structures resembling normal or atypical tooth germs may be found, with or without the presence of calcified dental tissues. In addition, an outstanding characteristic is the presence of sheets of typical ameloblastoma of one or another of the recognized types — usually basal cell, follicular or plexiform. Few mitotic figures are present even though the proliferative tendencies of the epithelial cells are obvious.

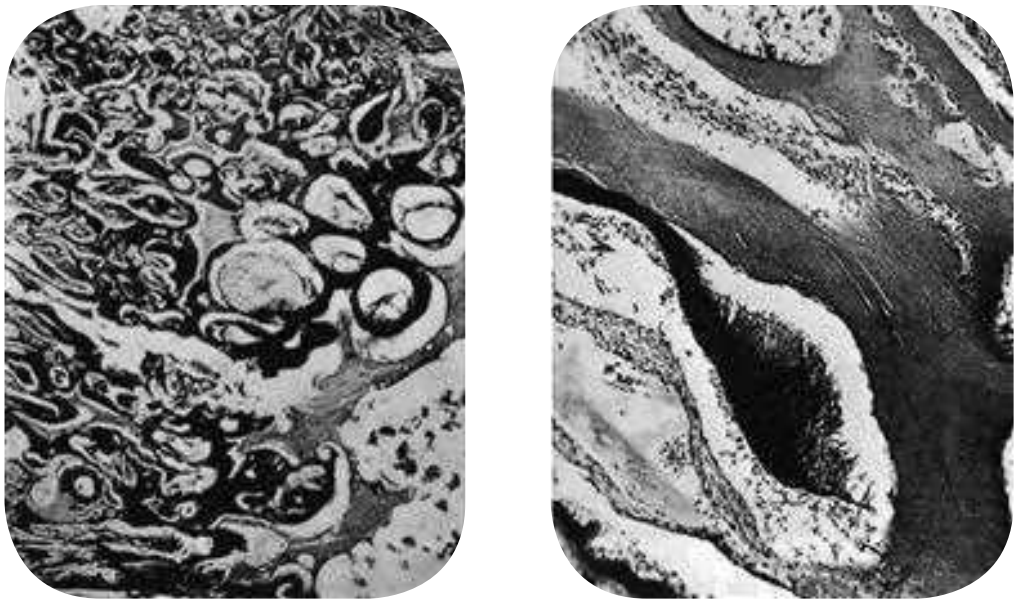
Treatment and Prognosis. The treatment of the ameloblastic odontoma is controversial, probably because there are few published cases. Some investigators believe that recurrence, associated with continued destruction of tissue, is common after conservative curettage or enucleation and that a more radical approach is necessary. Resection of the jaw, if possible preserving the inferior border of the mandible when this area is uninvolved, will certainly result in a permanent cure. The general behavior of this lesion is the same as that of the ameloblastoma component, and therefore, the same philosophy of management would also apply here as for the ameloblastoma.

Figure 4-37. Developing odontoma.

Calcifying Odontogenic Cyst and Dentinogenic Ghost Cell Tumor

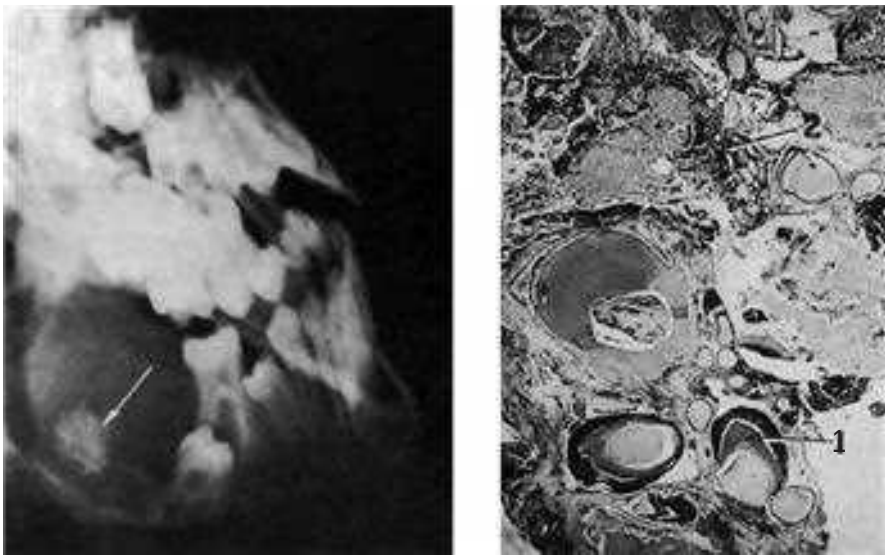
The calcifying odontogenic cyst was first described as a distinct clinicopathologic entity by Gorlin and his colleagues in 1962. Gold (1963) chose a similar, but not identical term for the lesion, namely **'keratinizing and calcifying odontogenic cyst'**. Perhaps the **Gorlin-Gold cyst** would be a fitting term for this interesting odontogenic lesion (Tomich CE, 2004). Kurt Thoma and Henry Goldman considered the lesions to be odontogenic tumors of ectodermal and mesodermal origin. They were not far from being correct. All of the investigators noted the unusual 'ghost cell' keratinization of the odontogenic epithelium which is the striking histologic feature of the entity. Gorlin and his associates suggested that the calcifying odontogenic cyst might be the oral analog of the 'calcifying epithelioma of Malherbe' (now preferably termed a 'pilomatricoma'); a well-recognized lesion of skin. The lesions have in common the peculiar abnormal keratinization of odontogenic and metrical (hair) epithelial cells that is termed 'ghost cell' or 'shadow cell' keratinization. Actually, the calcifying odontogenic cyst shares more histologic features with the rare, intracranial neoplasm known as 'craniopharyngioma.'

As more and more cases were studied, it became apparent that the lesion was not always a cyst; sometimes it was a solid lesion. Furthermore, it became apparent that the lesion could present centrally within the jaws or as an extraosseous gingival lesion. This raises the question: "Is the Gorlin cyst a cyst or is it a tumor that is frequently cystic?" In view of these findings, investigators suggested different names for this lesion. Fejerskov and Krogh suggested the term **'calcifying ghost cell odontogenic tumor'** and Freedman and his associates suggested the name **'cystic calcifying odontogenic tumor'**. Neither of these terms met with approval, possibly because of their similarity to the well-recognized lesion called the 'calcifying epithelial odontogenic tumor' or Pindborg tumor.



A B

Figure 4-38. Odontoma.
The admixture of dental tissues is illustrated in the photographs.



A B

Figure 4-39. Ameloblastic odontoma.
The radiograph **(A)** shows the destructive lesion of the mandible containing numerous small, irregular calcified masses. The photomicrograph **(B)** reveals that these are dental tissue, enamel and dentin (1), in association with an ameloblastoma (2).

The issue of 'cyst versus tumor' or 'cystic versus solid' has not been resolved totally. The calcifying odontogenic cyst can be classified mainly into two type:

- Cystic lesion
- Solid neoplastic lesion.

A third malignant counterpart of the neoplastic lesion may be added.

Clinical Features. The calcifying odontogenic cyst is not a common lesion; the dentinogenic ghost cell tumor is even less common and should be considered rare. Despite the uncommon occurrence of the calcifying odontogenic cyst and the rare dentinogenic ghost cell tumor, the former has gained wide recognition and a large series of cases have been reported in the literature. Although the calcifying odontogenic cyst may be seen in any decade of life, studies have shown predilection for persons in the second and third decades. The cyst occurs in both genders with almost equal frequency. Buchner's extensive review of 215 cases included 110 women and 105 men. The lesion has been seen in many racial groups. Buchner reported that in Asians there was a predilection for the maxilla, whereas in whites there was a 62% predisposition in the mandible.

Radiographic Features. The calcifying odontogenic cyst that occurs centrally in the jaws may present as a painless expansile lesion or it is discovered frequently on routine radiographic examination. The lesions may present as radiolucencies or radiolucencies with foci of opacification, particularly in the case of those that are associated with odontomas. Expansion may be evident in some cases. The dentinogenic ghost cell tumor is known to present as an expansile radiopacity. The lesions that occur peripherally (extraosseous) on the gingiva present as painless swellings or nodules. There are no pathognomonic clinical features that are diagnostic of the lesion.

Histologic Features. The main histopathologic criteria for the diagnosis of the calcifying odontogenic cyst are well established. The cyst lining should show proliferation to the point that it resembles ameloblastoma (i.e. columnar cells over which are stellate and spindled cells in an arrangement that suggest stellate reticulum). Within this proliferation of epithelium, cells undergo the characteristic 'ghost cell' keratinization. The calcifying odontogenic cyst is often encountered in association with an odontoma which may be identified in juxtaposition to the proliferative lining epithelium or intermixed with the ghost cells. This has been called 'dentinoid'. When this material is formed in abundance and the lesion is 'solid' rather than 'cystic', the lesion may be termed a 'dentinogenic ghost cell tumor'. Dystrophic calcification of the ghost cells may be seen; however, it is one of the less common and least important of the histologic features (Fig. 4-40). The presence of ghost cells within the proliferative odontogenic epithelium is the essential characteristic for the diagnosis. The presence of ghost cell keratinization alone is not sufficient enough for the diagnosis nor is it pathognomonic. Ghost cell keratinization may be observed in odontomas, ameloblastomas, ameloblastic fibro-odontomas, and in ameloblastic odontomas. Thus, one must observe ghost cells to make the diagnosis of the Gorlin cyst (Fig. 4-41).

The ghost cells contained nuclear remnants, remnants of cytoplasmic organelles, and numerous tonofilaments. The ghost cells differ from normal keratotic squames in that they are larger, often vacuolated, and the remnants of the nuclear membranes are more prominent. This may be due to intracellular edema and the presence of dilated degenerated membranous organelles.

Although Gorlin and his coworkers suggested that the calcifying odontogenic cyst is the oral counterpart of the

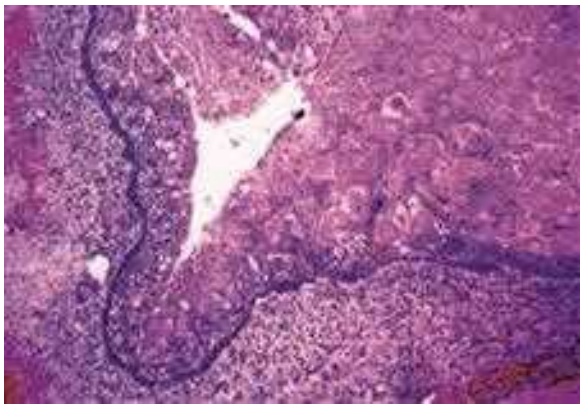


Figure 4-40. Calcifying odontogenic cyst.

cutaneous calcifying epithelioma of Malherbe (pilomatricoma), it is more likely to be the oral counterpart of the intracranial craniopharyngioma due to immunologic similarity. Both lesions demonstrated similar immunoreactivity to low and high molecular weight cytokeratins and involucrin—a protein that is characteristic of terminally-differentiated keratinocytes.

Treatment and Prognosis. The calcifying odontogenic cyst, with or without an associated odontoma, can be treated successfully by enucleation or thorough curettage. Peripheral lesions should be treated by conservative excision. The central (intraosseous) dentinogenic ghost cell tumor is treated by surgical excision. The removal of the tumor may require block excision or segmental resection, depending upon its size or anatomic extent. Recurrence following conservative treatment has been reported.

A rare malignant counterpart is recognized which was first reported in the Spanish language literature in 1965 by Astacio and Martinez. This tumor has been known by a variety of terms, including **malignant calcifying odontogenic cyst, odontogenic ghost cell carcinoma**, and **aggressive epithelial ghost cell odontogenic tumor**, to name a few. The designation **odontogenic ghost cell carcinoma** seems to be descriptive and specific. These tumors are unusual and rare lesions which develop in previously diagnosed calcifying odontogenic cysts or as de novo tumors. They are capable of locally aggressive behavior as well as distant metastasis.

ODONTOGENIC ECTOMESENCHYME WITH OR WITHOUT INCLUDED ODONTOGENIC EPITHELIUM

Peripheral Odontogenic Fibroma

There are a variety of different types of focal proliferative lesions which may occur on the gingiva, some neoplastic but others inflammatory, including such entities as the peripheral giant cell granuloma, pyogenic granuloma, giant cell fibroma, the simple fibroma, and the peripheral ossifying fibroma (q.v.). At one time, the terms 'peripheral ossifying fibroma' and 'peripheral odontogenic fibroma' were used quite interchangeably for one of these lesions. However, WHO, in its classification of odontogenic tumors, has used the term 'peripheral odontogenic fibroma' for a specific entity, quite separate from the peripheral ossifying fibroma, and designated specifically in the past also as an 'odontogenic gingival epithelial hamartoma' by Baden and his coworkers and as a 'peripheral ameloblastic fibrodentinoma' by numerous oral pathologists such as McKelvy and Cherrick.

The peripheral ossifying fibroma has been separated here from the peripheral odontogenic fibroma and is discussed in Chapter 2 in the Benign Connective Tissue Tumors section. The peripheral odontogenic fibroma, sometimes characterized as the 'WHO type', is considered here as an odontogenic tumor. An attempt at clarifying the distinction between these two conditions has been published recently by Gardner.

Clinical Features. The peripheral odontogenic fibroma, in distinct contrast to the peripheral ossifying fibroma, is a rare lesion. The largest series of cases reported has been that of Farman, who found only five cases in an extensive review of the English-language literature and added 10 new cases. There was no gender predilection in the 15 reported cases, while the ages of the patients ranged from five to 65 years, spaced throughout the various decades. There did seem to be a predilection for occurrence in the mandible, which was the site of 11 cases compared with only four cases in the maxilla.

The lesions appear to be slow growing, often present for a number of years. They are generally described as a solid, firmly attached gingival mass, sometimes arising, between teeth and sometimes displacing teeth (Fig. 4-42 A). Some lesions are found to contain a calcified stalk at the time of surgery and this, or other islands of calcified material, may be seen as radiopaque flecks on the radiograph.

Histologic Features. The peripheral odontogenic fibroma consists of a markedly cellular fibrous connective tissue

parenchyma, not the usual bland, acellular collagenous stroma of many tumors, with non-neoplastic islands, strands and cords of columnar or cuboidal, sometimes vacuolated odontogenic epithelium ranging from scanty to numerous. When numerous, the peripheral odontogenic fibroma has been occasionally mistaken for an epithelial neoplasm such as a peripheral ameloblastoma (Fig. 4-42B–E). This epithelium is usually deep in the lesion, away from the surface epithelium and is sometimes found 'cuffing' calcifications. Calcified tissue may or may not be present in the peripheral odontogenic fibroma. If found, it may resemble trabeculae of bone or osteoid, dentin or osteodentin (sometimes described as dysplastic dentin), or cementum like material. Mature fibrous connective tissue stroma is present and is sometimes highly vascularized, particularly in the less cellular areas. Myxomatous changes may also be found in the stroma, and the presence of inflammation is variable.

Treatment. The lesion is treated by surgical excision. In the series reported by Farman, no lesion was known to recur.

Central Odontogenic Fibroma

The odontogenic fibroma is a central tumor of the jaws which is seen so infrequently that little is known about this neoplasm. Of all the odontogenic tumors, this lesion has the most poorly defined parameters. The major explanation for the uncertainty regarding this tumor, as discussed by Gardner in his attempt at unification of the concept of the central odontogenic fibroma, is the lack of unanimity of definition of the lesion.

Three basic concepts have existed concerning this tumor:

- It is a lesion around the crown of an unerupted tooth resembling a small dentigerous cyst, although most investigators regard this as simply a hyperplastic dental follicle and not an odontogenic tumor.
- It is a lesion of fibrous connective tissue, with scattered islands of odontogenic epithelium, bearing some resemblance to the dental follicle but because of the size which it may attain appearing to constitute a neoplasm.
- It is a lesion which has been described by WHO as a fibroblastic neoplasm containing varying amounts of odontogenic epithelium, and in some cases, calcified material resembling

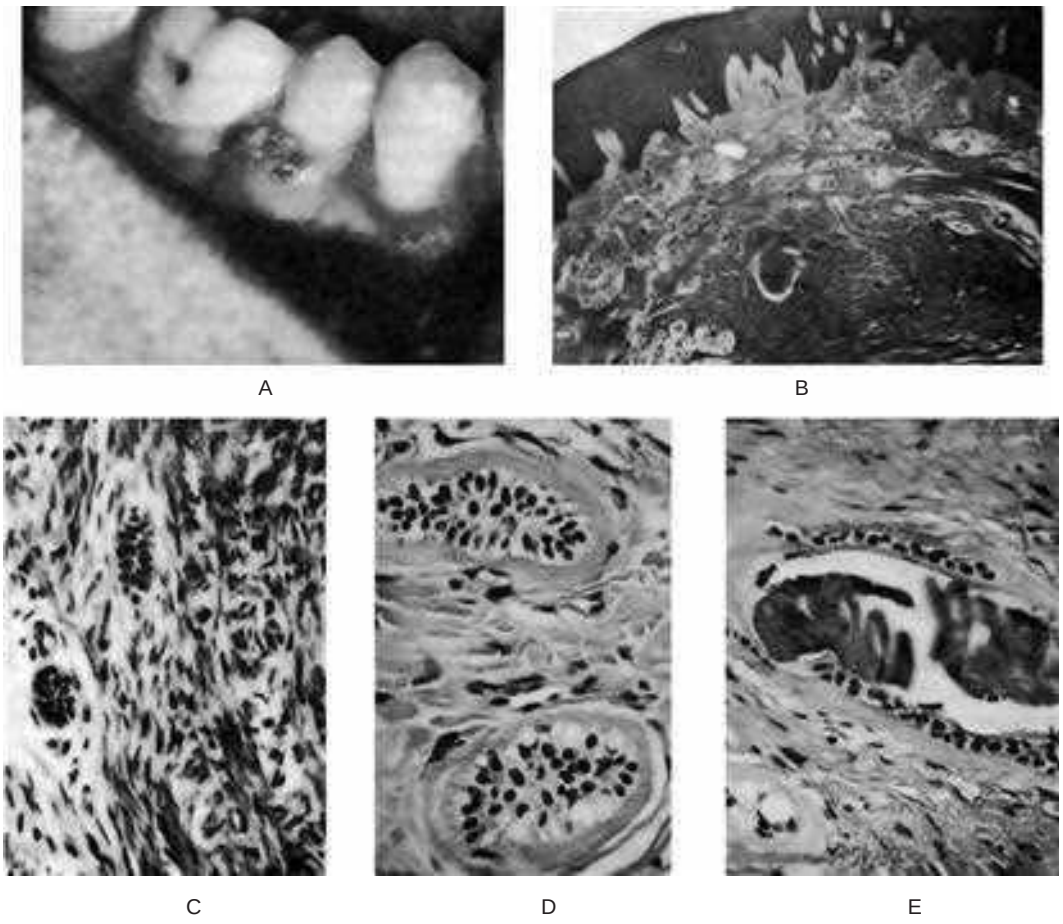

Figure 4-42. Peripheral odontogenic fibroma.
The mass on the gingiva **(A)** is characterized histologically by a cellular connective tissue containing islands of odontogenic epithelial cells, some of which show a clear vacuolated cytoplasm, and few foci of calcifications **(B, C, D, E)**. *(A, Courtesy of Dr Richard Henry; D and E, Courtesy of Dr Howard Goldstein).*

dysplastic dentin or cementum like material; thus, except for location, it is histologically identical to the peripheral odontogenic fibroma as described by the WHO group.

Since the occurrence of the latter two lesions in the jaws is undeniable even though their histogenesis is uncertain, Gardner has suggested referring to the tumor made up of connective tissue and odontogenic islands resembling dental follicle as the **simple central odontogenic fibroma** and to the tumor described by the WHO as the **WHO-type central odontogenic fibroma**. Until more cases of each are reported to clarify their histogenesis and their relationship, if any, this approach appears reasonable.

The simple central odontogenic fibroma has been discussed by Wesley and his associates, who reviewed eight cases, including one of their own, which they believed met the histologic criteria for this form of the lesion, while Dahl and her associates have added two more cases. Farman has reviewed eight cases of the WHO type of central odontogenic fibroma from the literature in his paper dealing basically with the peripheral form of this neoplasm. Thus, it may be seen that too few examples of either type of central odontogenic fibroma have been reported from which one may draw any significant conclusions regarding specific clinical features, treatment or prognosis.

Clinical Features. The odontogenic fibroma appears to occur more frequently in children and young adults, although a few cases have been reported in older persons, and has a predilection for occurrence in the mandible. It is generally asymptomatic except for swelling of the jaw.

Radiographic Features. This tumor sometimes produces an expansile, multilocular radiolucency similar to that of the ameloblastoma (Fig. 4-43 A).

Histologic Features. The odontogenic fibroma of both types has been described above. The **simple type** is characterized by a tumor mass made up of mature collagen fibers interspersed usually by many plump fibroblasts that are very uniform in their placement and tend to be equidistant from each other. Small nests or islands of odontogenic epithelium that appear entirely inactive are present in variable but usually in quite minimal amounts (Fig. 4-43 B).

The **WHO type** also consists of relatively mature but quite cellular fibrous connective tissue with few to many islands of odontogenic epithelium. Osteoid, dysplastic dentin or cementum like material is also variably present.

Care must be exercised not to misdiagnose other fibrous lesions of the jaws as an odontogenic fibroma. Lesions to be considered in the differential diagnosis include neurofibroma and desmoplastic fibroma.

Treatment and Prognosis. The treatment of this neoplasm is surgical excision. Little is known about recurrence.

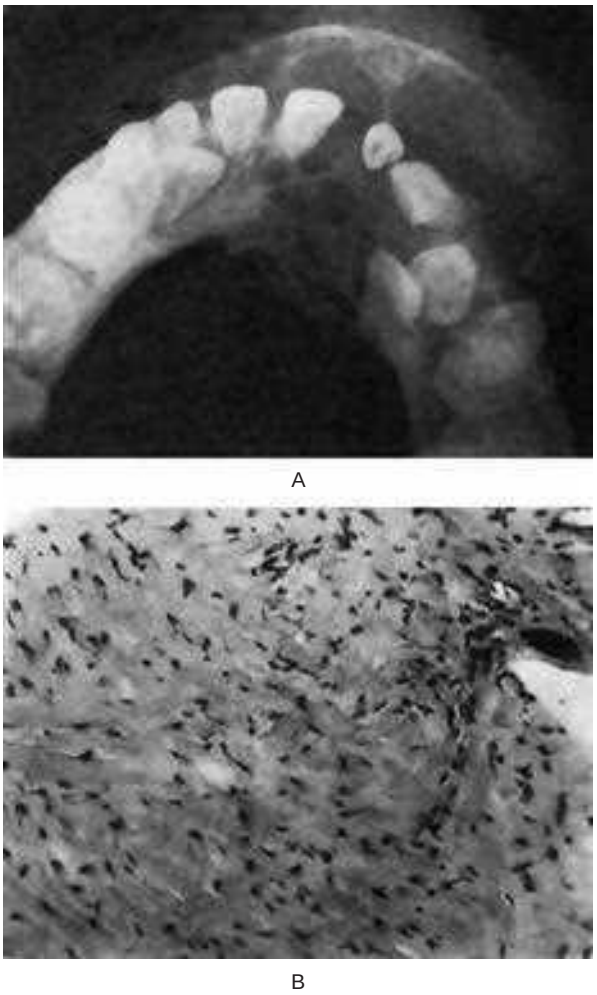

Figure 4-43. Central odontogenic fibroma.
The radiograph **(A)** exhibits expansion of the mandible with thinning of the cortical plates. The radiographic appearance is suggestive of ameloblastoma. The photomicrograph **(B)** shows the bundles of collagen fibers and an epithelial rest *(Courtesy of Dr Charles A Waldron).*

Odontogenic Myxoma
(Odontogenic fibromyxoma or myxofibroma)

The odontogenic myxoma is a tumor of the jaws which apparently arises from the mesenchymal portion of the tooth germ, either the dental papilla, the follicle or the periodontal ligament. Previous reports of this tumor have been discussed by many investigators, most recently White and his colleagues, who summarized pertinent data on over 90 individual and series of cases of odontogenic myxoma of the jaws, including their own group of nine cases. Absolute proof of origin from the odontogenic apparatus is lacking for this lesion, but it appears most likely because of the frequent occurrence of this lesion in the jaws and almost universal absence in any other bone of the skeleton. For example, in a study by McClure and Dahlin of 6,000 cases of bone tumors at the Mayo Clinic up to 1976, no cases involving bones other than the jaws were found.

Clinical Features. The odontogenic myxoma occurs most frequently in the second or third decade of life, the average age in the various reported series ranging from 23–30 years. It rarely occurs before the age of 10 years or after the age of 50. There is no particular gender predilection in the

occurrence of this tumor, and there is a slight predilection for occurrence in the mandible. Occasional cases occur outside the tooth-bearing areas, several cases having been reported in the condyle or neck of the condyle. In the series reported by Thoma and Goldman, nearly every case was associated with missing or embedded teeth. However, in many instances this is not the case.

The odontogenic myxoma is a central lesion of the jaws which expands the bone and may cause destruction of the cortex. It is not a rapidly growing lesion, and pain may or may not be a feature.

Radiographic Features. The radiograph may present a mottled or honeycombed appearance of bone in some cases, while others may appear as a destructive, expanding radiolucency which sometimes has a multilocular pattern (Fig. 4-44 A, B). Displacement of teeth by the tumor mass is a relatively common finding, but root resorption is less frequent. The tumor is often extensive before being discovered. Invasion of the antrum occurs frequently in lesions of the maxilla.

B

Figure 4-44. Odontogenic myxoma.
(Courtesy of Dr Paul and Dr Emmett Jurgens).

Figure 4-45. Odontogenic myxoma.
High-power view of randomly arranged, spindle-shaped, stellate, and rounded cells in a loose myxoid stroma (hematoxylin and eosin, original magnification x10) *(Courtesy of Dr RB Brannon).*

Histologic Features. The myxoma is made up of loosely arranged, spindle-shaped and stellate cells, many of which have long fibrillar processes that tend to intermesh. The loose tissue is not highly cellular, and those cells present do not show evidence of significant activity (pleomorphism, prominent nucleoli or mitotic figures). The intercellular substance is mucoid. The tumor is usually interspersed with a variable number of tiny capillaries and occasionally strands of collagen. Nests of odontogenic epithelium may be found infrequently (Fig. 4-45).

Hodson and Prout have reported the presence of two acid mucopolysaccharides in the odontogenic myxoma: relatively large quantities of hyaluronic acid and lesser amounts of chondroitin sulfate. They have suggested that this high hyaluronic acid component may be a significant factor in the neoplastic behavior of the tumor.

Histochemical studies by Mori and his associates have shown that the tumor cells with long anastomosing processes in the odontogenic myxoma exhibited high alkaline phosphatase and lactate dehydrogenase activity, while there was low acid phosphatase, glucose-6-phosphate dehydrogenase and isocitrate dehydrogenase activity. These enzymatic reactions differed from those present in osteogenic sarcomas or even benign proliferating fibrous lesions such as osteogenic fibroma or a fracture callus. This suggested to the investigators that the tumor cells of the myxoma are not as biologically active as other tumors of the jaws.

Ultrastructural studies have also been reported by several investigators. White and his associates described 'pale' cells which probably represented active secretory cells, the 'secretion' actually representing transportation of synthesized material though to be nonsulfated mucopolysaccharide, the myxoid material, into the intercellular compartment. The other cell type, the 'dark' cell, contained collagen fibrils, and this suggested a disturbance in the secretory process of collagen molecules so that they became crystallized into fibrils intracellularly.

The ultrastructural studies of Goldblatt have also led him to conclude that the myxoma cell is not a typical fibroblast, that there is an attempt at collagen fibrillogenesis with little ultimate success and that prominent secretory activity within tumor cells appears to result in excess production of acid mucopolysaccharide matrix. He also pointed out that, according to other investigators, there may be actual phagocytosis by tumor cells of the small amount of collagen present. Finally, he concluded that, while the myxoma cells showed many characteristics of fibroblasts of the odontogenic apparatus, tumor origin from nonodontogenic mesenchyme cannot be ruled out by existing ultrastructural studies.

Care must be used in distinguishing the odontogenic myxoma histologically from a variety of other myxoid lesions, including myxoid neurofibroma, myxoid liposarcoma, and myxoid chondrosarcoma.

Treatment and Prognosis. The treatment of odontogenic myxomas is surgical excision, followed by cautery. Extensive lesions may require resection to eradicate the tumor. Although this is a benign neoplasm, it frequently exhibits insidious local invasion, making its complete removal difficult, a problem augmented by the loose, gelatinous nature of the tissue itself. The prognosis is good despite unpredictable recurrence. The tumor is not sensitive to X-ray radiation.

A frankly malignant form of this tumor, an odontogenic myxosarcoma, is known but is exceedingly rare.

Cementoblastoma
(Benign cementoblastoma, true cementoma)

MALIGNANT ODONTOGENIC TUMORS

Odontogenic malignancies are very uncommon tumors. Presently the diagnosis of odontogenic malignancies is based on clinicoradiographic findings and subjective histopathologic evaluation. To be regarded as 'odontogenic', the tumor must arise in the gingiva or jaws (Table 4-3).

ODONTOGENIC CARCINOMAS

Metastasizing Ameloblastoma

Traditionally, ameloblastoma has been regarded as a benign tumor that can be locally aggressive but occasionally can metastasize and kill the patient. The prospect that all ameloblastomas could represent low-grade malignant neoplasms deserves consideration. The term 'metastasizing ameloblastoma' is used to describe a tumor that shows histologic features of classic ameloblastoma in the gingiva or jaw and has metastatic deposits elsewhere.

Clinical Features. Typically, the primary ameloblastoma arises in the mandible of a young adult. The average age at presentation is 30 years, but 33% of patients are younger than 20 years of age. After a mean interval of approximately 11 years, metastatic nodules develop in the lung (80%), cervical lymph nodes (15%), or extragnathic bones. Typically, the pulmonary metastases are multifocal and involve both lungs. The median survival after discovery of the metastatic lesion is about two years. Innocuous lung 'granulomas' that are seen on routine chest films of a patient who has ameloblastoma can prove to be silent metastases. Kunze et al (1985) noted that most patients had multiple recurrences of the jaw ameloblastoma. The multiple recurrences could result from an intrinsically more aggressive tumor or from surgery-associated tumor 'spillage' into adjacent tissue or tumor embolization into lymphatic or blood vessels. The primary ameloblastoma can become locally aggressive (with parapharyngeal and cranial base invasion) before pulmonary metastases arise.

Histologic Features. Ameloblastoma with metastatic potential is histologically indistinguishable from conventional ameloblastoma. The metastatic ameloblastoma usually does not show any greater cytologic atypia or mitotic activity than that seen in the primary. Metastasizing ameloblastoma, ambiguously termed 'malignant ameloblastoma', clearly demonstrates the biologic behavior of a well-differentiated low-grade carcinoma.

Treatment. Metastatic ameloblastoma is managed best by surgery, but there is no evidence that it improves survival. Cervical lymph node metastases are managed by neck dissection. If adequate pulmonary function can be preserved, lung metastases can be excised by lobectomy. At surgery, more numerous pulmonary metastatic deposits are often identified than were apparent in diagnostic imaging studies. Generally, chemotherapy has been ineffective, but a short-term partial response is possible.

Ameloblastic Carcinoma

Ameloblastic carcinoma is a malignant epithelial proliferation that is associated with an ameloblastoma (carcinoma exameloblastoma) or histologically resembles an ameloblastoma (de novo ameloblastic carcinoma). Ameloblastic carcinoma subjectively demonstrates greater cytologic atypia and mitotic activity than ameloblastoma. Some ameloblastomas exhibit

basilar hyperplasia and an increased mitotic index. These findings might warrant a designation of 'atypical ameloblastoma' or 'proliferative ameloblastoma', but they are probably insufficient to permit a diagnosis of ameloblastic carcinoma in the absence of nuclear pleomorphism, perineural invasion, or other histologic evidence of malignancy.

Ameloblastic carcinoma is an aggressive neoplasm that is locally invasive and can spread to regional lymph nodes or distant sites, such as lung and bones. Usually, ameloblastic carcinoma is managed as a squamous cell carcinoma with attempted complete surgical excision, elective or therapeutic neck dissection, and postoperative radiation therapy. The prognosis is poor.

Carcinoma ex Ameloblastoma. A carcinoma directly contiguous with an ameloblastoma is appropriately termed a 'carcinoma arising from an ameloblastoma' (carcinoma ex ameloblastoma, carcinoma in ameloblastoma) (Fig. 4-46). The carcinoma arises when an ameloblastoma undergoes 'dedifferentiation' (i.e. when a less-differentiated proliferative clone arises within an ameloblastoma). This aggressive clone overgrows the ameloblastoma and becomes the dominant component. A follicular or plexiform ameloblastoma blends through a narrow transition zone with a hypercellular poorly differentiated carcinoma that demonstrates sheets of disordered mitotically active small basaloid cells with hyperchromatic nuclei, larger squamoid or polygonal cells with pale vesicular nuclei or elongated spindled epithelial cells. The carcinomatous cells show mild to moderate nuclear pleomorphism. A low-grade spindled ameloblastic carcinoma also has been described, in which ameloblastomatous epithelium is associated with hypercellular stroma that displays elongated fibroblastic cells that show little cytologic atypia and scattered mitotic figures; the 'fibroblastic cells' display immunoreactivity for cytokeratin (Slater LJ, 2004). Hamakawa et al (2000) reported a squamous cell carcinoma that arose adjacent to an ameloblastoma with no apparent transition between the two components. They interpreted it as a probable **collision tumor,** two separate primary tumors—a squamous cell carcinoma of gingival or odontogenic epithelial origin that abutted a conventional ameloblastoma.

De novo Ameloblastic Carcinoma. If a carcinoma lacks a component of conventional ameloblastoma, its unequivocal categorization as an ameloblastic carcinoma is considerably less secure (Fig. 4-47). The diagnosis of de novo ameloblastic carcinoma is based on subjective interpretation. The tumor should demonstrate vague ameloblastomatous features: a plexiform architecture that exhibits budding and anastomosing epithelial processes with peripheral palisaded cuboidal to columnar cells and central polygonal to angular cells. Tumors that lack evidence of reverse polarization, the so-called 'Vickers-Gorlin' changes that are indicative of ameloblastic differentiation, can be accepted as examples of de novo ameloblastic carcinoma; the stringent criterion of reverse polarity has not been required.

The possibility of a variant of squamous cell carcinoma that shows peripheral palisaded cells should be considered before a diagnosis of ameloblastic carcinoma is rendered. But the distinction is of academic interest only, because squamous cell carcinoma and ameloblastic carcinoma are treated the same way.

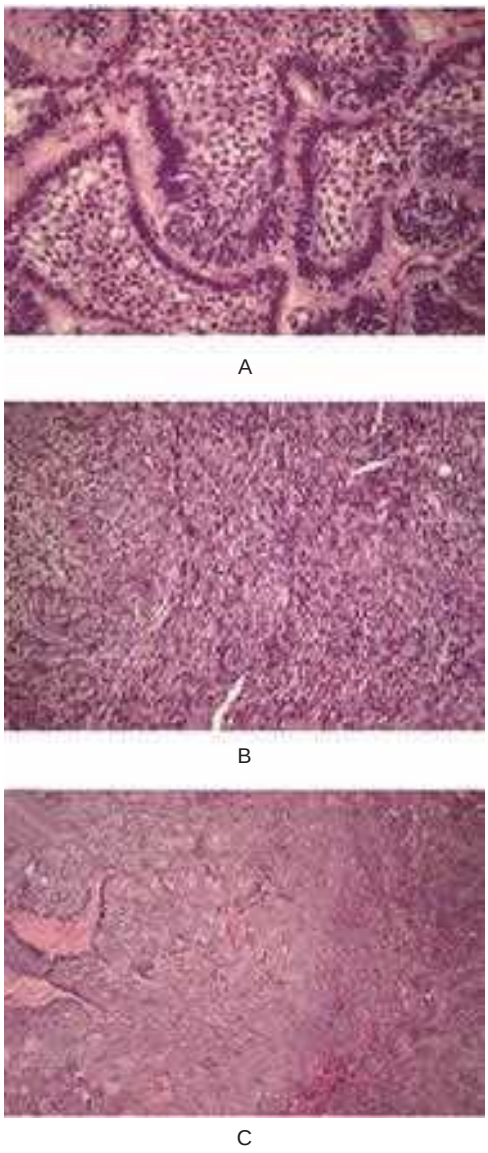

Figure 4-46. Carcinoma ex ameloblastoma.

Primary Intraosseous Carcinoma. Primary intraosseous carcinoma (PIOC) is a squamous cell carcinoma that occurs in the jaw bone. It is called 'primary' because it is not a secondary deposit; metastasis from a distant primary to the jaw must be excluded. It is termed 'intraosseous' because it develops centrally within bone; origin from surface stratified squamous or sinonasal epithelium must be ruled out. It lacks evidence of ameloblastic differentiation, otherwise it would be classified as a de novo ameloblastic carcinoma. If the intraosseous

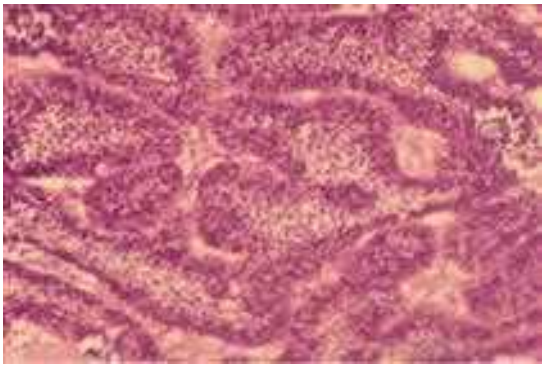

Figure 4-47. Ameloblastic carcinoma.
Budding and anastomosing epithelial trabecula that demonstrate peripheral palisaded tall cells, basilar hyperplasia (expansion of the proliferative compartment), and moderate nuclear pleomorphism; the central pale zones resemble stellate reticulum. It has the architecture of an ameloblastoma and sufficient cytologic atypia to warrant a diagnosis of carcinoma.

carcinoma demonstrates mucous cells, then a diagnosis of central mucoepidermoid carcinoma is appropriate.

Primary intraosseous carcinoma presents clinically as a diffuse enlargement of the jaw; if mucosal ulceration or mucosal tumefaction is present, the diagnosis of PIOC should be questioned. PIOC epithelium can become confluent with gingival surface stratified squamous epithelium after erosion of bone. Such confluence does not indicate necessarily that the carcinoma is of gingival origin if the tumor's overall growth pattern suggests an intraosseous origin. CT images can be useful in assessing whether a putative PIOC could have originated from a gingival squamous cell carcinoma, as well as buccal and lingual cortical destruction and trismus-inducing invasion of the masticator space before involving surface oral mucosa.

Primary intraosseous carcinoma is believed to arise from central odontogenic epithelium, but in rare cases, origin from incisive canal epithelium has been proposed. Cervical metastases have been identified synchronously or metachronously with a PIOC.

Solid Primary Intraosseous Carcinoma. Thomas et al, thoroughly reviewed the clinicoradiographic attributes of this rare tumor. The typical solid PIOC presents as a painful mass in the posterior mandible. Although the mean age at presentation is 52 years, 20% of patients are younger than 34 years and 39% are older than 65 years. Clinically, patients may present with pain, swelling and paresthesia.

Radiographically, 42% of patients demonstrate a cup-shaped radiolucent lesion, 26% demonstrate a poorly-circumscribed 'moth eaten' radiolucency, and 10% exhibit a well-circumscribed radiolucency. At presentation, 31% of patients have evidence of cervical metastases; however, the survival rate of patients who have regional metastases is apparently no worse than those who do not.

Most often, the tumor is treated by surgical excision and postoperative radiation therapy. Most deaths occur within two years of therapy. The overall five-year survival rate is 38%.

Cystic Primary Intraosseous Carcinoma. Cystic PIOC (PIOC arising in an odontogenic cyst, PIOC ex odontogenic cyst) is squamous cell carcinoma that demonstrates a cystic component with a lumen that contains fluid or keratin and a lining of stratified squamous epithelium that exhibits cytologic atypia (intraepithelial neoplasia, epithelial dysplasia). If the cystic component lacks cytologic atypia, the possibilities of a gingival carcinoma that eroded bone and collided with an odontogenic cyst or of a PIOC that arose adjacent to a benign cyst might be considered.

Intraosseous carcinomas that show a cystic and a solid component can mimic an odontogenic cyst radiographically.

Squamous cell carcinoma can exhibit a predominantly cystic architecture. The theoretic possibility of a squamous cell carcinoma metastasizing to the jaw as a cystic lesion, has not been reported.

Carcinoma ex Dentigerous Cyst. The most common odontogenic cyst to show carcinomatous changes is the dentigerous cyst. Intraepithelial neoplasia that involves sulcular gingival epithelium can mimic carcinoma ex dentigerous cyst histologically. It typically presents as an asymptomatic or painful pericoronal radiolucent lesion that is associated with an impacted mandibular third molar. The mean age of occurrence is 59 years with male predominance. Some lesions can cause osseous destruction. Most carcinomas that arise in dentigerous cysts occur in the mandibular molar area; occasionally they are associated with impacted canine teeth.

Histologically, the lesions demonstrate membranous connective tissue that is lined by stratified squamous epithelium that exhibits evidence of intraepithelial neoplasia (epithelial dysplasia) and is associated with an invasive well-differentiated or moderately-differentiated squamous cell carcinoma. The lining epithelium is derived from dental follicular epithelium or gingival sulcular epithelium (if the tooth is partially erupted).

Usually, the carcinoma is treated by surgical resection.

Carcinoma ex Odontogenic Keratocyst. Makowski et al (2001) identified 15 previously reported cases of squamous cell carcinoma that arose in an odontogenic keratocyst (OKC). In most cases, radiographic findings are those of a benign OKC.

In the maxilla, OKC lining epithelium can fuse with buccal vestibular surface stratified squamous epithelium to form a chronic sinus tract that drains pus-like keratinaceous material; this 'automarsupialized' cyst develops thickened nonkeratinized lining epithelium that is similar to that seen in a surgically decompressed OKC. PIOC that arises in a cyst that is lined by dysplastic thickened parakeratinized stratified squamous epithelium that lacks convincing features of classic OKC or orthokeratinized odontogenic cyst cannot be classified assuredly as carcinoma ex OKC.

Usually, the carcinomas have been treated by resection and postoperative radiation therapy, and infrequently with chemotherapy.

Intraosseous Mucoepidermoid Carcinoma. Intraosseous mucoepidermoid carcinoma (central mucoepidermoid carcinoma, PIOC with mucous cells) arises from odontogenic

epithelium or an odontogenic cyst. It represents a cystic primary intraosseous carcinoma that shows squamous differentiation and mucous cells. If a rare central mucoepidermoid carcinoma arises from ectopic salivary gland tissue that was enclaved within the mandible during development, it would be classified as a primary intraosseous carcinoma. A low-grade mucoepidermoid carcinoma that presents as a retromolar mucosal mass with an underlying broad 'cupped-out' radiolucency of the mandible may represent a conventional mucoepidermoid carcinoma derived from retromolar salivary glands that has secondarily eroded the mandible. With this presentation, a diagnosis of 'central mucoepidermoid carcinoma' should be questioned because central tumors do not present as mucosal masses. Some apparent maxillary intraosseous mucoepidermoid carcinomas probably arise from seromucous glands that are associated with sinonasal mucosa. Most tumors are low-grade cystic lesions that grow in a broad 'pushing' front and demonstrate a well-circumscribed unilocular or multilocular radiolucent lesion (Fig. 4-48). As for all neoplasms, the prognosis depends on the extent of disease (clinical stage) and the histologic grade of the tumor. High-grade tumors display a destructive permeative growth pattern and have metastatic potential. Typical low-grade tumors have a favorable prognosis. Death eventuates from uncontrolled local disease rather than from metastases (Slater LJ, 2004).

Varying surgical treatments have been used, including: curettage, partial resection, en bloc resection, and hemimandibulectomy. In several cases, curettage resulted in no evidence of disease after a follow-up period of 3–19 years.

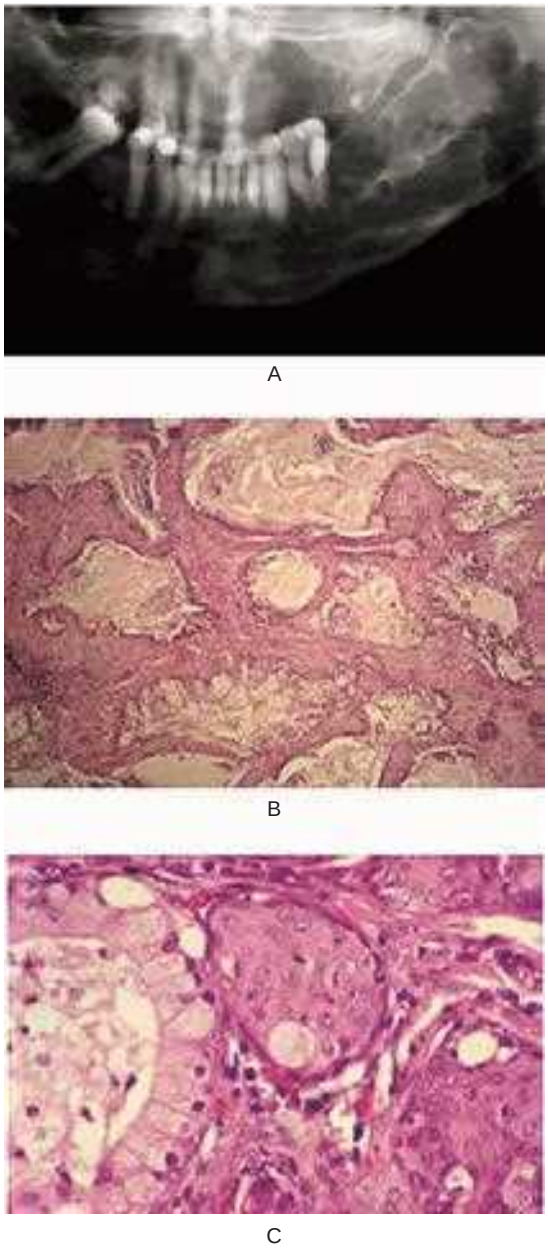

Figure 4-48. Central low-grade mucoepidermoid carcinoma.
(A) A 36-year-old woman had a painful expansile lesion of the left posterior mandible; radiographically, a multiloculated radiolucency is observed. **(B)** Multiple adjacent cystic structures contain mucus and are lined by epithelium that demonstrates numerous mucous cells. **(C)** At higher magnification, a cystic space is lined by mucous cells (left) and mural islands of epidermoid cells (center and right) are seen *(Courtesy of Dr LJ Slater) (Reprinted from Oral Maxfac Surg Clin N Am 16: 415, 2004 with permission).*

Ghost Cell Odontogenic Carcinoma

(Odontogenic ghost cell carcinoma, malignant epithelial odontogenic ghost cell tumor, aggressive [malignant] epithelial odontogenic ghost cell tumor, dentinogenic ghost cell tumor)

Ghost cell odontogenic carcinoma is an ameloblastic carcinoma that shows evidence of ghost cell keratinization. As such, it can be considered to be a variant of ameloblastic carcinoma. The biologic behavior of the lesion cannot be predicted from the presence of ghost cells. The tissue that surrounds the ghost cells gives the prognosis. For example, if a benign cyst contains ghost cells, its biologic behavior is that of a benign cyst; if an ameloblastoma contains ghost cells, its biologic behavior is that of an ameloblastoma; and if a carcinoma contains ghost cells, its biologic behavior is that of a carcinoma (Fukushima M, 1983).

Ghost cells are immunoreactive for amelogenin, a protein that is unique to enamel matrix; therefore, the presence of ghost cells in jaw tumors represents evidence of ameloblastic differentiation. As with all primary intraosseous carcinomas, the possibility of a metastasis should be excluded; carcinomas that demonstrate ghost cells include cutaneous pilomatrix carcinoma and visceral carcinomas.

The mean age at presentation was 38 years, but the age range was from 13–72 years; 75% arose in men. About 66% of cases occur in the maxilla. Ghost cell odontogenic carcinoma seems to be disproportionately more frequent in Asians.

Radiographically, it presents as an expansile multiloculated to poorly delineated radiolucent lesion; the radiographic features are not characteristic.

Ghost cell odontogenic carcinomas have a biologic behavior that is similar to that of an ameloblastoma or a low-grade

ameloblastic carcinoma. The tumor can be locally aggressive (e.g. maxillary tumors can invade the orbit). Apparently, the tumor has little metastatic potential.

Most of the ghost cell odontogenic carcinomas arise de novo. Most often, the carcinomas demonstrate sheets of small basaloid cells that show intraepithelial islands; stratified squamous epithelium that exhibit ghost cell keratinization. Approximately 50% have a prominent cystic component. Palisaded columnar cells at the periphery of tumor islands can create an ameloblastomatous pattern. Lesional tissue subjectively reveals features that warrant a malignant interpretation, including cytologic atypia, increased mitotic activity, an infiltrative growth pattern (perineural or intravascular invasion), and necrosis (Fig. 4-49), (Slater LJ, 2004).

It is treated by surgical excision, postoperative radiation therapy, and sometimes chemotherapy, as well.

Clear Cell Odontogenic Carcinoma

(Clear cell ameloblastic carcinoma, clear cell ameloblastoma, clear cell odontogenic tumor)

Clear cell odontogenic carcinoma is a low-grade carcinoma that is composed of cells that show uniform nuclei and clear cytoplasm. Approximately 90% of cases arise in the mandible—half in the anterior portion and half in the posterior segment. About 70% of patients are women with an age range of 17–89 years.

The tumor has a varied radiographic appearance. Often, it presents as a unilocular expansile radiolucent lesion with an indistinct periphery; however, some cases are multiloculated and well-circumscribed.

The classic case of clear cell carcinoma demonstrates budding and branching cords, islands, and sheets of neoplastic polygonal epithelial cells. Lesional cells exhibit central to eccentric small dark uniform nuclei; little evidence of nuclear pleomorphism or mitotic activity; abundant pale cytoplasm, 'clear cells'; and distinct cell borders. Tumor islands can display peripheral ameloblastomatous palisaded columnar cells; however, no evidence of central stellate reticulum, squamous differentiation, or cystic change is observed (Fig. 4-50). The clear cells contain periodic acid Schiff–positive diastase-sensitive glycogen, but they are mucicarmine negative. Recurrent lesions may be more proliferative than the original tumor, with cells showing greater mitotic index than those in the original tumor. The histologic differential diagnosis includes the clear cell variant of calcifying epithelial odontogenic tumor, metastatic renal cell carcinoma, the clear cell variant of mucoepidermoid carcinoma and clear cell squamous cell carcinoma. Salivary gland clear cell carcinomas are indistinguishable from clear cell odontogenic carcinoma based on histologic features, special stains, and immunohistochemical assays (Muramatsu T et al 1996).

The tumor is refractory to curettage. Resected tumors had a high recurrence rate; 10 of 21 (48%) resected tumors recurred following a median interval of 6.3 years.

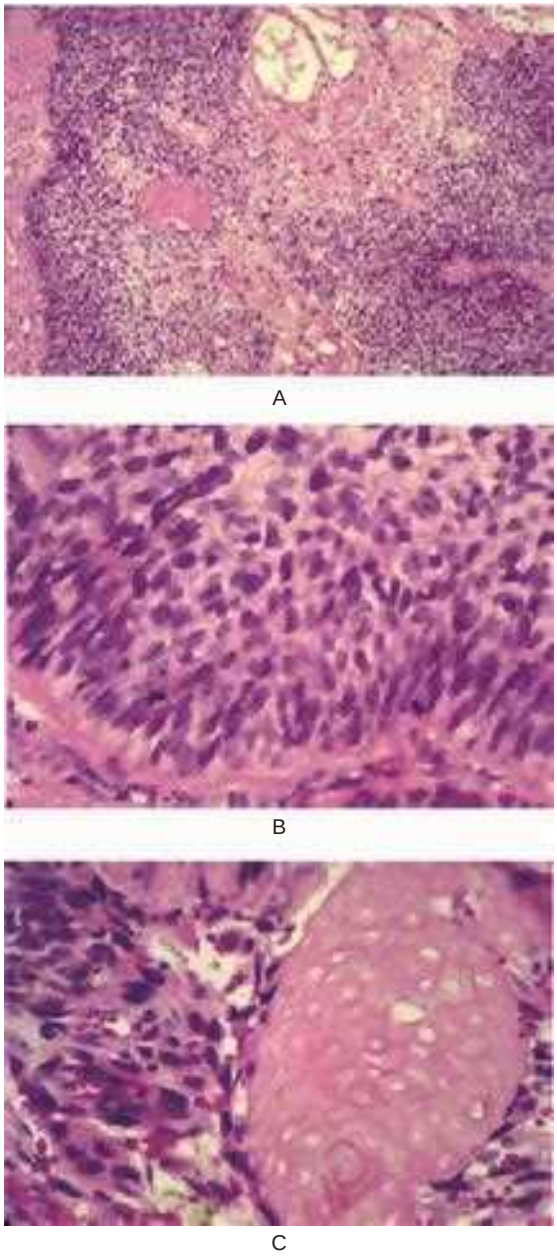

Figure 4-49. Ghost cell odontogenic carcinoma.
(A) Sheets of malignant epithelial cells demonstrate disordered dark basaloid cells at the periphery (left and right), central squamous differentiation with cystic change (top center), and an intraepithelial oval island of ghost cells (in center of left half of photograph). **(B)** Higher magnification of peripheral basaloid cells. **(C)** Higher magnification of an island of pink squamous epithelium that exhibits ghost cell keratinization (right half of photograph) *(Reprinted from Oral Maxfac Surg Clin N Am. 16: 416, 2004 with permission).*

Approximately 20% of tumors show cervical lymph node metastases; 17% display lung metastases; and about 20% of patients die of disease (after a median period of 14 years). In case of extensive extraosseous extension postoperative radiation therapy might be useful.

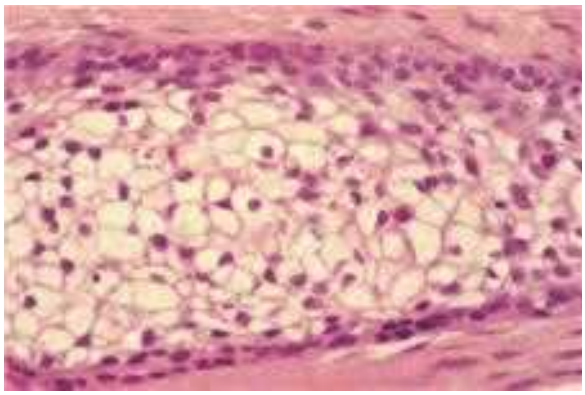

Figure 4-50. Clear cell odontogenic carcinoma.
Central large pale cells have abundant clear cytoplasm, small dark uniform nuclei, and distinct cytoplasmic borders. Peripheral basaloid cells display little cytologic atypia *(Courtesy of LJ Slater)*.

Ameloblastic Fibrosarcoma
(Odontogenic sarcoma, ameloblastic sarcoma)

Ameloblastic fibrosarcoma is a malignant proliferation of connective tissue cells that contains benign odontogenic epithelium that is similar to that seen in ameloblastic fibroma. Approximately 80% of cases occur in the mandible, predominantly the posterior segment; 60% occur in men. Often, it demonstrates an expansile radiolucency with indistinct margins and evidence of extraosseous soft tissue extension.

About 35% of cases arise in an ameloblastic fibroma. Although sarcoma ex ameloblastic fibroma presents in patients with a mean age of 33 years, de novo ameloblastic fibrosarcoma presents in younger patients with an average age of 22 years. Approximately 37% of patients have one or more recurrence and 19% die of disease. Typically, the patients do not develop metastases; they die of a locally aggressive neoplasm.

Varying radiographic patterns can be seen, that include destructive/permeative, unilocular, or multilocular sometimes, associated with an impacted molar.

Ameloblastic fibrosarcoma has the histologic architecture of an ameloblastic fibroma. Slender budding and branching epithelial cords of bland cuboidal to columnar cells with uniform nuclei or epithelial islands that are indistinguishable from those that are seen in follicular ameloblastoma are separated widely by hypercellular connective tissue that exhibits plump polygonal to fusiform stromal cells that show mild to moderate cytologic atypia and numerous mitotic figures in a pale hypocollagenous myxoid extracellular matrix. If the tumor recurs, it tends to display greater stromal cell cellularity, increased mitotic activity, more pronounced nuclear atypia, and less evidence of odontogenic epithelium with each recurrence. In some cases, the sarcomatous component completely overgrows the epithelial component; such recurrent tumors are devoid of epithelium (Fig. 4-51). Ameloblastic fibrosarcoma can demonstrate focal evidence of dentin formation or dentin and enamel formation; and this insignificant dental hard tissue component has resulted in the terms 'ameloblastic dentinosarcoma' and 'ameloblastic odontosarcoma', respectively. The histologic differential diagnosis includes a low-grade spindled ameloblastic carcinoma (Philips VM et al 1998).

The sarcoma is treated most often by a wide surgical excision and postoperative radiation therapy, without elective neck dissection.

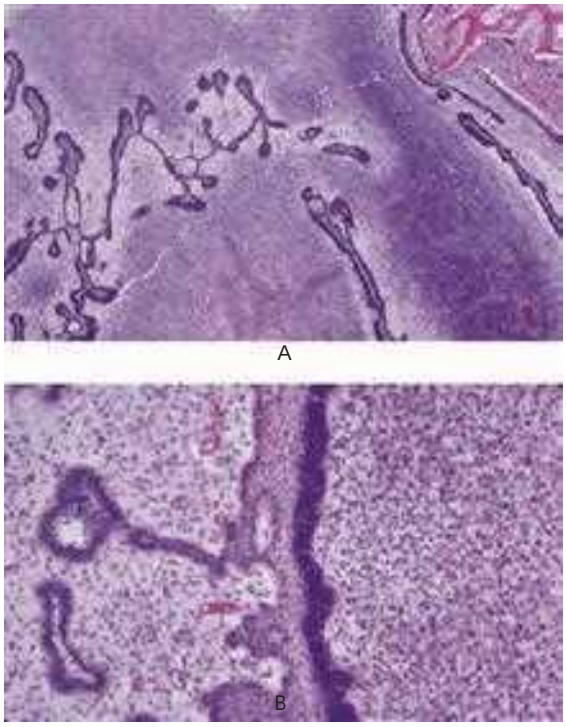

Figure 4-51. Ameloblastic fibrosarcoma.
(A) The neoplasm has the architecture of an ameloblastic fibroma that demonstrates slender budding and anastomosing cords that 'open up' to form central pale stellate reticulum; the dark band of sarcoma cells (lower right) is particularly hypercellular. **(B)** The pale connective tissue to the left of the epithelium is less cellular than the obviously sarcomatous dark polygonal cells at the right *(Courtesy of Dr LJ Slater)*.

SECTION II

Diseases of Microbial Origin

SECTION OUTLINE

“This page intentionally left blank"

CHAPTER 5

Bacterial Infections of the Oral Cavity

■ B SIVAPATHASUNDHARAM AND N GURURAJ

CHAPTER OUTLINE

Certain bacteria, viruses and fungi produce diseases, which are manifested in or about the oral cavity. Some of these diseases or lesions are of the specific nature and are produced by a specific microorganism. Others are clinically specific, but may be caused by any of the broad group of microorganisms. This microbial specificity or nonspecificity is characteristic of infectious diseases wherever they may occur in the body, and is necessarily confined to those of the oral cavity.

SCARLET FEVER

(Scarlatina)

Scarlet fever is a contagious systemic infection occurring predominantly in children, caused by β-hemolytic streptococci, *Streptococcus pyogenes* which produces a pyrogenic exotoxin. It is similar in many respects to acute tonsillitis and pharyngitis caused by streptococci, paralleling the occurrence of these conditions in its epidemiology. It is regarded as a separate entity because of the nature of the toxin. A number of different strains of streptococci may produce the disease. The rash occurs because of three exotoxins, A, B, C; previously described as erythrogenic or scarlet fever toxin. These organisms produce clear hemolysis around colonies in blood agar plates. Local erythematous reaction occurs in susceptible individuals injected with exotoxin, but no such reaction was found in those with specific immunity. Various studies suggest that development of scarlet fever may reflect a hypersensitivity reaction requiring prior exposure to the toxin.

Clinical Features. Scarlet fever is common in children. After the entry of the microorganisms into the body, which is believed to occur usually through the pharynx, there is an incubation period of three to five days; after which the patient exhibits severe pharyngitis and tonsillitis, headache, chills, fever, abdominal pain, and vomiting. Accompanying these symptoms may be enlargement and tenderness of the regional cervical lymph nodes. The diagnosis of scarlet fever is frequently not established until the characteristic diffused, bright, scarlet-skin rash appears on the second or third day of illness. This rash, which is particularly prominent in the areas of the skin folds, is a result of the toxic injury to the endothelium which produces dilatation of the small vessels and consequent hyperemia. These rashes blanch on pressure and typically begin first on the upper trunk, spreading to involve extremities but sparing the palms and soles. Small papules of normal color erupt through these rashes giving a characteristic 'sandpaper' feel to the skin. This rash that is particularly prominent in the areas of skin folds is called 'pastia lines.' The rash subsides after six or seven days followed by the desquamation of palms and soles. The color of the rash varies from scarlet to dusky-red.

Oral Manifestations. The chief oral manifestations of scarlet fever have been referred to as **stomatitis scarlatina**. Small punctate red macules may appear on the hard and

soft palate and uvula. These are called Forchheimer spots; however, these are not diagnostic since they may be present in other infectious conditions like rubella, roseola, infectious mononucleosis, and septicemia. The palate and the throat are often fiery red. The tonsils and faucial pillars are usually swollen and sometimes covered with a grayish exudate.

More important are the changes occurring in the tongue. Early in the course of the disease, the tongue exhibits a white coating and the fungiform papillae are edematous and hyperemic, projecting above the surface as small red knobs. This phenomenon has been described clinically as 'strawberry tongue'. The coating of the tongue is soon lost; beginning at the tip and lateral margins, and this organ becomes deep red, glistening and smooth except for the swollen, hyperemic papillae. The tongue in this phase has been termed as the 'raspberry tongue'. In severe cases, ulceration of the buccal mucosa and palate has been reported, but this appears to be due to secondary infection. Signaling the clinical termination of the disease is the desquamation of the skin, which usually occurs within a week or 10 days. Soon after, the tongue and the remainder of the mucosa assume a normal appearance. Scarlet fever should be differentiated from the other exanthematous diseases like measles and other viral exanthemas, Kawasaki disease, toxic shock syndrome, drug eruptions, and the like.

Complications. Occasional complications may arise referable to local or generalized bacterial dissemination or to hypersensitivity reactions to the bacterial toxins. These may include peritonsillar abscess, rhinitis and sinusitis, otitis media and mastoiditis, meningitis, pneumonia, glomerulonephritis, rheumatic fever, and arthritis.

Diagnosis. Diagnosis is usually based on clinical findings. Routine blood examination shows marked leukocytosis with increased neutrophilia. There is an elevation of ESR and C-reactive protein. Culturing the flora of intraoral lesions, pharynx, and saliva can be used to confirm the diagnosis.

Prevention and Treatment. There are no available methods for the prevention of scarlet fever. The administration of antibiotics like penicillin, dicloxacillin, and cephalexin will ameliorate the disease and also helps in controlling possible complications. Local applications like mupirocin topical ointment also can be used to relieve discomfort.

DIPHTHERIA

Diphtheria is an acute, life-threatening, infectious, and communicable disease of the skin and mucous membrane caused by toxemic strains of *Corynebacterium diphtheriae,* an anaerobic gram-positive organism. It is characterized by local inflammation and the formation of a grayish adherent pseudomembrane, which bleeds on removal. It occurs in the months of winter in temperate zones and throughout the year in the tropical region. Historically, it was described as Egyptian or Syrian ulcer in the second century.

It is a disease of the children. Humans are the principal reservoirs and the organisms may persist in discharges from the nose, throat, eye, and skin lesions for two to six weeks after infection. It is transmitted mainly by respiratory droplets, direct skin contact and from the skin to the respiratory tract through hands. In some instances carriers of the disease are responsible for dissemination of the microorganisms. Exposure to the diphtheria bacillus, particularly in the adult, may result in a subclinical infection, which is usually sufficient to establish immunity through the development of circulating antitoxins. Infection is most common in groups living in crowded conditions. It can occur in both immunized and partially immunized individuals.

Since 1990, this epidemic has occurred throughout the Russian Federation, Ukraine, Thailand, and Laos. These epidemics are largely due to decreasing immunization coverage among infants, waning immunity in adults, large-scale movement of population, and irregular supply of vaccine. Available data indicate a declining trend of diphtheria in India, due to increasing coverage of child population by immunization. Schick test surveys in India have shown that about 70% of children over the age of three and 99% over the age of five are already immune to diphtheria. Recent diphtheria outbreaks in a number of countries have demonstrated a shift in age distribution of cases to adults and old age people. The outbreaks warrant the need of booster immunization.

Pathogenesis. *C. diphtheriae* has an air-borne mode of transmission and localizes in the mucous membrane of the respiratory tract. It also invades open skin lesions resulting from insect bites or trauma. Diphtheria is, in fact, a toxemia, since the bacillus remaining at the site of entry multiplies and liberates toxins. These toxins induce initial edema and hyperemia followed by epithelial necrosis and acute inflammation.

Coagulation of the fibrin and purulent exudates produce pseudomembrane and the inflammatory reaction accompanied by vascular congestion extends into the underlying tissues. Thus the pseudomembrane consists of dead cells, leukocytes, erythrocytes, and bacteria. Systemically the toxin produces myocarditis, neuritis, and focal necrosis in various organs including kidneys, liver, and adrenal glands. Cutaneous diphtheria is caused by nontoxemic strains of diphtheria.

Clinical Features. Patients with *C. diphtheriae* in the respiratory tract are classified as diphtheria cases if the pseudomembrane is present and as diphtheria carriers if the pseudomembrane is absent. The pseudomembrane is seen on the tonsils. It is wash-leather, elevated grayish-green membrane with a well-defined edge surrounded by acute inflammation. The incubation periods for respiratory diphtheria are two to five days and rarely up to eight days. Cutaneous diphtheria is a secondary infection on pre-existing skin lesions, which develops at an average of seven days after the appearance of primary lesions. Various clinical types of diphtheria, classified by the location of the pseudomembrane are tonsillar, pharyngeal, laryngeal, tracheal, nasal, conjunctival, cutaneous, and genital. There may be swelling of the neck (bull neck) and tender enlargement of the lymph nodes.

Onset is gradual. It manifests as fever, sore throat, weakness, dysphagia, headache, and change of voice. Patients without toxicity exhibit discomfort and malaise associated with local

infection whereas toxic patients develop restlessness, pallor, and tachycardia and rapidly progressed to vascular collapse. Multiple sites may involve other than the primary site. The spread of infection from one site either upward or downward is common.

Initial findings include erythema of the posterior pharyngeal wall followed by white or gray spots that coalesce to form a thin veil-like membrane, which thickens and becomes gray. The larynx and trachea may be involved primarily or by extension from the pharynx and nose. It manifests as hoarseness of voice, respiratory stridor, and dyspnea, which may progress to severe respiratory obstruction and death in young children owing to the small airway size. Cutaneous manifestations include deep punched-out ulcers with a leathery discharge. Most lesions occur on the extremities but trunk and genital may also be affected.

Oral Manifestations. There is formation of a patchy 'diphtheritic membrane' which often begins on the tonsils and enlarges, becoming confluent over the surface. This false membrane is grayish-green, thick, and fibrinous, and is composed of dead cells, leukocytes and bacteria overlying necrotic, ulcerated areas of the mucosa tends to be adherent and leaves a bleeding surface if stripped away. The membrane is asymmetric and extends to involve the tonsil, soft palate and tongue, lips, gingiva, buccal mucosa and site of erupting teeth. Its advancing border is reddened and bleeding occurs on scraping the membrane. The submandibular and anterior cervical nodes are enlarged with soft tissue edema. Severely affected patients will give a bull neck appearance.

In the oral cavity, it appears as nonspecific ulcer. The soft palate may become temporarily paralyzed, usually during the third to fifth weeks of the disease. These patients have a peculiar twang, and may exhibit nasal regurgitation of liquids during drinking. The paralysis usually disappears in a few weeks or a few months at the most. If the infection spreads unchecked in the respiratory tract, the larynx may become edematous and covered by the pseudomembrane which results in a husky voice. This is especially serious because it produces a mechanical respiratory obstruction and the typical cough or diphtheritic croup. If the airway is not cleared, suffocation may result.

Complications. During or after this disease complications frequently arise in the cardiovascular and nervous systems as a result of toxemia. Thus both myocarditis and polyneuritis may develop, but usually there is complete recovery. Kidney lesions, particularly acute interstitial nephritis, are also possible serious sequelae. Obstruction of the airway, acute circulatory failure, post diphtheria paralysis, pneumonia, bleeding and otitis media are other complications.

The mortality rate is still of such proportions that diphtheria should be considered a serious disease. In the past this disease was a leading cause for death in children and was referred to as 'the strangling angel of children'. It should be differentiated from other conditions including streptococcal pharyngitis, Vincent's angina, Ludwig's angina, retropharyngeal and peritonsillar abscess, infectious mononucleosis, candidiasis, leukemia, and agranulocytosis.

Diagnosis is mainly based on clinical signs and symptoms but definite diagnosis is arrived by the isolation of organisms from the affected sites. Material should be obtained beneath the membrane or a portion of the membrane itself can be submitted for culture. Various media include Pai agar and cystine-tellurite agar and special stains like Albert's stain, Ponder's stain or Neisser's stains to demonstrate metachromatic granules.

Treatment. Administration of diphtheria antitoxin neutralizes the circulating diphtheria toxin and prevents the disease progression. Apart from antibiotic administration usually done by penicillin and erythromycin; maintaining the airway is also necessary.

Prevention. The disease may be prevented by prophylactic active immunization with diphtheria toxoid.

TUBERCULOSIS

Tuberculosis (TB) is a specific infectious granulomatous disease caused by *Mycobacterium tuberculosis.* It remains a major health problem in most developing countries. It commonly affects lungs but also affects the intestines, meninges, bones, joints, lymph glands, skin, and other tissues of the body. The disease also affects animals like cattle and is known as bovine tuberculosis; and is sometimes communicated to man.

Etiology. *M. tuberculosis* is a facultative intracellular parasite. Human strains are responsible for many cases, but the bovine strain may also produce illness through the ingestion of unpasteurized cow's milk. Rarely atypical or opportunistic mycobacteria can cause pulmonary or generalized infection in immunocompromised individuals.

M. tuberculosis is a rod-shaped, nonspore forming, and thin aerobic bacteria called acid-fast bacilli, due to the fact that once stained, it cannot be decolorized by acid alcohol. Its acid-fastness is due to the high content of mycolic acids, long chain cross-linked fatty acids and other cell wall lipids. Males are more affected than females in India though it affects all ages, from an average of 1% in the under-five age group.

Epidemiology. Developed countries have achieved spectacular results in the control of tuberculosis. Incidence has steadily declined in developing countries as well. This is due to early and accurate diagnosis of the disease through various tools and improved socioeconomic conditions. In developing countries, the Southeast region, the Western Pacific, and Africa accounts for 95% cases of TB. Among the world population, the Southeast Asian region carries a disproportionate 88% of the world's burden of TB.

India accounts for nearly one fifth (20%) of the global burden of TB. Every year 1.8 million persons develop tuberculosis of which about 0.8 million are new smear-positive highly infectious cases and about 0.32 million people die of TB every year. The vulnerability to TB in developing countries results from poverty, economic recession and malnutrition. Many new patients have multidrug resistance to TB. People with HIV infection are much more likely to develop TB. An increase in HIV prevalence represents a serious threat to TB control in India. WHO has launched a strategy for controlling TB called DOTS or Directly Observed Therapy Short-term,

a community based treatment protocol. Today in India it is recognized as fastest expanding program.

Pathogenesis. The interaction of the bacilli and the host begins when droplet nuclei from infectious patients are inhaled. The majority of the bacilli are trapped and exhaled by ciliary action and a fraction less than 10% enters alveoli.

In the initial stage of the host-bacterial interaction, either host's macrophages control the multiplication of the bacteria or the bacteria grow and kill the macrophages. Nonactivated monocytes attracted from blood stream to the site by various chemotactic factors ingest the bacilli released from the lysed macrophages. Initial stages are asymptomatic; about 2–4 weeks after infection tissue damaging and macrophage activating responses develop. With the development of specific immunity and accumulation of a large number of activated macrophages at the site of primary lesion, granulomatous reaction or tubercles are formed. The hard tubercle consists of epithelioid cells, Langhans giant cells, plasma cells, and fibroblasts. These lesions develop when host resistance is high. Due to cell-mediated immunity in the majority of individuals, local macrophages are activated and lymphokines are released, which neutralize the bacilli and prevent further tissue destruction. The central part of the lesion contains caseous, soft, and cheesy necrotic material (caseous necrosis). This necrotic material may undergo calcification at a later stage called Ranne complex, in the lung parenchyma and hilar lymph nodes in few cases. Caseous necrotic material undergoes liquefaction and discharges into the lungs leading to the formation of a cavity. Spontaneous healing of the cavity occurs either by fibrosis or collapse. Calcification of the cavities may occur in which bacteria persist.

In early stages, the spread of infection is mainly by macrophages to lymph nodes, other tissues, and organs. However, in children with poor immunity, hematogenous spread results in fatal military TB or tuberculous meningitis.

Clinical Features. The signs and symptoms of tuberculosis are often remarkably inconspicuous. The patient may suffer episodic fever and chills, but easy fatigability and malaise are often the chief early features of the disease. There may be gradual loss of weight accompanied by a persistent cough with or without associated hemoptysis.

Tuberculosis is either pulmonary or extrapulmonary. Pulmonary TB may be primary, secondary, or miliary. Extrapulmonary sites include lymph nodes, pleura, genitourinary tract, bones, joints, meninges, and peritoneum. As a result of hematogenous dissemination in HIV infected individuals, the extrapulmonary type is seen more commonly.

Primary pulmonary TB is usually seen in children but may also occur in adults. In a majority of cases, it is asymptomatic. A few may be present with febrile illness and cough, which may be dry or productive.

Symptoms of post-primary TB or secondary TB include fever, cough, chest pain, and hemoptysis.

Symptoms of miliary TB in children include acute febrile illness but in adults it is more insidious with gradual development of ill health, anorexia, loss of weight, and fever. Bilateral crackles on auscultation, hepatosplenomegaly, and lymphadenopathy may be present. Choroid tubercles are seen in children, but are rare in adults.

Tuberculous infection of submandibular and cervical lymph nodes, or scrofula, a tuberculous lymphadenitis, may progress to the formation of an actual abscess or remain as a typical granulomatous lesion. In either case, swelling of the nodes is obvious clinically. They are tender or painful, often show inflammation of the overlying skin, and when an actual abscess exists, typically perforate and discharge pus. It has been suggested that this specific form of tuberculosis probably arises as a result of lymphatic spread of organisms from a focus of infection in the oral cavity such as the tonsils. However, as Popowich and Heydt have stated, no published studies have confirmed the relationship between tuberculous cervical lymphadenitis and a primary source of infection elsewhere. For example, in the series of 22 cases reported by Ord and Matz, there was no history or clinical evidence of pulmonary tuberculosis in any patient. These investigators also emphasized that this disease can be caused by atypical mycobacteria and also that organisms frequently cannot be cultured from the lesions.

Primary tuberculosis of the skin or lupus vulgaris may occur either in children or adults and is a notoriously persistent disease. It appears as papular nodules, which frequently ulcerate. These are particularly common on the face, but may occur anywhere.

Oral Manifestations Tuberculous lesions of the oral cavity do occur, but are relatively uncommon. Reported studies on incidence vary considerably. The studies of Farber and his associates indicated that less than 0.1% of the tuberculous patients whom they examined exhibited oral lesions. Katz on the other hand, found that approximately 20% of a series of 141 patients examined at autopsy manifested such lesions, the majority of which occurred on the base of the tongue and were not discovered clinically. The obscure location of the tuberculous lesions found by Katz might account for the disparity in incidence of occurrence in these studies.

There is general agreement that lesions of the oral mucosa are seldom primary, but rather secondary to pulmonary disease. Although the mechanism of inoculation has not been definitely established, it appears most likely that the organisms are carried in the sputum and enter the mucosal tissue through a small break in the surface. It is possible that the organisms may be carried to the oral tissues by a hematogenous route, to be deposited in the submucosa and subsequently to proliferate and ulcerate the overlying mucosa.

The possibility that the dentist may contract an infection from his contact with living tubercle bacilli in the mouth of patients who have pulmonary or oral tuberculosis is a problem of great clinical significance. It has been shown on numerous occasions that the viable acid-fast microorganisms may be recovered from swabs or washings of the oral cavities of tuberculous patients. Abbott and his associates reported that tubercle bacilli were cultured from 45% of 300 samples of water used to wash the teeth and gingiva of 111 tuberculous patients.

Lesions of secondary tuberculosis may occur at any site on the oral mucous membrane, but the tongue is most commonly affected, followed by the palate, lips, buccal mucosa, gingiva, and frenula. The usual presentation is an irregular, superficial or deep, painful ulcer which tends to increase slowly in size (Fig. 5-1A,B,C). It is frequently found in areas of trauma and may be mistaken clinically for a simple traumatic ulcer or even carcinoma. Occasional mucosal lesions show swelling, granular, nodular or fissured lesions, but no obvious clinical ulceration. Primary oral tuberculosis usually involves gingiva and is present as diffuse, hyperemic, nodular, or papillary proliferation of the gingival tissues (Figs. 5-2, 5-3). Primary oral tuberculosis is usually associated with regional lymphadenopathy.

Tuberculosis may also involve the bone of the maxilla or mandible. One common mode of entry for the microorganisms is into an area of periapical inflammation by way of the blood stream; an anachoretic effect that has been noted in the oral cavity under other circumstances. It is conceivable also that these microorganisms may enter the periapical tissues

by direct immigration through the pulp chamber and root canal of a tooth with an open cavity. The lesion produced is essentially a tuberculous periapical granuloma or tuberculoma. These lesions were usually painful and sometimes involve a considerable amount of bone by relatively rapid extension.

Diffuse involvement of the maxilla or mandible may also occur, usually by hematogenous spread, but sometimes by direct extension or even after tooth extraction. Tuberculous osteomyelitis frequently occurs in the later stages of the disease and has an unfavorable prognosis.

Histologic Features. Tuberculous lesions in the mouth do not differ microscopically from tuberculous lesions in other organs of the body. The characteristic histopathologic appearance is due to the cell-mediated hypersensitivity reaction. Formation of granuloma exhibiting foci of caseous necrosis surrounded by epithelioid cells, lymphocytes, and occasional multinucleated giant cells (Fig. 5-4). Caseous necrosis is not inevitably present, however.

Diagnosis. The diagnosis of active infection must be confirmed by demonstration of the organisms by special microbial stains and culture of the infected tissue or sputum. The presence of acid-fast bacilli (AFB) in sputum smear is the gold standard for the diagnosis of TB. Imaging techniques like radiograph of the affected part like chest and tuberculin test are most useful in supplementing the diagnosis of TB.

CT scan is used to diagnose mediastinal or hilar lymphadenopathy, cavities and intralesional calcification. Postcontrast peripheral enhancement of a lymph node is taken as indirect evidence of tuberculous etiology. A high resolution CT scan can be used to differentiate miliary TB and other diffuse forms of TB from other diffuse lung diseases. MRI is most useful for diagnosis of extrapulmonary TB.

Identification of Mycobacteria from Respiratory Specimens. The demonstration of tubercle bacilli in a respiratory specimen like sputum is a direct evidence of TB. WHO defines any patient whose sputum smear is positive for acid-fast bacilli as a case of pulmonary tuberculosis. Respiratory specimens can be subjected to smear and microscopy for acid-fast bacilli, as well as culture. The following respiratory specimens can be used to demonstrate *Mycobacterium*, sputum, spot samples collected early morning, laryngeal swab, bronchoalveolar lavage, transtracheal aspiration, or gastric contents aspirated by a nasogastric tube in children who swallow sputum.

Microscopical smears for acid-fast bacilli are stained by the following methods: Ziehl-Nielsen (Z-N) staining, Kinyoun's cold staining methods, and rhodamine staining for fluorescent microscopy. A minimum of five acid-fast bacilli on fluorescent microscopy and three on Z-N staining is reported as positive. A sputum smear examination is less than 60% sensitive.

Mycobacterial Culture. Conventional *Mycobacterium* cultures are done on Lowenstein-Jensen medium or one of the agar based media like Middlebrook medium. It takes four to six weeks for the growth of *M. tuberculosis.*

Other faster methods of culture:

- Rapid slide culture technique involves growing *Mycobacterium* on slides examining microcultures under a microscope.
- Radiometric culture method is based on the detection of utilization of a radioisotope of carbon by mycobacteria.

Tuberculin test or the **Mantoux test** involves subcutaneous injection of 0.1 ml of 5 tuberculin units of purified protein derivative of Siebert stabilized with Tween 80 or 1 tuberculin unit of PPDRT 23 into the forearm. It is positive if induration is seen after 48–72 hours. The maximum diameter of the induration measured by palpation and not redness, is recorded and interpreted as follows: more than 15 mm or ulceration, strongly positive; more than 10mm, positive; 5–9 mm, indeterminate; and less than 5mm, negative.

The tuberculin skin test has greater value in excluding tuberculosis than in diagnosing it. A positive reaction indicates that a *Mycobacterium* has replicated in the tissues of the individual at some time but does not indicate an active disease. A strongly positive test may indicate recent infection. The test is positive in 85% of infected individuals but may be falsely negative in tuberculosis pleurisy, miliary tuberculosis, immuno suppressed conditions, and viral fevers. 10% of recent tuberculin converters may develop active disease in their life time and 5% do so within the first two years of infection.

Extensively drug resistant tuberculosis (XDR TB)

A variant of tuberculosis which does not respond to one or more of the antituberculous drugs is known as multidrug resistant tuberculosis (MDR TB). Extensively drug resistant TB is relatively a rare form of MDR TB, which is resistant to almost all types of antituberculous drugs. Since XDR TB is resistant to most powerful first-line and second-line antituberculous drugs, the treatment outcome is usually worse, particularly in patients with impaired immune system, as in HIV infection.

Specific purified protein derivative (PPD) is available for the diagnosis of atypical mycobacterial strains. In HIV positive patients, when the CD4 count goes below 400, tuberculin energy is present and reflects the immune status of the host.

Newer methods of diagnosis of tuberculosis include radioimmunoassays (RIAs), soluble antigen fluorescent antibody (SAFA) test and enzyme linked immunosorbent assay (ELISA), polymerase chain reaction (PCR) to detect the bacterial DNA, and antibody assays to detect the release of interferon gamma in response to mycobacteria.

Treatment. Multiple drug therapy is often recommended as *M. tuberculosis* mutates and resists single drug therapy. Isoniazid (INH) combined with rifampicin for nine months or INH, rifampicin and pyrazinamide for two months followed by INH and rifampicin for four months. Other drugs used are streptomycin and ethambutol.

LEPROSY

(Hansen's disease)

Leprosy is a chronic granulomatous infection caused by *Mycobacterium leprae.* It multiplies very slowly and the incubation period is about five years. It may take as long as 20 years for the symptoms to develop. The disease is only slightly contagious. It mainly affects skin, peripheral nerves, the upper respiratory tract, eyes, and testes, but also affects muscles, bones, and joints. When untreated, it results in characteristic deformities. Nowadays because of early diagnosis and induction of appropriate therapy, major complications can be prevented. Binford et al, have published the most thorough and concise review of this disease. Recent studies and reports indicate that the incidence and prevalence is reduced due to multidrug therapy.

Etiology. *M. leprae* is an obligate intracellular, gram-positive, acid-fast bacillus. It is the only bacterium to infect peripheral nerve. It is unique in exhibiting dopa oxidase activity and acid fastness. It grows best in cooler tissues like skin, peripheral nerves, upper respiratory tract, anterior chamber of the eye, and testes; sparing warmer areas like axilla, groin, scalp, and midline of back. Taking smears from the skin, nasal mucosa of the affected persons, and staining with the Ziehl and Nielsen method can demonstrate the presence of bacilli. Living leprosy bacillus appears as solid staining pink rod whereas non-living leprosy bacilli may be granular or fragmented. It can be grown well in mouse footpad and nine banded armadillo and grows at 30–33° C with a doubling time of 12 days. It can remain viable in the environment for 10 days.

Epidemiology. Leprosy is almost exclusively a disease of developing countries. It is common in Asia, Africa, Latin America, and the Pacific. Africa has the highest disease prevalence and Asia has the most cases. More than 60% of the cases occur in India, China, Myanmar, Indonesia, Brazil, and Nigeria. Leprosy is still endemic in 28 countries. India accounts for 80% of the detection of leprosy cases in the world. The annual case detection rate in India is among the highest in the world (53 per 100,000).

In India prevalence is high in Bihar, Uttar Pradesh, Madhya Pradesh, Tamil Nadu, Andhra Pradesh, Orissa, and West Bengal. According to WHO, the official reports received from 109 countries and territories, the global registered prevalence of leprosy at the beginning of 2007 stood at 224,717 cases, while the number of new cases detected during 2006 were 259,017. Leprosy is very rare in infants and has a bimodal age distribution with peaks at 10–14 and 35–44 years. The mode of infection is not known but the probable spread could be through nasal secretion.

Pathogenesis. An immunologic and epidemiological study suggests most people develop a subclinical infection and very few develop infection. Once infected, both cell mediated and humoral responses are elicited by bacterial antigen DNA glycolipids. Lipoarabinomannan, a component of the cell membrane, induces immune suppression by inhibiting the interferon gamma mediated activation of macrophages.

The bacteria are taken by histiocytes in the skin and Schwann cells in the nerves. This usually results in an inflammatory response involving histiocytes and lymphocytes. It is clinically called indeterminate type represented as hypopigmented or erythematous macule. The clinical spectrum and ultimate outcome of disease depends upon the intensity of specific cell mediated immunity. Individuals prone to tuberculoid type have an intense cell mediated immune response and low bacillary load; whereas, patients with lepromatous type have low specific cell mediated immune response and a high bacillary load. These two different types are genetically controlled.

Clinical Features. Various types of clinical presentation occur in patients infected with this bacillus corresponding to patient's immune response. Leprosy manifests in two polar forms, namely, tuberculoid type and lepromatous type. Host resistance is high in tuberculoid type.

Between these two, the borderline and indeterminate forms occur depending upon the host response.

General features of leprosy are hypopigmented patches, partial or total loss of cutaneous sensation in the affected areas. The earliest sensation to be affected is usually light touch. The thickening of nerves and the presence of acid-fast bacilli in the skin or nasal smear are common. Tuberculoid lesions are characterized by single or multiple macular, erythematous eruptions, with dermal nerve and peripheral nerve trunk involvement resulting in the loss of sensation, often accompanied by the loss of sweating of the affected skin. The lepromatous lesions develop early erythematous macules or papules that subsequently lead to progressive thickening of the skin and characteristic nodules. These may develop in considerable numbers on any skin area and produce severe disfigurement.

Facial paralysis occurs with some frequency due to facial nerve involvement, and this has been discussed by Reichart et al. Features of advanced disease are nodules or lump in skin of the face and ears, plantar ulcers, loss of fingers and toes, nasal depression, foot drop, claw toe, and others. Although the disease is a crippling and disfiguring one, it runs a chronic course and seldom causes sudden death.

Oral Manifestations. The oral lesions that have been reported generally consist of small tumor like masses called lepromas, which develop on the tongue, lips, or hard palate. These nodules show a tendency to break down and ulcerate. Gingival hyperplasia with loosening of the teeth has also been described, but Reichart and his associates found that most of the gingival and periodontal changes occurring in a group of 30 leprosy patients were nonspecific.

Paralysis of facial and maxillary division of trigeminal nerve is reported. The dental manifestations are described as odontodysplasia leprosa. Premaxilla is affected in childhood due to granulomatous involvement. There will be a circumferential hypoplasia, shortening of roots, usually involving maxillary anterior teeth. Long standing lepromatous lesions may show granulomatous invasion of pulp and pinkish discoloration of crowns.

Histologic Features. The typical granulomatous nodule shows collections of epithelioid histiocytes and lymphocytes in a fibrous stroma. Langhans type giant cells are variably present. Sheets of lymphocytes with vacuolated macrophages called lepra cells are scattered throughout the lesions. In tuberculoid pattern, there is a paucity of organisms and they can be demonstrated only with acid-fast stains in contrast to lepromatous type where there is an abundance of organisms.

Diagnosis is based mainly on clinical and bacteriological examination. Culturing of the organism is difficult. So far the organism has been grown in the footpads of mice and armadillos.

Nasal smears and scrapings stained with modified Ziehl-Nielsen method to detect lepra bacilli at a concentration greater than 10^{11} gm of tissue. The morphological index is a measure of the number of AFB in skin scrapping that stain uniformly bright correlated with viability.

The bacteriologic index, a logarithmic scaled measure of density of *M. leprae* in the dermis, may be as high as 4t-6t in untreated patients falling by one unit per year during effective therapy.

Other investigations are skin biopsy, nerve biopsy, and foot culture histamine test. Tests for humoral response are monoclonal antibodies, ELISA, PCR, etc. In children, the sweat function test is used.

Leprosy should be differentiated from sarcoidosis, leishmaniasis, lupus vulgaris, lymphoma, syphilis, yaws, and other disorders having hypopigmentation.

Treatment. Specific long-term chemotherapy is initiated upon diagnosis. In 1981, WHO study group recommended multidrug therapy (MDT) and it consists of rifampicin, dapsone and clofazimine. The widespread use of MDT dramatically reduces the disease burden. Rifampicin and dapsone for six months in case of tuberculoid type and rifampicin and dapsone along with clofazimine in case of lepromatous type is usually advocated. However, drug regimen evaluation is very difficult in certain situations. Once the infection is treated, the management is directed towards the reconstruction of the damage caused by this disease.

ACTINOMYCOSIS

Actinomyces species are classified as anaerobic, gram positive and filamentous bacteria despite their fungal and bacterial characteristics. Actinomycosis is a chronic granulomatous suppurative and fibrosing disease caused by anaerobic or microaerophilic gram-positive nonacid fast, branched filamentous bacteria. They are a normal saprophytic component of oral flora, colon, and vagina and none are known to be recoverable from the environment.

Most of the species isolated from actinomycotic lesions have been identified as *A. israelii, A. viscosus, A. odontolyticus, A.naeslundii* or *A. meyeri.* These microorganisms have been identified in dental plaque, dental calculus, necrotic pulp, and tonsils.

These microorganisms were believed to be fungi at one time. However, as our knowledge of their biochemical and serologic aspects evolved, it became apparent that they were actually bacteria, their filaments frequently breaking up into bacillary and coccoid forms.

The usual pattern of this disease is one characterized chiefly by the formation of abscesses that tend to drain by the formation of sinus tracts. If the pus from the abscesses is examined on a clean glass slide, it shows the typical 'sulfur granules' or colonies of organisms, which appear in the suppurative material as tiny, yellow grains. Another infection that produces this type of sulfur granules is botryomycosis. Actinomycosis is classified anatomically according to the location of the lesions, and thus we recognize:

- Cervicofacial
- Abdominal
- Pulmonary forms.

It is well established that the actinomycete is a common inhabitant of the oral cavity even in the complete absence of

any clinical manifestations of specific infection. Thus, the organisms may be cultured from carious teeth, nonvital root canals, tonsillar crypts, dental plaque, calculus, gingival sulcus, and periodontal pockets.

The pathogenesis of actinomycosis is not entirely known. lt appears to be an endogenous infection and not communicable. Furthermore, it does not appear to be an opportunistic infection in a situation of depressed cell-mediated immunity. Trauma seems to play a role in some cases by initiating a portal of entry for the organisms, since they are not highly invasive. Thus the extracted socket, periodontal pocket, nonvital tooth, or mucosal abrasion may act as the portal of entry for the infection.

Epidemiology. Infection occurs throughout the lifetime with peak incidence in the middle age. Males are more commonly affected than females. Incidence has decreased presently due to improved oral hygiene and antibiotics.

Pathogenesis. The disruption of the mucosal barrier is the main step in the invasion of bacteria. Initial acute inflammation is followed by a chronic indolent phase. Lesions usually appear as single or multiple indurations. Central fluctuance with pus containing neutrophils and sulphur granules is diagnostic of the disease. The fibrous walls are typically described as woody. It occurs in association with HIV infection, transplantation, chemotherapy, herpes, and cytomegaloviral ulcerative mucosal lesions. It is also reported in osteoradionecrosis and in patients with systemic illness.

Clinical Features. Cervicofacial actinomycosis is the most common form of this disease and is of the greatest interest to the dentist. It has been emphasized by Norman that two-thirds of all cases are of this type. Stenhouse and associates, who also emphasized the surprisingly high incidence of occurrence of *Actinomyces* in routine pathologic and bacteriologic specimens, have reported a series of 39 cases of cervicofacial and intraoral actinomycosis. The organisms may enter the tissues through the oral mucous membranes and may either remain localized in the subjacent soft tissues or spread to involve the salivary glands, tongue, very rarely gingiva, bone or even the skin of the face and neck, producing swelling and induration of the tissue. These soft tissue swellings eventually develop into one or more abscesses, which tend to discharge upon a skin surface, rarely a mucosal surface, liberating pus containing the typical 'sulfur granules' (Fig. 5-5 A). The skin overlying the abscess is purplish red, indurated and has the feel of wood or often fluctuant. It is common for the sinus through which the abscess has drained to heal, but because of the chronicity of the disease, new abscess develop and perforate the skin surface. Thus the patient, over a period of time, may show a great deal of scarring and disfigurement of the skin.

The infection of the soft tissues may extend to involve the mandible, or less commonly, the maxilla which results in actinomycotic osteomyelitis. If the bone of the maxilla is invaded, the ensuing specific osteomyelitis may eventually involve the cranium, meninges, or the brain itself. Once the infection reaches the bone, the destruction of the tissue may be extensive.

Such destructive lesions within the bone may occur or localize at the apex of one or more teeth and simulate a pulp-related infection such as a periapical granuloma or cyst. Such a case has been reported by Wesley and his colleagues, who noted 12 other similar cases in the literature.

Abdominal actinomycosis is an extremely serious form of the disease and carries a high mortality rate. In addition to generalized signs and symptoms of fever, chills, nausea and vomiting, intestinal manifestations develop, followed by symptoms of the involvement of other organs such as the liver and spleen.

A B

Figure 5-5. Cervicofacial actinomycosis.
Clinical photograph **(A)** showing multiple graining abscess and photomicrograph **(B)** showing actinomycotic colony in a smear of the pus *(Courtesy of Dr Leela Poonja, Dr G Sriram, Dr Vaishali Natu).*

Pulmonary actinomycosis produces similar findings of fever and chills accompanied by a productive cough and pleural pain. The organisms may spread beyond the lungs to involve adjacent structures.

Histologic Features. The typical lesion of actinomycosis, either in soft tissue or in bone, is essentially a granulomatous one showing central abscess formation within which may be seen the characteristic colonies of microorganisms. These colonies appear to be floating in a sea of polymorphonuclear leukocytes, often associated with multinucleated giant cells and macrophages particularly around the periphery of the lesion. The individual colony, which may appear round or lobulated, is made up of a meshwork of filaments that stains with hematoxylin, but shows eosinophilia of the peripheral club shaped ends of the filaments (Fig. 5-5 B). This peculiar appearance of the colonies, with the peripheral radiating filaments, is the basis for the often-used term 'ray fungus.' The tissue surrounding the lesion exhibits fibrosis. Methenamine silver stain can demonstrate the organisms better.

Diagnosis. It should be differentiated from osteomyelitis caused by other bacterial and fungal organisms and soft tissue infections caused by staphylococcus. The diagnosis of actinomycosis depends not only upon clinical findings in the patient and the demonstration of the organisms in the tissue section or smear, but also upon their culture. However, as Brown pointed out in his extensive review of 181 cases of actinomycosis, the organisms are difficult to culture. Of the 67 cases in which culture was attempted, the organism was isolated in only 16 instances. Various organisms isolated are A *israelii, A. naeslundii, A. odontolyticus, A. viscosus, A. meyeri, A. gerencseriae,* and *Propionibacterium propionicum.* They are established but are a less common cause of the disease. Most actinomycosis is polymicrobial. *Actinobacillus actinomycetemcomitans, Eikenella corrodens, Enterobacteriaceae* and species of *Fusobacterium*, *Bacteroides*, *Capnocytophaga*, *Staphylococcus* and *Streptococcus* are commonly isolated depending upon the site of infection.

Treatment and Prognosis. The treatment of this disease is difficult and has not been uniformly successful. Long standing fibrosis cases are treated by draining the abscess, excising the sinus tract with high doses of antibiotics. Long term high dose penicillin, tetracycline and erythromycin have been used most frequently, but the course of the disease is still often prolonged, In addition to this surgical drainage of the abscesses and excision of sinus tract is necessary to accelerate healing.

BOTRYOMYCOSIS

(Bacterial actinophytosis, actinobacillosis)

Botryomycosis is a chronic granulomatous infection which was recognized over 130 years ago when it was first found to affect horses. Since that time, approximately more than 50 cases occurring in humans have been reported in literature, and the first case involving the oral cavity was reported by Small and Kobernick. There is some confusion as to the actual causative organism in this disease, although an *Actinobacillus* has been thought to be the one involved. Nevertheless, a variety of other types of organisms have been reported which may or may not represent secondary invaders. The *Actinobacillus* is often characterized as an 'associate' organism with the *Actinomycetes,* and some workers feel that the presence of Actinobacilli is necessary for the disease process of actinomycosis. However, actinomycosis is known to occur from a 'pure culture' of *Actinomycetes.* Whether 'pure cultures' of Actinobacilli can produce botryomycosis is not known, but many workers believe that a number of common bacteria such as *Staphylococcus, Streptococcus, Escherichia, Pseudomonas* and probably many others may serve as etiologic agents of the disease.

Clinical Features. Human botryomycosis is usually a localized granulomatous infection of the skin or mucosa. It has been reported in patients with impaired immunity or with underlying systemic conditions such as diabetes mellitus, cystic fibrosis or HIV infection. It may disseminate, involving the liver, lungs or kidneys, in which case the disease is usually fatal. The significance of this disease lies in the fact that the localized infection may closely mimic actinomycosis by producing a chronic granulomatous mass with multiple ulcers and sinuses. The oral case reported by Small and Kobernick involved the tongue and presented clinically as a firm, nodular infiltration of the body and base of the tongue. However, there were no sinuses present.

Differential diagnoses for botryomycosis include mycetoma, tuberculosis, nocardiosis, cat-scratch disease, and fungal infections.

Histologic Features. The chronic granulomatous nodules are characterized by the presence of suppurative foci which contain grains or granules that are recognized as forming around microorganisms in certain cases as apparently a nonspecific reaction between agent and host, possibly related to hypersensitivity. In the ordinary H and E stained section these granules may be indistinguishable from those of actinomycosis. These grains or granules are eosinophilic and PAS negative and negative to methenamine silver. The eosinophilic, peripheral clubs formation typical of actinomycetes is usually not identifiable in this disease.

Treatment. The suggestion has been made that botryomycosis may be caused by a variety of different microorganisms of low virulence, and therefore, the pathogenesis may be related more to a modified host resistance or tissue hypersensitivity than to a specific microorganism. Therefore, treatment is nonspecific. However surgical intervention aids in cure.

TULAREMIA

(Rabbit fever)

Tularemia is a disease caused by the gram-negative, non-motile, bacillus *Francisella tularensis,* also known as *Bacterium tularensis* and *Pasteurella tularensis.* This infection is contracted through contact with infected rodents and rabbits. This exposure and subsequent infection may occur during skinning and dressing freshly killed infected animals, through ingestion of contaminated meat and water, or through the bite of an infected deer fly or tick. This disease is highly communicable from infected

mammals to human. The organisms can persist for longer period of time in mud, water and decaying animal carcasses.

Clinical Features. Based on the site of infection tularemia has six characteristic clinical syndromes namely ulceroglandular (the most common type), glandular, oropharyngeal, pneumonic, oculoglandular and typhoidal. After a variable incubation period of upto seven days, the patient usually suffers a sudden headache, nausea, vomiting, chills, and fever. A single cut or sore on the skin develops into a suppurative ulcer. The lymphatic vessels become swollen and painful and the lymph nodes remarkably enlarged. This general sequel of events is the most common course of the disease and is called ulceroglandular tularemia. The eyes also become involved, with conjunctivitis developing through localization of the disease in the conjunctivital sac, oculoglandular tularemia. Tularemic pneumonia and pleuritis are complications of the disease, which may eventuate in gangrene and lung abscesses.

The disease occurs most frequently in adults. However, as Hughes has reported, children are sometimes affected and, in such cases, the correct diagnosis may be easily overlooked.

Oral Manifestations. The oral lesions account for 3–4% of all cases and are manifested as necrotic ulcers of the oral cavity or pharynx, usually accompanied by severe pain. In some cases it has been reported that a generalized stomatitis develops rather than isolated lesions; single nodular, masses eventually developing into abscesses have also been described. Regional lymphadenitis may arise in the submaxillary and the cervical groups of nodes.

Treatment. The disease responds well to antibiotic therapy. Streptomycin is the drug of choice. This disease also responds to adequate doses of gentamicin and tetracycline. Before the availability of the newer antibiotics, the disease was considered a serious one and even today, in some persons, it may run such a fulminating course that death occurs despite all forms of therapy.

Since *F. tularensis* is easy to aerosolize, highly infective, and the number of organisms needed to infect is very less, it is considered to be a biological weapon.

MELIOIDOSIS

Melioidosis is a specific infection in man and animals, caused by the bacillus *Burkholderia pseudomallei,* an aerobic, gram-negative nonacid-fast, and rod-shaped bacilli. This disease is endemic in certain areas of the far East, including Burma, Ceylon, India, Indochina, Malaysia, Thailand and Dutch East Indies. Military operations in that part of the world by United States Armed Forces have increased the significance of this disease, and cases have now been diagnosed in American servicemen who have returned from duty in Southeast Asia.

Clinical Features. There are two recognized forms of the disease, acute and chronic. In the acute form, the patients rapidly develop a high fever, evidence of acute pulmonary infection, diarrhea, and hemoptysis. There is widespread visceral involvement as a result of hematogenous dissemination of microorganisms. Death, as a result of fulminating septicemia may occur in a few days to weeks.

The chronic form of the disease usually develops in patients who have survived the acute form. It is of granulomatous type, characterized by multiple, small, nonspecific abscesses occurring subcutaneously or in the viscera, lymph nodes or bones, which often develop draining sinus tracts. These may involve the cervicofacial area and mimic fungal infection or tuberculosis.

The most important risk factor for developing melioidosis is diabetes mellitus. Other risk factors include thalassemia and kidney disease. The mode of transmission is not from one man to another man or from contact with the affected animals or animal excretions. The causative organism is abundant in soil and stagnant water where the disease occurs. It is believed that most human infections occur through contamination of skin abrasions by the soil or water. Diagnosis is usually made by culturing the organism from any one of the clinical sample and the throat sample is most sensitive.

Treatment. Incision and drainage, accompanied by massive antibiotic therapy, have proven moderately successful in treating the disease. Tetracycline alone or in combination with chloramphenicol were considered to be drugs of choice.

TETANUS

(Lock-jaw)

Tetanus is an acute infection of the nervous system characterized by intense activity of motor neurons and results in severe muscle spasms. It is caused by the exotoxin of the anaerobic, gram-positive bacillus *Clostridium tetani* that is commensal in human and animal gastrointestinal tracts and soil. It acts at the synapse of the interneurons of inhibitory pathways and motor neurons to produce blockade of spinal inhibition. The organisms can enter the body through even the most trivial injury.

Epidemiology. Tetanus is now a comparatively rare disease in developed countries. It occurs sporadically and almost always affects nonimmunized persons, partially immunized and even, less often, fully immunized individuals. It is common in areas where the soil is cultivated, rural areas, warm climates, and during summer. It is more common in males than females. It usually occurs after acute injuries such as laceration or abrasion. It may be acquired during farming, gardening, etc. It may also occur in patients with abscesses, ulcers and gangrene. It is associated with burns, frostbite, middle ear infection, surgery, abortion, and childbirth. Neonatal tetanus is fatal with a mortality rate of 80–90%. However, in Asia, especially in China, Myanmar, Indonesia and India, the death rate due to neonatal tetanus is greatly reduced due to immunization coverage of pregnant woman with a protective dose of tetanus toxoid. Bhutan, Korea, the Maldives, Sri Lanka and Thailand have declared neonatal tetanus, elimination.

Tetanus occurs mainly in Asia due to four reasons:

- In newborns where the umbilical cord is cut with an unsterile instrument

- In children with otorrhea
- In women with unsterile handling of genital tracts
- After acute trauma.

Pathogenesis. Under the suitable anaerobic conditions with low oxidation-reduction, potential spores of the *Cl. tetani* germinate and produce a potent neurotoxin (tetanospasmin) in the wounds. Once released it binds to the peripheral motor nerve terminal, enters the axon and is transported to the nerve cell body in the brainstem and spinal cord by retrograde intraneuronal transport. The toxin migrate across the synapse to presynaptic termina, where it blocks the release of glycine and gamma-aminobutyric acid (GABA). Once the inhibitory action is diminished, the resting-fixing rate of locomotor neuron increases, producing rigidity. The length of the nerve travelled determines the time of ascent and explains why the disease manifests first in muscles supplied by the short cranial nerves.

Clinical Features. The incubation period ranges from 3 days to 4 weeks. However, it may be as short as one day or as long as months due to dormant spores in the wound. The prophylaxis against tetanus can also prolong the incubation period.

Generalized tetanus is characterized by lock-jaw or trismus due to spasm of masseter, which is the initial symptom and a dental surgeon is the first person often to be consulted.

Dysphagia, stiffness or pain in the neck, shoulder or back muscles appear concurrently. Marked rigidity interferes with the movement of chest and impairs cough and swallowing reflexes. Laryngeal spasms may lead to asphyxia. The involvement of various muscles produces rigid abdomen and stiff proximal limb muscles. Hands and feet are relatively spared and sustained contraction of facial muscles results in a grimace or sneer called as risus sardonicus. The contraction of muscles of the back produces an arched back called opisthotonus. The spasms occur repetitively or spontaneously or provoked by slight stimulation.

Local tetanus manifests as spasm of muscles near the wound and is uncommon. Cephalic tetanus characterized by trismus and facial palsy is rare one, and may occur after head injury or ear infection.

This disease, which has been reviewed in depth by Smith and Myall, is of significance to the dentist because of the acute trismus which may develop in these patients and simulate acute oral infection, trauma, temporomandibular dysfunction and even hysteria.

It should be differentiated from other inflammatory conditions of oral cavity, strychnine poisoning, drug-induced reactions, and hypocalcemic tetany.

Treatment

General measures. The aim of treatment is to remove spores at the site of the wound, prevent toxin production, neutralize unbound toxins and prevent muscular spasms. Cardiopulmonary monitoring should be maintained continuously. Sedation, airway, and nutrition should be maintained. Antibiotics should be given to eradicate vegetative organisms or source of toxins. Penicillin 10–12 million units IV for 10 days, metronidazole 1 gm every 12 hours should be administered. Clindamycin or erythromycin is an alternative for penicillin allergic patients,

Antitoxin is injected to neutralize circulating toxin and unbound toxin.

Human tetanus immunoglobulin (TIG) 3000–6000 units IM individual doses. Though the optimum dose is not known, a 500 unit dose is as effective as higher doses.

Prophylaxis. Wound debridement and booster doses of TT.

Unimmunized individuals. Anti-tetanus serum 1500 units or TIG 250 units should be given.

An active immunization schedule requires three doses triple vaccine in the first year of life with subsequent doses or booster doses of TT at school entry and at 5–10 year interval should be given.

SYPHILIS
(Lues)

Syphilis is a centuries-old infectious disease that has protean clinical features. The name was probably derived from a handsome and wealthy shepherd who was affected by the disease. It is said to have evolved from between 15,000 and 3,000 BC and transported to Asia by Portuguese sailors led by Vasco da Gama. It was an extremely common infection a few decades ago. Widespread use of antibiotics after World War II reduced the incidence of syphilis. However, within the past three decades there has been as astonishing upsurge in the incidence of the disease, much of it in teenagers. Its return is associated with the emerging HIV pandemic.

Syphilis is caused by *Treponema pallidum,* a spirochete, and is characterized by episodes of active disease interrupted by the period of latency. This gram-positivea, motile, microaerophilic spirochete is pathogenic to humans, which may be best demonstrated by the dark field microscope, since it stains poorly except by silver impregnation. In 1998, the complete genetic sequence of *T. pallidum* was reported which might help in understanding the pathogenesis of syphilis.

The route of transmission of syphilis is usually by sexual contact, although there are examples of congenital syphilis via transmission from mother to child in utero.

Epidemiological studies demonstrate that sexually transmitted diseases including syphilis, and particularly genital ulcers associated with primary syphilis, are associated with an increased risk of HIV infection.

Acquired Syphilis

The acquired form of syphilis is contracted primarily as a venereal disease, after sexual intercourse with an infected partner, although persons, such as dentists, working on infected patients in a contagious stage, have innocently acquired it in many cases. The disease, if untreated, manifests three distinctive stages throughout its course, so that it is customary to speak of primary, secondary and tertiary lesion of acquired syphilis.

In the **primary stage,** a lesion known as chancre develops at the site of inoculation approximately 3–90 days after contact with the infection. Chancre is usually solitary but may be multiple at times. It most commonly occurs on the penile in the male and on the vulva or cervix in the female. About 95% of chancres occur on the genitalia, but they are also found in other areas. In recent years, there appears to have been an increase in the occurrence of extragenital syphilis as result of an increase in altered sexual activity and increased contact among infected male homosexuals. Of particular interest to the dentist are those lesions occurring on the lips, tongue, palate, gingiva, and tonsils. The chancre has been reported developing even at the site of a fresh extraction wound. The usual primary lesion is an elevated, ulcerated nodule showing local induration and producing regional lymphadenitis. Such a lesion on the lip may have a brownish, crusted appearance (Fig. 5-6). Very rarely, it appears vascular, mimicking a pyogenic granuloma.

The intraoral chancre is an ulcerated lesion covered by a grayish-white membrane, which may be painful because of secondary infection. The chancre abounds with spirochetes, easily demonstrable by dark field examination of a smear, and is highly infectious. The *Treponema microdentium,* which is found in many nonsyphilitic people, may be confused with *T. pallidum* on dark field examination. Therefore, lesions contaminated by saliva should not be diagnosed by dark field examination of the lesion, but by dark field examination of an affected regional lymph node. An enlarged lymph node is almost always found along the lymphatic draining of the area of the chancre.

The chancre appears microscopically as a superficial ulcer showing a rather intense inflammatory infiltrate. Plasma cells are particularly numerous. The microorganisms are present in the tissue and may be demonstrated by silver stain, although the diagnosis should not be established by this means but, rather, by any one of a variety of serologic tests. Of considerable importance is the fact that not every patient with a primary lesion exhibits a positive serologic reaction despite the presence of a spirochete. The chancre heals spontaneously in three weeks to two months.

Figure 5-6. Chancre of lip.
(Courtesy of Dr Boynton H Booth).

The **secondary or metastatic stage,** usually commencing about six weeks after the primary lesion, is characterized by diffuse eruptions of the skin and mucous membranes. In contrast to the solitary lesion in the primary stage, lesions of the secondary stage are typically multiple. On the skin, the lesions often appear as macules or papules which are painless. The oral lesions, called 'mucous patches,' are usually multiple, painless, grayish-white plaques overlying an ulcerated surface (Fig. 5-7). They occur most frequently on the tongue, gingiva, or buccal mucosa. They are often ovoid or irregular in shape and are surrounded by an erythematous zone. Mucous patches are also highly infectious, since they contain vast numbers of microorganisms. In the secondary stage the serologic reaction is always positive. The lesions of the secondary stage undergo spontaneous remission within a few weeks, but exacerbations may continue to occur for months or several years.

A B

Figure 5-7. Secondary syphilis.
(A) Mucous patch of lip in secondary syphilis. **(B)** Annular, circinate lesions of skin in secondary syphilis *(Courtesy of Dr Edward V Zegarelli)*.

Secondary syphilis can be present as an explosive and widespread form known as **lues maligna**, characterized by fever, headache, and muscle pain followed by necrotic ulcerations involving the face and the scalp. This form is reported in patients with a compromised immune system, particularly acquired immune deficiency syndrome.

After second-stage patients are free from lesions and symptoms, they enter the latent stage which may last for 1–30 years till the next stage, tertiary syphilis, develops. Patients demonstrate reactive serological test for syphilis.

Tertiary syphilis, also called late syphilis, does not usually appear for several years and involves chiefly the cardiovascular system, the central nervous system, and certain other tissues and organs. Late syphilis is noninfectious. Classic lesion of the tertiary syphilis is gumma. It is the result of hypersensitivity reaction between the host and the treponemes or their breakdown products. Gumma occurs most frequently in the skin and mucous membranes, liver, testes, and bone. It consists of a focal, granulomatous inflammatory process with central necrosis. The lesion may vary in size from a millimeter or less to several centimeters in diameter.

The intraoral gumma most commonly involves the tongue and palate. In either situation the lesion appears as a firm nodular mass in the tissue, which may subsequently ulcerate, to form a deep painless ulcer. Lesions of the palate cause perforation by sloughing of the necrotic mass of tissue. (Fig. 5-8). Such an occurrence frequently follows vigorous antibiotic therapy, a Herxheimer reaction.

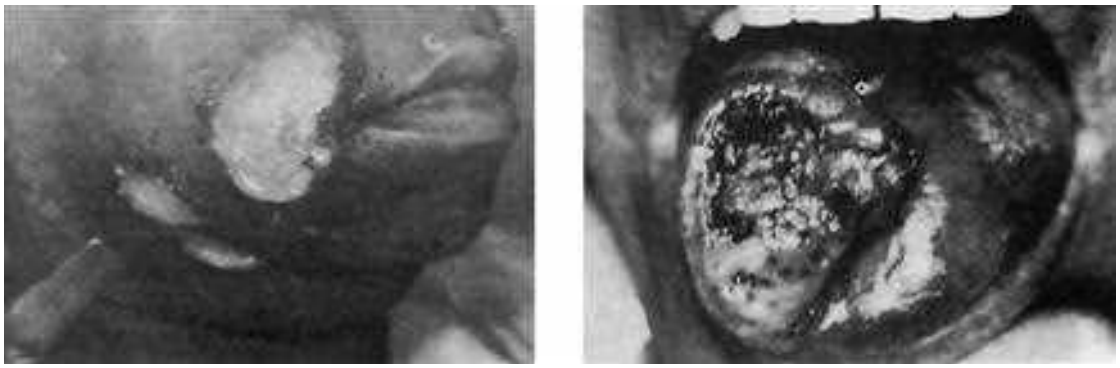
Meyer and Shklar have reported oral manifestations in 81 cases of acquired syphilis, and have stressed that tertiary lesions are far more common than lesions in either primary or secondary syphilis. However this ratio is probably changing. Atrophic or interstitial glossitis is the most characteristic and important lesion of syphilis and is due to endarteritis obliterans.

In syphilitic glossitis, the surface of the tongue gets broken up by fissures due to atrophy and fibrosis of tongue musculature; and hyperkeratosis frequently follows. Syphilitic glossitis is found almost exclusively in males. The predilection for syphilitic glossitis to undergo carcinomatous transformation has been recognized for many years. The incidence of such malignant transformation has been as high as 30% in various reported series. However, in the series of Meyer and Shklar, the development of epidermoid carcinoma in luetic glossitis occurred in only 19% of the cases. In a separate study, the same authors reported that only 7.5% of the patients in a series of 210 cases of carcinoma of the tongue had a past history of syphilis. The prominent apparent decrease in the relationship between syphilis and lingual carcinoma was suggested to be related to the early and intensive treatment of the disease with antibiotics since 1940.

Congenital (Prenatal) Syphilis

Congenital syphilis is transmitted to the offspring only by an infected mother and is not inherited. Though congenital syphilis is totally preventable, it still continues to be a major problem in many countries. It is recognized that if treatment with antibiotics begins in infected pregnant women before their fourth month of pregnancy, approximately 95% of the offspring of these mothers will be free of the disease. It is to be noted that not all infected pregnant women deliver children with congenital syphilis. One-third of pregnancies result in abortion or stillbirth; one-third deliver normal children and the rest deliver children with congenital syphilis. Persons with congenital syphilis manifest a great variety of lesions, including frontal bossae (found in 87% of a series of 271 patients with congenital syphilis reported by Fiumaraand Lessell), short maxilla (in 84%), high palatal arch (in 76%). saddle nose(in 73%), mulberry molars (in 70%); Higoumenakis sign or irregular thickening of the sternoclavicular portion of the clavicle (in 39%), relative protuberance of mandible (in 26%), rhagades (in 7%), and saber shin (in 4%) (Fig. 5-9). Reportedly pathognomonic of the disease is the occurrence of Hutchinson's triad: hypoplasia of the incisor and molar teeth, eighth nerve deafness, and interstitial keratitis (q.v.).

In the above reported series, 75% of the persons with congenital syphilis had one or more of the components of



A B

A B

Figure 5-9. Congenital syphilis.
Saddle nose **(A)** and rhagades or radiating fissures **(B)** of congenital syphilis *(Courtesy of Dr Wilbur C Moorman and Dr Robert J Gorlin)*.

Hutchinson's triad. It is unusual; however, for all features of this triad to occur simultaneously in the same person.

Diagnosis and Treatment. Wassermann test and Hinton test (based on flocculation) were considered to be effective tests for the diagnosis of syphilis, but the disadvantage is false positive results. The diagnosis can be made by examining the exudates of the active lesion under a dark field microscope for spirochaetes. Care should be taken to eliminate salivary contamination since false positive results are possible due the presence of *T. microdentium, T. macrodentium,* and *mucosum.* Specific and highly sensitive serological tests are fluorescent treponemal antibody absorption and *T. pallidum.* hemagglutination assays.

Penicillin is the drug of choice. Erythromycin or tetracycline is used if the patient is allergic to penicillin. Surgical correction of the facial defects gives good esthetic results.

GONORRHEA

Gonorrhea is primarily a venereal disease affecting the male and female genitourinary tract and is transmitted by sexual intercourse. It is an infection of epithelium and commonly manifests as cervicitis, urethritis, prostatitis, and conjunctivitis. It is caused by *Neisseria gonorrhoeae* a gram-negative, nonmotile, nonspore forming organism that grows in pairs *(diplococci).* The common age group affected is 15–29 years with about half in the adolescent age.

It is a significant cause of morbidity in developing countries and may play a role in the transmission of HIV. In India gonorrhea is more widely prevalent than syphilis and 80% of infected women are reported to be asymptomatic carriers. It predominantly affects young persons.

The incidence of gonorrhea has increased in developing countries, but the exact incidence is difficult to ascertain because of limited surveillance and variable diagnostic criteria. It is transmitted from males to females and vice versa. Oropharyngeal gonorrhea occurs in 20% of women who practice fellatio with infected partners. The incubation period is one to five days.

Clinical Features. Infection in males results in acute urethritis, dysuria and urethral discharge of a purulent nature. Some patients may have mucoid discharge. It may lead to epididymitis, chronic prostatitis, balanitis and posterior urethritis.

In females, it manifests as cervicitis with candidal or trichomonal vaginitis. Mostly they are symptomatic. Carrier symptoms include vaginal discharge, discomfort, and dysuria. It may affect the rectum, oropharynx, and the eye.

Oral Manifestations. Extragenital gonorrheal infection of oral cavity is being seen with increasing frequency, especially among but not confined to homosexuals, and occurs as a result of oral-genital contact or inoculation through infected hands. Transmission by fomites is rare. Schmidt and coworkers have reviewed the literature on gonococcal stomatitis and have pointed out the clinical similarity between the oral lesions of this disease and the oral lesions of erythema multiforme, erosive or bullous lichen planus, and herpetic stomatitis. Chue has also reviewed this disease, describing the various oral lesions in detail. The lips may develop acute painful ulceration, limiting motion; the gingiva may become erythe-matous, with or without necrosis; and the tongue may present red, dry ulcerations or become glazed and swollen with painful erosions, with similar lesions on the buccal mucosa and palate.

Gonococcal pharyngitis and tonsillitis are also well recognized lesions. These appear as vesicles or ulcers with a gray or white pseudomembrane. Oral lesions are commonly accompanied by fever and regional lymphadenopathy. Finally, gonococcal parotitis, presumably a result of an ascending infection from the duct to the gland, has been reported on numerous occasions.

Complications. Epididymitis, salpingitis, pelvic inflammatory disease, and bartholinitis are the usual copmlications. Gonococcal bacteremia leads to dermatitis and arthritis. Joint

involvement leads to arthritis or arthralgia with effusion. Patients with gonorrhea are at risk for additional sexually transmitted diseases, most commonly *Chlamydia trachomatis.*

Diagnosis. Rapid diagnosis is done by Gram staining of urethral discharge. Samples can be collected with Dacron or Rayon swabs. Special media used for gonococcus are Thayer-Martin media or Stuart or Armies media.

Treatment. Antibiotics and other preventive measures should be followed.

GRANULOMA INGUINALE

(Granuloma venereum, donovanosis)

Granuloma inguinale was first recognized in India by McLeod in 1882. This disease is a progressive, chronic, infectious, granulomatous disease caused by microorganisms, probably bacilli, formerly designated as Donovania granulomatis and popularly called Donovan bodies, but now carrying the name **Calymmatobacterium granulomatis**. Their taxonomic status is uncertain. It is considered to be a venereal disease, but is only mildly contagious. Care should be exercised not to confuse granuloma inguinale with lymphogranuloma venereum, a venereal disease that is caused by strains of *Chlamydia trachomatis,* once designated as viruses but now morphologically classified as bacteria. The oral cavity is not notably involved in this latter disease.

Clinical Features. The disease is most prevalent in the tropical zones, but is found in the southern portion of the United States. It chiefly affects adult blacks of either gender, but may occur in any race. The primary lesions of granuloma inguinale appear on the external genitalia, anus, and in the inguinal region. They are manifested as papules or nodules, which ulcerate to form clean, granular lesions with rolled margins and which show a tendency for peripheral enlargement. Occasionally, verrucous, necrotic, or cicatricial lesions have been reported. Satellite lesions often arise through lymphatic extension. Inguinal ulceration is commonly secondary to the genital lesions and arises initially as a fluctuant swelling known as a pseudobubo.

Extragenital lesions also may occur on the oral mucous membranes, usually through autoinoculation rather than as a primary infection, as well as in the pharynx, esophagus, and larynx. Finally, metastatic spread to bones and soft subcutaneous tissues has been, reported. Two separate investigators have reported an incidence of extragenital lesions of granuloma inguinale to be 6% and 1.5%, respectively.

Oral Manifestations. Oral lesions appear to be the most common extragenital form of granuloma inguinale. Ferro and Richter, who described additional cases, have reviewed the reported cases. The lesions of the oral cavity are usually secondary to active genital lesions and appear in a variable period of time after the primary lesion, frequently months to several years later. The definitive diagnosis rests upon the demonstration of Donovan bodies in tissue from the lesions. Lesions may occur in any oral location such as the lips, buccal mucosa, or palate, or they may diffusely involve the mucosal surfaces. The varied clinical appearance of the lesions is the basis for their classification into one of three types: ulcerative, exuberant, and cicatricial. Thus there may be painful ulcerated lesions, sometimes bleeding, suggestive but not pathognomonic of the disease. Or, in other instances, the lesions may appear as proliferative granular masses, with an intact epithelial covering. The mucous membrane generally may be inflamed and edematous. Cicatrization is one of the most characteristic of the oral manifestations of granuloma inguinale. Fibrous scar formation may become extensive, and if present in areas such as the cheek or lip, may also limit mouth opening as to necessitate surgical relief.

Histologic Features. The microscopic pattern of the various forms of granuloma inguinale is one of granulation tissue with infiltration of polymorphonuclear leukocytes and plasma cells. There is usually a marked overlying pseudoepitheliomatous hyperplasia. Pathognomonic of the disease is the presence of large mononuclear phagocytes, each containing intracytoplasmic cysts within which are found the Donovan bodies. These bodies are tiny, elongated, basophilic and argyrophilic rods and are present in profuse numbers within the macrophages. Differential diagnoses of oral lesions include all granulomatous lesions of the oral cavity. Where genital lesions are also present, other sexually transmitted disease must be considered in differential diagnosis.

Treatment. Tetracycline, chloramphenicol, streptomycin garamycin, and cotrimoxazole are effective in the treatment of this disease. Complete healing usually occurs within two to three weeks. It has been noted that, after treatment, improvement of the genital lesions is usually accompanied by improvement of the extragenital oral lesion; conversely, exacerbation of genital lesions usually results in worsening of the oral condition.

RHINOSCLEROMA

(Scleroma)

Rhinoscleroma is a chronic, slowly progressive, localized infectious, granulomatous disease caused by the bacillus *Klebsiella rhinoscleromatis* (Klebsiella type 3), a gram-negative non-motile bacillus. This etiologic agent has been discussed in detail by Hoffman. This disease has worldwide distribution and is endemic in countries such as China, India, Indonesia, Africa, South and Central America, and in central parts of Eastern Europe. The mode of transmission is through infected nasal exudate.

The granulomatous, nodular lesions that occur in rhinoscleroma are found chiefly in the upper respiratory tract, often originating in the nose, but involvement of the lacrimal glands, orbit, skin, paranasal sinuses, and intracranial invasion have also been described. The proliferative nasal masses may produce the configuration known as the 'Hebra nose,' which is typical of this disease.

Oral lesions appearing as proliferative granulomas are also known to occur. In addition, impairment of the sensation of taste, anesthesia of the soft palate and enlargement of the uvula and upper lip are described. Three cases of rhinoscleroma

seen in a maxillofacial practice in Nigeria have been discussed by Edwards and associates, who have included an extensive bibliography of the disease.

Treatment of this disease consists of administration of tetracycline or ciprofloxacin. If left untreated the outcome will be fatal.

NOMA

(Cancrum oris, gangrenous stomatitis)

Noma, which means to devour (a spreading sore), is a rapidly spreading mutilating, gangrenous stomatitis that occurs usually in debilitated or nutritionally deficient persons associated with high morbidity and mortality. It is seen chiefly in children but is also found in adults under certain conditions, such as those existing among the malnourished internees of the Belsen concentration camp reported by Dawson after World War II. Today, the disease is rare in North America and Western Europe. Most cases occur in Africa, Southeast Asia and South America. For example, one of the last reports of an extensive series was that of Enwonwu, who described 69 cases of noma in 'miserably malnourished' Nigerian children between the ages of two and seven years. He also documented occurrence of necrotizing ulcerative gingivitis (NUG) in 27% of Nigerian children hospitalized for treatment of protein-calorie malnutrition.

Predisposing factors play an important role in the development of this condition, since it occurs chiefly in persons who are undernourished or debilitated from infections such as diphtheria, dysentery, measles, pneumonia, scarlet fever, syphilis, tuberculosis, and blood dyscrasias, including anemia. Thus noma may be considered a secondary complication of systemic disease rather than a primary disease.

Noma appears to originate as a specific infection by Vincent's organisms, an acute necrotizing gingivostomatitis, which is soon complicated by secondary invasion of many other microbial forms, including streptococci, staphylococci, and diphtheria bacilli.

Selye reported the production of a noma-like condition in rats as a result of simultaneous administration of cortisone and clipping of the mandibular incisors, forcing the animals to chew with their gingiva and thus to cause excessive mechanical injury to the mucosa. This condition usually began around the gingiva and progressed to destroy the floor of the mouth and the lower lip. The increase in susceptibility of the rat tissues to injury, induced by the cortisone, could be eliminated by the simultaneous administration of pituitary growth hormone (somatotrophic hormone, or STH). On the basis of his experimental findings, Selye suggested that noma may not necessarily be due to a specific pathogenic agent, but may be due to a 'pathogenic situation' resulting from faulty adaptation to a nonspecific injury or stress.

Clinical Features. Noma usually begins as a small ulcer of the gingival mucosa which rapidly spreads and involves the surrounding tissues of the jaws, lips, and cheeks by gangrenous necrosis (Fig. 5-10). The initial site is commonly an area of stagnation around a fixed bridge or crown. The overlying skin

Figure 5-10. Noma.

becomes inflamed, edematous and finally necrotic, with the result that a line of demarcation develops between healthy and dead tissue, and large masses of the tissue may slough out, leaving the jaw exposed. The commencement of gangrene is denoted by the appearance of blackening of the skin. It is reported that the subcutaneous fat pad and buccal fat pad undergo necrosis in advance of the other adjoining tissues.

The odor arising from the gangrenous tissues is extremely foul. The palate and occasionally the tongue may become involved in this process, but this is not common. Patients have a high temperature during the course of the disease, suffer secondary infection and may die from toxemia or pneumonia.

Treatment and Prognosis. The mortality rate of noma approximated 75% before the availability of antibiotics. Although the disease is still serious, the prognosis is considerably better if antibiotics are administered before the patient reaches the final stages. Immediate treatment of any existing malnutrition further improves the probability of saving the patient.

CAT-SCRATCH DISEASE

(Cat-scratch fever, benign lymphoreticulosis, benign nonbacterial regional lymphadenitis)

Cat-scratch disease was first reported by Debre and his coworkers in 1950. Once it was thought to be a viral infection and was even called nonbacterial regional lymphadenitis. Though common in the USA and Britain, it is relatively rare in the Indian subcontinent. The causative organism is *Bartonella henselae,* a gram-negative bacillus demonstrable with silver stain.

Clinical Features. This disease, occurring at any age, but predominantly in children and young adults, is thought to arise after a traumatic break in the skin due to the scratch or bite of the household cat. On rare occasions, dogs and monkeys have served as the vector. Actually, there is a definite history of scratches in only 55–60% of patients, according to Rickles and Bernier, although 90% of patients with the disease had recent contact with cats. The primary lesion is often a papule, pustule or vesicle that develops at the site of the injury. Within one to three weeks, a regional lymphadenitis without lymphangitis develops. The cat apparently serves only as a carrier of the disease, since the animal is not ill and does not respond to the intradermal antigen test.

The lymphadenopathy is usually the cause for the patients seeking professional advice. In a series of 115 patients with clinical cat-scratch disease reported by Margileth, 57% had lymphadenopathy involving the extremities, and 43%, the head and neck. The nodes are painful and may be several centimeters in diameter. The overlying skin may be inflamed. This lymphadenopathy may persist for one to six months and may be accompanied in the early stages of the disease by a low-grade fever, headache, chills, nausea, malaise, or even abdominal pain. Other manifestations occasionally seen include a nonpruritic macular or maculopapular rash, parotid swelling, conjunctivitis, and grand mal seizures. Another unusual manifestation of the disease, reported by Carithers, is the oculoglandular syndrome of Parinaud. This consists of a localized granuloma of the eye and preauricular lymphadenopathy. The lymph nodes gradually become soft and fluctuant, owing to necrosis and suppuration. Pus has been reported in numerous studies to be bacteriologically sterile. Occasionally, an abscessed node will perforate the skin and drain.

If the preauricular, submaxillary, or cervical chain of nodes are involved, the dentist may be consulted to rule out dental disease as an etiologic factor. Cat-scratch disease may also resemble more serious infectious granulomatous diseases such as tuberculosis or tularemia, lymphogranuloma venereum, infectious mononucleosis, or Hodgkin's disease and lymphosarcoma.

Diagnosis is usually established by a positive intradermal skin test of antigen from a patient with proved cat-scratch disease. This test is not invariably positive, however. Indirect immunofluorescent antibody assay is used for detecting antibodies to *Bartonella henselae.* The alternate one is finding IgM antibodies to the organism by ELISA.

Histologic Features. Early in the course of the disease the involved lymph nodes manifest reticuloendothelial hyperplasia; later, destruction of lymph node architecture with focal granulomas, suppuration, and necrosis develops with capsular thickening. Epithelioid cells and multinucleated giant cells are occasionally seen. The microscopic appearance is not particularly pathognomonic, but is certainly suggestive. Warthin-Starry silver staining demonstrates the causative organisms taken in areas free from significant necrosis. Brown-Hopps Gram staining method may also be used to highlight the bacilli.

Prognosis. The prognosis is good, since the disease is self-limiting and regresses within a period of weeks or months. Incision and drainage of the involved node may be necessary. Antibiotic therapy is ineffective.

PYOGENIC GRANULOMA

(Granuloma pyogenicum)

It is a distinctive clinical entity originating as a response of the tissues to a nonspecific infection. It is a tumor like growth that is considered as an exaggerated, conditioned response to minor trauma. The term pyogenic granuloma was applied based on an identical lesion on the skin, thought to be caused by pyogenic organisms. However, this is no longer accepted. It is of particular significance because of its common intraoral occurrence and because of its alarming clinical course sometimes.

Etiology. Pyogenic granuloma was originally believed to be a botryomycotic infection, an infection in horses thought to be transmissible to man. Subsequent work suggested that the lesion was due to infection by either staphylococci or streptococci, partially because it was shown that the microorganisms could produce colonies with fungus like characteristics. It is now generally agreed; however, that the pyogenic granuloma arises as a result of some minor trauma to the tissues, which provides a pathway for the invasion of nonspecific types of microorganisms. The tissues respond in a characteristic manner to these organisms of low virulence by the overzealous proliferation of a vascular type of connective tissue. Some investigators think that penetration of microorganisms into the tissues does not occur or is negligible, since microorganisms can seldom be demonstrated deep in the lesion with appropriate bacterial staining techniques. The surface of the pyogenic granuloma, especially in areas of ulceration, abounds with typical colonies of saprophytic organisms.

This tissue response reiterates the well-known biologic principle that any irritant applied to living tissue may act either as a stimulus or as a destructive agent, or as both. In adult tissues, the relative quiescence of the cells may be due either to an active restraint of growth or to a passive absence of stimulus for growth. Tissue culture studies of adult cells have shown that there is no active restraint of growth. It may then be assumed that tissues of embryos and young animals contain stimuli for the proliferation of cells. The sulfhydryl radical is probably one of the most essential stimulating agents. Burrows believed that all cells give off a stimulating substance. If many cells are present in a small volume of tissue and there is a relative reduction of blood flow through the area, as in inflammation, the concentration of this stimulating substance will be high and growth will be stimulated. As differentiation and maturation are attained, the cells become widely separated; the concentration of the substance falls, and little growth occurs. In the type of inflammation which results in the formation of pyogenic granuloma, the destruction of the fixed tissue cells is slight, but the stimulus to proliferation of the vascular endothelium persists and exerts its influence over a long period of time.

Clinical Features. The pyogenic granuloma of the oral cavity arises most frequently on the gingiva accounting around 75% of all cases. It may also occur on the lips, tongue and buccal mucosa, and occasionally on other areas. The lesion is usually an elevated, pedunculated or sessile vascular mass with a smooth, lobulated, or even a warty surface, which commonly is ulcerated and shows a tendency for hemorrhage either spontaneously or upon slight trauma (Fig. 5-11). The lesions are more common in the facial aspect than the lingual or palatal aspects of gingiva and can occur involving both sides including interdental papilla. It may be single or occurs at more than one site, unilateral or bilateral especially when it involves gingiva. Sometimes there is exudation of purulent material, but this is not a characteristic feature despite the suggestive

A B

Figure 5-12. Pyogenic granuloma.
(A) Low-power photomicrograph of pyogenic granuloma covered on the surface by epithelium and on the other by a fibrinous exudate; the vascularity of the lesion is obvious. **(B)** High-power photomicrograph of A demonstrates the numerous endothelium-lined blood channels and fibroblasts.

name of this lesion. It is deep red or red purple, depending upon its vascularity, painless, and rather soft in consistency. Some lesions have a brown cast if hemorrhage has occurred into the tissue.

The pyogenic granuloma may develop rapidly, reach full size and then remain static for an indefinite period. The lesion is more common in the maxillary anterior region than the posterior region. The lesions in different cases may vary considerably in size, ranging from a few millimeters to a centimeter or more in diameter. In an excellent study of the pyogenic granuloma, in which he reported 289 cases, Kerr stated that the age group incidence was not significant, cases having been seen in both very young infants and elderly persons with no apparent predilection for any one age group. Nor were any significant differences in occurrence found between the genders. However, in a series of 835 cases discussed by Angelopoulos, he noted that about 60% of the lesions occurred in persons between 11 and 40 years of age, that over 70% involved females. The reason for female predilection is because of vascular effects of female hormones.

An **intravenous pyogenic granuloma** occurring on the neck and upper extremities has been reported by Cooper and his associates in a series of 18 patients between 15 and 66 years of age. These lesions, which appear to represent a different entity from that known as intravascular papillary endothelial hyperplasia (q.v.), have not been reported in the oral cavity.

Histologic Features. The histologic appearance of the pyogenic granuloma is similar to that of granulation tissue except that it is exuberant and is usually well localized (Fig. 5-12). The overlying epithelium, if present, is generally thin and atrophic, but may be hyperplastic. If the lesion is ulcerated, it shows a fibrinous exudate of varying thickness

over the surface. The most startling features are the occurrence of vast numbers of endothelium-lined vascular spaces and the extreme proliferation of fibroblasts and budding endothelial cells. In addition, there is usually a moderately intense infiltration of polymorphonuclear leukocytes, lymphocytes, and plasma cells, but this finding will vary, depending upon the presence or absence of ulceration. The connective tissue stroma is typically delicate, although frequently fasciculi of collagen fibers are noted coursing through the tissue mass. If the lesion is not surgically excised, there is gradual obliteration of many capillaries, and it assumes a more fibrous appearance. This maturation of the connective tissue elements is construed as evidence of healing of the lesion. Both clinically and microscopically, an old lesion may resemble a fibroepithelial polyp or even a typical fibroma, and it is likely that many so-called intraoral fibromas are healed pyogenic granulomas.

Pregnancy tumor is histologically identical to pyogenic granuloma of the gingiva frequently occurring during pregnancy and often has been called the pregnancy tumor. This is a well-defined lesion, which appears about the third month of pregnancy or sometimes later, gradually increases in size and, after delivery, may or may not regress (Fig. 5-13). If surgically removed during pregnancy, it frequently recurs. It is now believed by most workers that the pregnancy tumor is simply a pyogenic granuloma which occurs as a result of local minor trauma or irritation and in which the tissue reaction is probably intensified by the endocrine alteration occurring during pregnancy. There appears to be no justification for retaining the term pregnancy tumor, since lesions of an identical clinical and histologic nature are seen in men as well as in non-pregnant women.

Treatment and Prognosis. Pyogenic granulomas are treated by surgical excision. The lesion occasionally recurs because it is not encapsulated, and the surgeon may have difficulty in determining its limits and excising it adequately. Some recurred lesions may represent examples of a second episode of irritation with reinfection of tissue.

When excising a pyogenic granuloma of the gingiva, extreme care should always be taken to scale the adjacent tooth and make certain that it is free of calculus, since the calculus may act as the irritation leading to recurrence of the lesion. Careful microscopic examination of excised pyogenic granulomas will almost invariably reveal fragments of calculus on the inner surface of the lesion which was adjacent to the tooth.

PYOSTOMATITIS VEGETANS

Pyostomatitis vegetans is an uncommon inflammatory disease of the oral cavity originally described by McCarthy in 1949. The name was suggested because of the clinical similarity between the oral lesions of this disease and the skin lesions in a dermatologic disease known as 'pyodermatite végetanté'. The disease has been described in even greater detail by McCarthy and Shklar, who pointed out that the oral lesions are one part of a syndrome in which the patients also manifest concomitantly ulcerative colitis or other gastrointestinal disturbances. In fact, the history of colitis or a gastrointestinal disturbance often points to the diagnosis of the oral lesions. Regional enteritis or regional ileitis, also known as Crohn's disease, is a granulomatous inflammation of the intestine of unknown etiology which is also recognized as one form of gastrointestinal disturbance that may be associated with pyostomatitis vegetans. This has been discussed by Cataldo and his associates who illustrated a case in which the oral lesions ultimately led to the diagnosis of the intestinal disease. A few patients with liver disease also have oral manifestations related to pyostomatitis vegetans.

Oral Manifestations. The oral lesions consist of large numbers of broad based papillary projections, tiny abscesses or vegetations developing in areas of intense erythema (Fig. 5-14). These lesions may occur in any area of the oral cavity, although tongue involvement appears to be uncommon. The oral lesions may precede or occur concurrently with systemic disease. These many small projections are red or pink in color, but careful examination may show tiny pustules beneath the epithelium, which liberate purulent material when ruptured. These leave areas of ulceration, which may coalesce, into large areas of necrosis known as snail track ulcerations. The protean oral manifestations of 24 cases of Crohn's disease have been

Figure 5-13. Pyogenic granuloma occurring in women during the later months of pregnancy.

Figure 5-14. Pyostomatitis vegetans.
(Courtesy of Dr Nathaniel H Rowe).

reviewed in detail by Bernstein and McDonald. They noted that the most frequently affected area was the buccal mucosa which presented a 'cobblestone' appearance, while the vestibular lesions appeared as folds and ulcers, the lips were diffusely swollen and indurated, gingival and alveolar mucosal lesions were granular, and erythematous swellings, and palatal lesions appeared as multiple aphthous ulcers.

Histologic Features. The papillary projections generally show hyperplastic stratified squamous epithelium with an underlying loose connective tissue which is generally densely infiltrated by large numbers of plasma cells, lymphocytes, and occasional polymorphonuclear leukocytes, sometimes with a preponderance of eosinophils. Tiny areas of focal necrosis and microabscess formation, either intraepithelial or subepithelial, are common features of the lesions. In some instances, focal areas of degeneration and necrosis of the overlying epithelium are present.

Laboratory Findings. Bacteriologic studies are generally nonspecific, since only organisms of the normal oral microbial flora can be cultured from smears of the lesions.

Treatment. The treatment of pyostomatitis vegetans is not specific, since the oral lesions are usually refractory to antibiotic therapy. It has been found that the oral lesions tend to regress when the intestinal disturbance is brought under control. However, exacerbations of the gastrointestinal disease frequently result in exacerbation of the oral lesions as well.

CHAPTER 6

Viral Infections of the Oral Cavity

■ B SIVAPATHASUNDHARAM, N GURURAJ AND K RANGANATHAN

CHAPTER OUTLINE

The Latin word *virus* means venom or poison. Viruses are ultramicroscopic, metabolically inert, infections organism. They live and multiply in the living cells. Viruses are almost infinite in distribution, affecting not only plants and animals, including man, but also insects and even bacteria. The size of viruses has been measured by various techniques and ranges between 10 millimicrons or less to more than 200 millimicrons. Virus consists of a central core of DNA or RNA (but never both) surrounded by a capsid made up of proteins or an ensheathed outer envelope made of glycoproteins and lipids derived from the host cell membranes. It has been suggested that virally infected cells produce the nucleic acid characteristics of the virus and that, therefore, the susceptibility of cells to viral infection may depend upon the availability of suitable nucleic acid within the cell to sustain the virus.

Viruses have long been known to cause certain infectious diseases, and many of them produce a long-lasting immunity against reinfection by the same virus. In addition, there are many neoplasms in animals that have been transmitted by cell free extracts of the tumor to other animals, establishing a viral etiology. More recent proof of the viral origin of certain animal leukemias has given impetus of the search for specific viruses in the cause of human cancer and the possibility of immunization against this disease.

The mechanism of viral replication (adsorption, penetration, uncoating, synthesis, maturation and release) in the susceptible host cell is unique to the different group of viruses, and influences the pathogenesis, diagnosis, management and clinical manifestations. The sequelae of viral infection of the host cell could be

Acute infection	:	Usually due to lysis of the cell, example: polio virus
Latent infection	:	With periodic activation, example: herpes virus
Persistent infection	:	Persistent for many years, example: HIV, hepatitis B
Transformation	:	Transformation into malignant cells, example: certain subtypes of HPV and retroviruses

The classification of viral diseases is difficult because of the size of viruses and their incompletely understood metabolic systems. However, their classification based on the biologic, chemical and physical properties of the animal viruses, separating them into groups according to the type of nucleic acid, and the size, shape and substructure of the particle, has been undertaken by the International Committee

on Nomenclature of Viruses of the International Association of Microbiological Societies. This classification, with examples of human diseases in the various groups, is shown in Table 6-1.

Table 6-1: Classification of major virus groups and virus diseases

RNA viruses
- (a) Orthomyxovirus
  - Influenza
- (b) Paramyxovirus
  - (i) Measles (rubeola)
  - (ii) Mumps
- (c) Rhabdovirus
  - (i) Rabies
  - (ii) Hemorrhagic fever
- (d) Arenavirus
  - (i) Lymphocytic choriomeningitis
  - (ii) Lassa fever
- (e) Calicivirus
- (f) Coronavirus
  - (i) Upper respiratory infection
- (g) Bunyavirus
- (h) Picornavirus
  - (i) Poliomyelitis
  - (ii) Coxsackie diseases
  - (iii) Common cold
  - (iv) Foot-and-mouth disease
  - (v) Encephalomyocarditis
- (i) Reovirus
- (j) Togavirus
  - (i) Rubella
  - (ii) Yellow fever
  - (iii) St. Louis encephalitis
- (k) Retrovirus (RNA tumor virus)

DNA viruses
- (a) Herpesvirus
  - (i) Herpes simplex virus 1
    Gingivostomatitis, keratoconjuctivitis, genital and skin lesions
  - (ii) Herpes simplex virus 2
    Genital and skin lesions, keratoconjuctivitis, neonatal infections, meningitis
  - (iii) Varicella zoster virus
    Varicella (Chicken pox)
  - (iv) Cytomegalovirus
    Cytomegalic inclusion disease
  - (v) Epstein-Barr virus
    Infectious mononucleosis, hepatitis, encephalitis
  - (vi) Human herpes virus 6
    Otitis media, encephalitis
  - (vii) Human herpes virus 7
    Roseola infantum
  - (viii) Human herpes virus 8
    Infectious mononucleosis, febrile exanthema
  - (ix) Simian herpes virus
    Mucocutaneous lesions, encephalitis
- (b) Poxvirus
  - (i) Smallpox
  - (ii) Molluscum contagiosum
- (c) Adenovirus
  - (i) Pharyngoconjunctival fever
  - (ii) Epidemic keratoconjunctivitis
- (d) Parvovirus
- (e) Iridovirus
- (f) Papovavirus
  - (i) Human warts or papillomas
  - (ii) Tumorigenic viruses in animals

Modified after JR McGhee, SM Michalek, and GH Cassell: Dental Microbiology. Philadelphia, Harper and Row, 1982.

Diagnostic confirmation of viral infection by laboratory investigations is slow and difficult. Thus, most viral infections are diagnosed by their clinical presentation.

HERPES SIMPLEX

(Acute herpetic gingivostomatitis, herpes labialis, fever blisters, cold sores)

Herpes simplex, an acute infectious disease, is probably the most common viral disease affecting man, with the exception of viral respiratory infections. The tissues preferentially involved by the herpes simplex virus (HSV), often referred to as herpes virus hominis, are derived from the ectoderm and consist principally of the skin, mucous membranes, eyes, and the central nervous system. HSV is composed of double stranded DNA, protein capsid, tegument and lipid envelope, which contains glycoproteins derived from the nuclear membrane of host cells. There are two immunologically different types of HSV: type 1 and type 2. They differ antigenically and biologically, but share 50% of the nucleotide sequence. Many types of specific regions exist in both HSV 1 and 2 and are responsible for host immunity. These subtypes can be distinguished serologically or by restriction endonuclease analysis of the DNA. A state of latency and reactivation is common in many viral infections, especially the herpes group. The incubation period is 1–26 days and can occur throughout the year. Transmission is mainly through close contact, kissing, sharing of glasses, cutlery or crockery, etc.

Pathogenesis. The primary HSV infection is usually acquired through direct contact with affected area or through secretions. The virus once attached to the cells at inoculation site through specific receptors; it replicates too many virions to the maximum number and discharges to neighboring cells. Subsequently it affects adjacent cells, spreads to distant sensory nerve endings and autonomic axons, further to adjacent related ganglia, and remains latent there. The lymph node is involved through viral proteins by mobile dendritic cells and begins its primary immune response. The reason for the wide anatomical distribution and multiple crops may be due to descending spread of virions back to periphery from various neuronal site. Initial or primary infection is asymptomatic and occurs commonly in childhood or infancy. This disease manifests as characteristic vesicles containing desquamated cells, multinucleated giant cells, and free viruses with edema fluid. Though both subtypes produce orofacial and genital lesions, which are clinically indistinguishable, HSV-1 predominantly affects the face, lips, the oral cavity, and upper body skin; and HSV-2 usually affects the genitals and skin of the lower half of the body. Primary infection resolves and the virus can no longer be recovered from ganglia but viral DNA can be found in the ganglion cells. Both humoral and cell mediated immunity is responsible for the clinical manifestation, latency, and recurrence of the disease. Immune-compromised individuals, especially with impaired cellular immunity, are more prone for dissemination and recurrence of the primary disease.

An in-depth summary of the structure, composition, growth cycle, and cytopathogenic effects of HSV-1 has been published by Hicks and Terezhalmy. Gruter was among the first to offer evidence that the herpes simplex infection was caused by an infectious agent and that the fluid of vesicles from patients with herpes simplex would produce keratitis when inoculated on scarified rabbit cornea. Subsequently, the virus has been found to multiply well on the chorioallantoic membrane of the chick embryo. Andrews and Carmichael, in 1930, found that neutralizing antibodies against the herpes simplex virus were present in the circulating blood of most normal adults and persisted throughout life, but that recurrent herpetic lesions frequently developed in these persons.

These and other studies have finally led to the established principle that two types of infection with the herpes simplex virus occur. The first is a **primary infection** in a person who does not have circulating antibodies, and the second is a **recurrent infection** in persons who have such antibodies. It is impossible to differentiate clinically between the lesions of a primary and a recurrent attack, although the primary infection is accompanied more frequently by severe systemic manifestations and is occasionally fatal. It has been shown; however, that most adults have circulating antibodies in the blood, but have never exhibited a severe primary illness. Thus, it is reasoned, subclinical primary infections must be common. The relation between the primary and secondary forms of the herpes simplex infection is shown in Figure 6-1.

Herpes genitalis, caused by HSV-2, is a relatively common disease of the uterine cervix, vagina, vulva, and penis. The incidence of this form of the infection has increased precipitously in the United States within the past decade, and in fact, is now often termed the 'new epidemic venereal disease,' since it is transmitted through sexual contact. This virus differs immunologically from type 1 herpes virus, which is responsible for most cases of herpetic infection of the oral cavity. The type 2 virus of genital herpes is somewhat more virulent than type 1, and significantly, has been associated repeatedly with carcinoma of the uterine cervix, thus suggesting a possible cause and effect relationship. However, because of changing sexual practices, there has been rather widespread translocation in the usual habitats of type 1 and type 2 HSV. Thus, it is not unusual today to find HSV-2 on the lips or oral mucous membranes and HSV-1 on the genitalia.

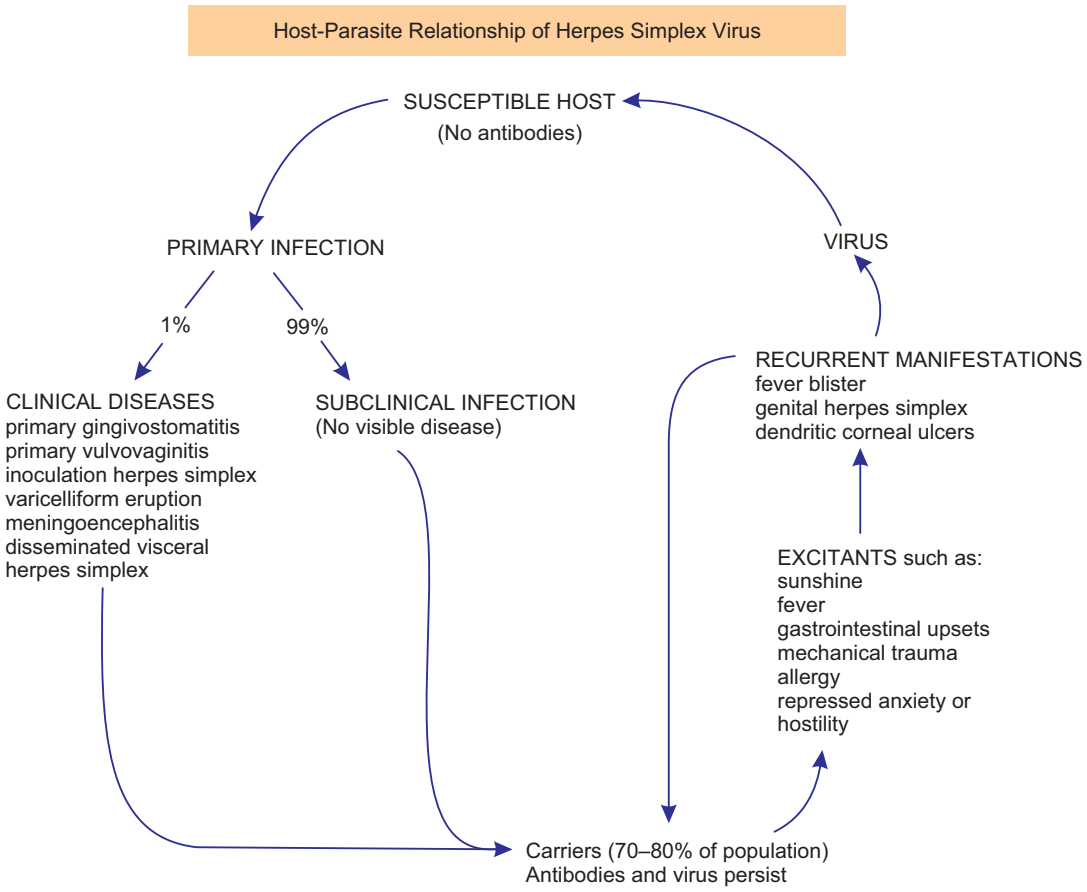

Figure 6-1. Relationship of primary and recurrent herpes simplex.
(Courtesy of Dr Harvey Blank. From H. Blank and G. Rake: Viral and Rickettsial Diseases of the Skin, Eye and Mucous Membranes of Man. Boston, Little, Brown and Company, 1955).

Herpetic meningoencephalitis is a serious form of this infection, characterized by sudden fever and symptoms of increased intracranial pressure. Paralysis of various muscle groups occurs, while convulsions and even death may ensue. It is difficult to differentiate clinically between meningoencephalitis caused by the herpes virus and that produced by other viruses.

Herpetic conjunctivitis, or keratoconjunctivitis, is a rather common disease and is characterized by swelling and congestion of the palpebral conjunctiva, although keratitis and corneal ulceration also may occur. Herpetic vesicles of the eyelids are typical, but these eye lesions usually heal rapidly.

Herpetic eczema (Kaposi's varicelliform eruption) is an epidermal form of the herpetic infection superimposed upon a pre-existing eczema (possibly an example of anachoresis) and is characterized by diffuse vesicular lesions of the skin, usually of an extremely serious nature. In addition to this atopic dermatitis, the herpetic infection may also be superimposed on severe seborrheic dermatitis, impetigo, scabies, Darier's disease, and pemphigus vulgaris or foliaceus. It is most frequently due to the primary herpetic attack and may be fatal. The patients, usually children, exhibit a high fever, coincident with the typical umbilicated vesicles as well as other systemic manifestations.

Disseminated herpes simplex of the newborn is a relatively uncommon disease in which the newborn baby acquires the infection during passage through the birth canal of a mother who is suffering from herpetic vulvovaginitis. However, occasional cases of transplacental infection by the virus have been reported. These infants usually manifest the disease by the fourth to seventh day of life, exhibit a wide variety of signs and symptoms of the disease and with few exceptions, usually die on the 9th to 12th day of life. Surviving infants frequently show residual neurological involvement.

Herpetic whitlow occurs in fingers due to autoinoculation.

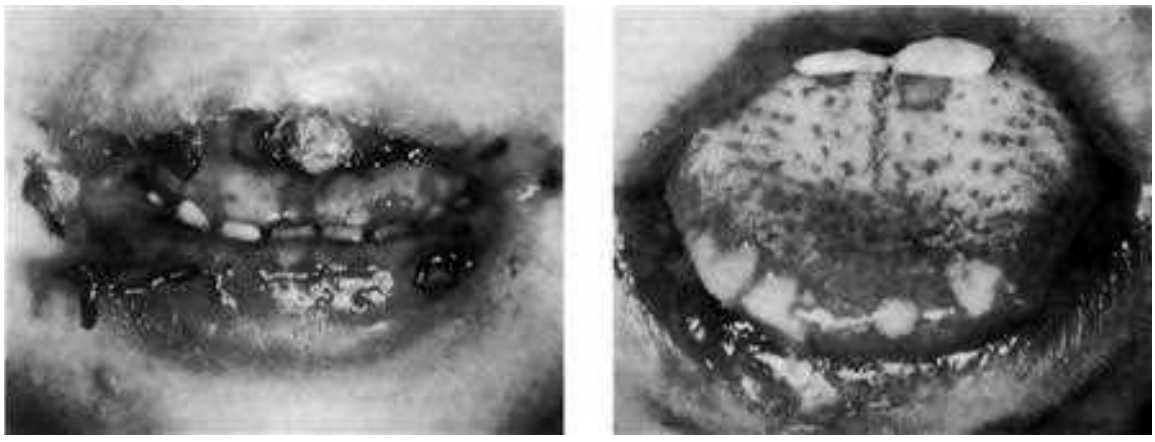
Herpes gladiatorum occurs in wrestlers.

Primary Herpetic Stomatitis

Dodd and her coworkers reported that the herpes simplex virus could be isolated from patients suffering from a gingivostomatitis with a particular clinical configuration. Burnet and Williams reported similar findings, and in addition, demonstrated that infants with this disease developed circulating antibodies during the convalescent period.

Clinical Features. Herpetic stomatitis is a common oral disease transmitted by droplet spread or contact with the lesions. It affects children and young adults. However, it has been suggested by Sheridan and Herrmann that the primary form of the disease is probably more common in older adults than was once thought. It rarely occurs before the age of six months, apparently because of the presence of circulating antibodies in the infant derived from the mother. The disease occurring in children is frequently the primary attack and is characterized by the development of fever, irritability, headache, pain upon swallowing, and regional lymphadenopathy. Within a few days, the mouth becomes painful and the gingiva which is intensely inflamed appears erythematous and edematous. The lips, tongue, buccal mucosa, palate, pharynx, and tonsils may also be involved. Shortly, yellowish, fluid-filled vesicles develop. These vesicles rupture and form shallow, ragged, extremely painful ulcers covered by a gray membrane and surrounded by an erythematous halo (Fig. 6-2). It is important to recognize that the gingival inflammation precedes the formation of the ulcers by several days. The ulcers vary considerably in size, ranging from very tiny lesions to lesions measuring several millimeters or even a centimeter in diameter. They heal spontaneously within 7–14 days and leave no scar.

Utilizing culture techniques, August and Nordlund found that the HSV-1 could be isolated from facial, labial, and oral herpetic lesions for a mean duration of three-and-a-half days, with a range of 2–6 days, after the onset of the lesions, while



A B

Figure 6-2. Primary herpetic gingivostomatitis.
The children in both cases exhibited severe involvement of the lips and oral cavity *(Courtesy of Dr Warren B Davis and Dr John R Mink).*

HSV-2 could be isolated from genital lesions for a mean duration of five-and-a-half days, with a range of 2–14 days, after onset. They also noted that viral persistence in lesions did not seem to differ between mild primary infection and recurrent infection. In addition, Turner and his colleagues have shown that HSV could survive for two to four hours on environmental surfaces such as cloth and plastic as well as on the skin of the hands contaminated by direct contact with labial or oral lesions.

It is now well established that the HSV does not remain latent at the site of the original infection in the skin or oral mucosa. Instead, the virus reaches nerve ganglia supplying the affected areas, presumably along nerve pathways, and remains latent there until reactivated. The usual ganglia involved are the trigeminal for HSV-1 and the lumbosacral for HSV-2. Viral DNA can be demonstrated in these ganglia. Unfortunately, this incorporation of viral DNA into host DNA ensures a lifelong infection beyond the reach of antibody, cell mediated immune responses or chemotherapy.

Mode of Transmission. The fact that the herpes virus may be recovered from the saliva of patients during the course of the disease leads to the assumption that transmission may occur by droplet infection, although some workers believe that direct contact is necessary. There is no animal reservoir for this virus. It has been reported in one series of patients that a history of contact with affected persons was present in nearly 50% of the cases. After such contact, the incubation period appears to range from 2–20 days, with an average of six days before development of lesions. There also have been occasional epidemics of herpetic stomatitis, such as that reported by Hale and his associates in an orphanage nursery. In addition, it has been noted that primary herpetic eruptions are commonly associated with pneumonia, meningitis, and common cold.

Histologic Features. The herpetic vesicle is an intraepithelial blister filled with fluid. The infected cells are swollen and have pale eosinophilic cytoplasm and large vesicular nuclei, described as 'ballooning degeneration,' while others characteristically contain intranuclear inclusions known as Lipschütz bodies. These are eosinophilic, ovoid, homogeneous structures within the nucleus, which tend to displace the nucleolus and nuclear chromatin peripherally. The displacement of chromatin often produces a peri-inclusion halo. Cytoplasm of the infected cells forms giant cells. The subjacent connective tissue is usually infiltrated by inflammatory cells. When the vesicle ruptures, the surface of the tissue is covered by exudates made up of fibrin, polymorphonuclear leukocytes, and degenerated cells. The lesions heal by peripheral epithelial proliferation.

Diagnosis. It can be diagnosed both clinically and by laboratory procedures. Scrapings obtained from the base of the lesions are stained with Wright's, and Giemsa stain. Pap stain demonstrates balloon cells, multinucleated giant cells and intranuclear inclusions. Though cytological procedures give a quick result but it will not differentiate between HSV and varicella zoster virus (VZV). More than that, identification of giant cells requires experience.

HSV can be demonstrated in the laboratory by isolation of virus in tissue culture or by DNA in the scrapings from lesions. The most sensitive and accurate method for diagnosing these lesions is PCR technique.

Treatment. Antiviral drugs have significant impact on the course of the disease, if it is diagnosed early. Antibiotic therapy helps in the prevention of secondary infection. Nonsteroidal anti-inflammatory drugs and topical anesthetic gel may relieve the discomfort considerably.

Latency

It is a state in viral infection in which the viral genome is present in non-replicating stage in an infected cell, but can become active intermittently. Establishment of latency is contributed by host factors like neurons, IgG, CD8+ cytotoxic T-lymphocytes, and cytokines and viral factors include downregulation of α gene expression and DNA replication. Latent stage is maintained by viral genes expressed primarily during latency. Expression of these latency-associated genes may function to keep the viral genome from being digested by cellular ribozymes or being found out by the immune system.

Recurrent or Secondary Herpetic Labialis and Stomatitis

Recurrent herpetic stomatitis is usually seen in adult patients and manifests itself clinically as an attenuated form of the primary disease. It has been reported by Nahmias and Roizman that between 80 and 100% of adults in the lower socioeconomic levels have HSV-1 and/or HSV-2 circulating antibodies, whereas only 30–50% of adults in the higher socioeconomic levels, including medical, dental, and nursing personnel, have such antibodies. Those without antibodies are at higher risk of contact and infection, especially the latter groups because of the nature of their occupation. Also, as pointed out by Rowe and his coworkers, recurrent lesions of the fingers or hands (herpetic whitlow) and eyes may be encountered in these professional groups more frequently than in the general population.

The recurrence is related to reactivation of infection and various theories namely (i) ganglionic trigger theory due to nerve section, surgery, or fever (ii) skin trigger theory due to UV light or trauma and (iii) emotional theory due to stress, have been put forward for reactivation. The recurrent form of the disease is often associated with other factors like fatigue, menstruation, pregnancy, upper respiratory tract infection, allergy, or gastrointestinal disturbances. The mechanism through which these various precipitating factors elicit an outbreak of lesions is unknown. The viruses, once introduced into the body, appear to reside dormantly within the regional ganglia, and when reactivation is triggered, spread along the nerves to sites on the oral mucosa and skin where they destroy the epithelial cells and induce the typical inflammatory response with the characteristic lesions of recurrent infection.

Figure 6-3. Recurrent herpetic vesicle of the lip.
(Courtesy of Dr Ajayprakash P and Dr Susma P, Kamineni Institute of Dental Sciences and Hospitals, Narketpally, Andhra Pradesh).

Clinical Features. Recurrent herpes simplex infection may occur at widely varying intervals, from nearly every month in some patients to only about once a year or even less in others. The lesions may develop either at the site of primary inoculation or in the adjacent area supplied by the involved ganglion. It may develop on the lips (recurrent herpes labialis, Fig. 6-3) or intraorally (Fig. 6-4). In either location, the lesions are frequently preceded by a burning or tingling sensation and a feeling of tautness, swelling or slight soreness at the location in which the vesicles subsequently develop. These vesicles are generally small (1 mm or less in diameter), tend to occur in localized clusters, and may coalesce to form somewhat larger lesions. These gray or white vesicles rupture quickly, leaving a small red ulceration, sometimes with a slight erythematous halo. On the lips, these ruptured vesicles become covered by a brownish crust. The degree of pain present is quite variable.

It has been emphasized by Weathers and Griffin that the recurrent intraoral herpetic lesions almost invariably develop on the oral mucosa that is tightly bound to periosteum. Seldom do they occur on mobile mucosa, in contrast to the recurrent aphthous stomatitis (q.v.) which almost invariably occurs only on mobile mucosa. Thus, the most common sites for the recurrent intraoral herpetic lesions are the hard palate and attached gingiva or alveolar ridge. Interestingly, herpes labialis is seldom seen concurrently with intraoral lesions.

The lesions gradually heal within 7–10 days and leave no scar.

Histologic Features. A number of investigators, beginning with Blank and his associates, have shown that the Papanicolaou smear, using fresh scrapings from the base of a vesicle, is a reliable technique for the diagnosis of active herpes simplex infection if herpes zoster/varicella infection is ruled out, since no other conditions produce a similar cytopathic effect. 'Ballooning degeneration,' chromatin margination and typical Lipschütz bodies as described earlier are all seen in smears from these lesions, as well as characteristic multinucleated giant cells originally observed by Tzanck (Fig. 6-5). Nowakovsky and her coworkers have thoroughly reviewed

Figure 6-4. Recurrent intraoral herpes simplex infection.

the manifestations of viral infections in exfoliated cells. The histologic findings in biopsy specimens from the recurrent lesions are identical to those described under the primary form of the disease.

Laboratory Findings. Isolation of the herpes simplex virus can be accomplished in tissue culture, particularly in the early stages of the recurrent infection. According to Tokumaru, the virus is easily isolated when there is a low production of γ-A globulin, but there is a rapid clearing of the virus, often within one day, after a rebound production of γ-A globulin. Similarly, smears would be positive for only a short time after the virus has cleared because of the rapid degeneration of the affected cells.

Current diagnostic methods for herpes viral diagnosis have been reviewed by Burns. These have included:

- Viral isolation and identification in various systems, including eggs, and mice, as well as cell culture technique.
- Immunofluorescent staining of smears, impressions, or cryostat sections with fluorescein-labeled HSV protein or antibody protein.
- Immunoperoxidase technique, which is reportedly far more sensitive than the immunofluorescence technique, is similar in basic principle but does not require fluorescence microscopy.
- Serologic assays such as the complement fixation assay, radioimmunoassay (RIA) and enzyme-linked immunosorbent assay (ELISA).

Treatment. Until recently, little could be provided in the way of actual therapy except for symptomatic relief, although many drugs have been tested over the years.

Several specific antiviral chemotherapeutic agents are presently available for use under certain conditions and with certain forms of HSV infection. The most prominent of these are: (1) acyclovir (9– [2– hydroxyethoxymethyl] guanine); (2) vidarabine (adenine arabinoside); and (3) idoxuridine (5–iodo-2'-deoxyuridine). However, these must only be used according to prescribed indications and do not represent curative drugs for this disease.

Differential Diagnosis. A consideration of differential diagnosis is of great importance, since numerous diseases may bear some resemblance to herpes simplex. Thus, some

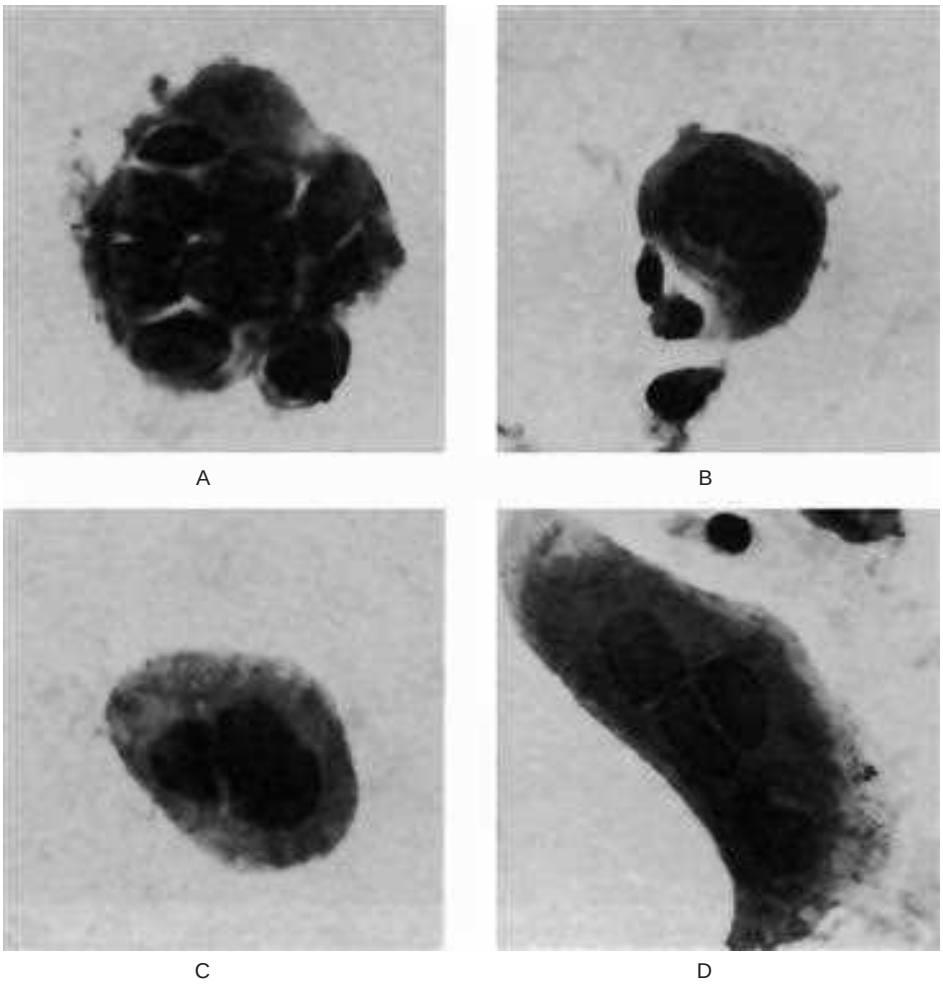


Figure 6-5. Recurrent intraoral herpes simplex infection.
Cytologic smear of lesions shows typical alterations in epithelial cells infected by herpes simplex virus.

difficulty may be encountered in distinguishing herpes simplex particularly from the recurrent aphthous stomatitis (q.v.). Other conditions to be considered are herpes zoster, impetigo, erythema multiforme, and related diseases, smallpox, pemphigus, epidermolysis bullosa, food or drug allergies, and chemical burns.

HERPANGINA

(Aphthous pharyngitis, vesicular pharyngitis)

Herpangina is a specific viral infection, which was described by Zahorsky in 1920 and later named by him. Studies by Huebner and coworkers proved that Coxsackie group A viruses are the cause of the disease, with types 1 through 6, 8, 10, 16, and 2 , as well as other enteroviruses, being isolated at various times. Infection occurs through ingestion, direct contact, or through droplet spread and multiple cases in a single household are common.

Clinical Features. The incubation period is probably 2–10 days. It is most commonly seen in young children; older children and adults are only occasionally affected. Herpangina is chiefly a summer disease, and many children may actually harbor the virus at this time without exhibiting clinical manifestations of the disease.

The clinical manifestations of herpangina are comparatively mild and of short duration. It begins with sore throat, cough, rhinorrhea, low-grade fever, headache, sometimes vomiting, prostration, and abdominal pain. The patients soon exhibit small vesicles which rupture to form crops of ulcers, each showing a gray base and an inflamed periphery on the anterior faucial pillars and sometimes on the hard and soft palates, posterior pharyngeal wall, buccal mucosa; and tongue (Fig. 6-6). Vesicles preceding the ulcers are small and of short duration, and are frequently overlooked by the examiner. The ulcers do not tend to be extremely painful, although dysphagia may occur. The systemic symptoms resolve within few days. Ulcers generally heal within 7–10 days.

Children have been affected several times in one season by infection with different strains of the Coxsackie virus. A permanent immunity to the infecting strain usually develops rapidly, and most adults have neutralizing antibodies against numerous strains.

Laboratory Findings. The Coxsackie virus can be isolated in suckling mice or hamsters by inoculation of scrapings

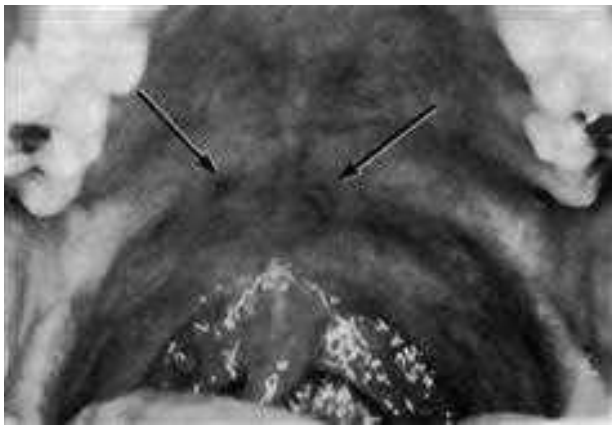

Figure 6-6. Herpangina.
Small ulcers are shown on the soft palate and fauces.

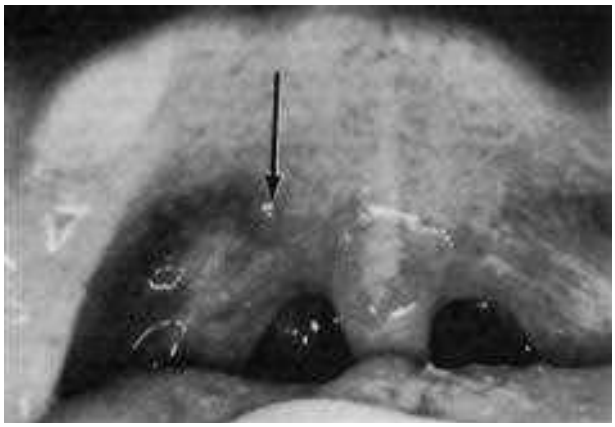

Figure 6-7. Acute lymphonodular pharyngitis.
Small papules are present on the soft palate and fauces.

from the throat lesions or stool specimens of nearly all patients who manifest clinical signs and symptoms of the disease or who have had contact with infected patients. Although there are distinct immunologic differences between various strains of herpangina virus, animal inoculation of any type produces the same manifestations—destruction of skeletal muscles followed by death. Even after the disappearance of clinical manifestations of the disease in the human patient, the virus may still be isolated from him/her for one to two months.

Treatment. No treatment is necessary, since the disease appears to be self-limiting and presents few complications. Those reported have consisted of acute parotitis, meningitis, hemolytic anemia, and hemorrhagic diathesis.

ACUTE LYMPHONODULAR PHARYNGITIS

Acute lymphonodular pharyngitis is an acute febrile disease, first reported by Steigman and coworkers in 1962. It is caused by a strain of Coxsackie virus A10. The first recognized outbreak of the disease occurred in the vicinity of Louisville and Fort Knox, Kentucky, during the fall of 1960. Since then it has been recognized as occurring with a wide distribution. Delay in recognition of the disease as an entity may have occurred because of the marked resemblance between this and herpangina.

Clinical Features. The disease affects predominantly children and young adults, although older adults are also occasionally involved. The chief complaints consist of sore throat, an elevation of temperature varying from 100°–105° F, mild headache, and anorexia. Typically, the patients do not manifest rhinorrhea, cough, tracheitis, gingivostomatitis, skin eruptions, arthralgia, otitis media, or lymphadenopathy.

The symptomatic course varies from 4–14 days and the local oral lesions resolve within 6–10 days, although a residual ring of fading erythema may sometimes be seen for several days. The estimated incubation period of the disease is 2–10 days.

Oral Manifestations. The lesions, characteristic of the disease, are raised, discrete, whitish or yellowish to dark pink solid papules or nodules, surrounded by a narrow zone of erythema (Fig. 6-7). The lesions are not vesicular and do not ulcerate. The lesions characteristically appear on the uvula, soft palate, anterior pillars, and posterior oropharynx.

Laboratory Findings. Primary isolation of Coxsackie A10 virus can be established in suckling mice by inoculation of throat swab or fecal material. Serologic evidence of infection by this virus is also positive.

Histologic Features. The papules or nodules consist of hyperplastic lymphoid aggregates. In some cases the overlying epithelium show inclusion of bodies which in some instances are intranuclear but in others, cytoplasmic.

Treatment. No specific treatment is necessary as the disease is self-limiting. It has been found that antibiotic therapy is of no benefit.

HAND, FOOT AND MOUTH DISEASE

Hand, foot and mouth disease is an epidemic infection, first reported by Robinson and coworkers in 1958. It is caused by the enterovirus Coxsackie A16 and has been reported to be caused less frequently by types A5 and A6, and occasionally even by B2, B5 or enterovirus 71. This first recognized outbreak of the disease occurred in Toronto, Canada, but since then it has appeared in many parts of the United States, as well as in many other countries around the world. Despite the similarity in names, it bears no relationship to foot-and-mouth (hoof-and-mouth) disease, another viral disease with an animal vector.

Clinical Features. The disease is primarily one affecting young children, the majority of cases occurring between the ages of six months and five years. It is characterized by the appearance of maculopapular, exanthematous, and vesicular lesions of the skin, particularly involving the hands, feet, legs, arms, and occasionally the buttocks. The patients commonly manifest anorexia, low-grade fever, coryza and sometimes lymphadenopathy, diarrhea, nausea, and vomiting.

Oral Manifestations. A sore mouth and refusal to eat is one of the most common findings in the disease. This is due to the small, multiple vesicular, and ulcerative oral lesions that are more numerous than seen in herpangina. In the series of cases reported by Adler and his associates, sore mouth was the principal symptom in 90% of the patients, and oral lesions were present in 100% of the patients. The most common sites for the oral lesions were the hard palate, tongue, and buccal mucosa, with a much smaller percentage of patients showing involvement of the lips, gingiva and pharynx, including the tonsils. The tongue may also become red and edematous.

Laboratory Findings. Intracytoplasmic viral inclusions can sometimes be demonstrated in vesicular scrapings of the lesions. It has been found that these inclusions are indistinguishable from those found in vaccinia. In addition, viral isolates may usually be obtained from rectal or throat swabs from vesicular fluid itself. Finally, there is generally a remarkable rise in acute or convalescent serum antibody titer to Coxsackie A16. In a few patients there is concomitant rise in herpes simplex virus antibody titer, but this is probably a fortuitous occurrence. Nevertheless, the clinical findings of hand, foot and mouth disease and of herpes simplex infection may be remarkably similar so that the two may be separated only with appropriate laboratory viral tests.

Treatment. No specific treatment is necessary since the disease is self-limiting and generally regresses within one to two weeks.

Differential Diagnosis. There is an obvious similarity in the clinical appearance of the oral lesions of hand, foot and mouth disease and a variety of other conditions which may be encountered. In an excellent review of this disease, McKinney has listed several such conditions to be considered in the differential diagnosis, including herpetic gingivostomatitis, herpangina, erythema multiforme, recurrent aphthous ulcers, and animal foot-and-mouth disease.

FOOT-AND-MOUTH DISEASE

(Aphthous fever, hoof-and-mouth disease, epizootic stomatitis)

Foot-and-mouth disease is a viral infection, which only rarely affects man, but does affect dogs and sheep as well as cattle. Transmission of the disease occurs through contact with infected animals; in human beings this is usually through the use of milk from affected animals or through the handling of tissues from these animals. An excellent review of foot-and-mouth disease in human beings was published by Roset. This disease should not be confused in nomenclature with hand, foot and mouth disease, a Coxsackie virus infection previously discussed.

Clinical Features. When it is transmitted to the human, foot-and-mouth disease manifests itself clinically by fever, nausea, vomiting, malaise, and the appearance of ulcerative lesions of the oral mucosa and pharynx. Development of vesicles on the skin also occurs in some cases. These vesicular lesions appear most commonly on the palms and soles.

Oral Manifestations. The lesions of the oral mucosa may occur at any site, although the lips, tongue, palate, and oropharynx appear to be those chiefly affected. These lesions begin as small vesicles, which rapidly rupture, but heal usually within two weeks.

MEASLES

(Rubeola, red spots, morbilli)

Measles is an acute, contagious, dermatropic and endemic viral infection, primarily affecting children and occurring many times in epidemic form. It is caused by paramyxovirus belonging to the family paramyxoviridae, which is a RNA virus. Outbreaks are often cyclic in their appearance and are seen commonly at two- or three-year intervals. Spread of the disease occurs by direct contact with an affected person or by droplet infection, the portal of entry being the respiratory tract.

Epidemiology. Measles has a worldwide distribution but incidence is more in developing countries. In Asia, incidence was reduced after the introduction of a vaccine schedule, but resurgence of measles may be due to failure to immunize infants and young children, and failure of vaccination or waning immunity. The mortality rate is high among children and adults. It varies from 1–10% in developing countries. It is contagious from first or second day even before the onset of serious illness or appearance of rash. It is transmitted mainly through respiratory secretions and also through direct contact of droplets. The incubation period is generally from 8–12 days. It is mainly transmitted in large families, crowded homes and slums. It is a self-limiting disease in healthy immune competent children, but morbidity and mortality is high in malnourished and immunocompromised individuals.

Pathogenesis. Upon invasion of respiratory epithelium it reaches reticuloendothelial system through blood stream and thereby infect skin, respiratory tract, and other organs. The invasion of T lymphocytes and increased levels of suppressive cytokines leads to transient suppression of cellular immunity. Monocyte is mainly infected. Symptoms show mainly due to the infection of the entire respiratory epithelia and the secondary infection with bacteria. Viremia develops, but specific antibodies are not developed before the onset of rash. Cellular immunity plays a major role in host defense against measles.

Clinical Features. There are three stages in measles namely pre-eruptive stage or prodromal stage, eruptive stage and post-eruptive stage. Incubation period of 8–10 days, is characterized by the onset of fever, malaise, cough, conjunctivitis, photophobia, lacrimation, and eruptive lesions of the skin and oral mucosa. Skin eruptions usually begin on the face, in the hair line and behind the ears, and spread to the neck, chest, back, and the extremities. These appear as tiny red macules or papules which enlarge and coalesce to form blotchy, discolored, irregular lesions which blanch upon pressure and gradually fade away in four to five days with a fine desquamation.

Oral Manifestations. The oral lesions are prodromal, frequently occurring two to three days before the cutaneous rash,

and are pathognomonic of this disease. These intraoral lesions are called Koplik's spots and have been reported to occur in as high as 97% of all patients with measles. The Koplik's spots are white papules resembling table salt like crystals with red base which appear usually on the buccal mucosa opposite to first and second molar teeth. Immune reaction to the virus in the endothelial cells of dermal capillaries plays a role in the development of spots. The spots disappear after the onset of rash. In actual practice, they are seldom seen unless the affected child has had a known contact with measles and the dentist or parent watches carefully, since the child is often well at the time they appear. These characteristic spots are small, irregularly shaped flecks which appear as bluish, white specks surrounded by a bright red margin. These macular lesions increase in number rapidly and coalesce to form small patches. Palatal and pharyngeal petechiae as well as generalized inflammation, congestion, swelling, and focal ulceration of the gingiva, palate and throat may also occur.

Histopathological features show pathognomonic multinucleated giant cells called Warthin–Finkeldey giant cells.

Complications. Measles is a disease which lowers the general body resistance, and for this reason, often leads to complications. These may include diarrhea, bronchial pneumonia, encephalitis, otitis media, and occasionally, noma. In addition, it has been recognized that measles has an immunosuppressive effect through impairment of cell-mediated immunity. Thus, while it may result in a delay in wound healing, it may also cause induction of remission of leukemia and Hodgkin's disease. The disease is rarely fatal except in the case of secondary complications.

Control Measures. Measles vaccines are available as single or in combination (MMR). In Asian countries, especially in India, the Edmonton–Zagreb (E-Z strain) 5 ml of vaccine is given subcutaneously. Studies have suggested the age for vaccination as nine months. A second dose should be given in the form of MMR at 15–18 months for adequate immunity.

RUBELLA

(German measles)

Rubella or the German measles should not be confused with rubeola. In rubella, Koplik's spots do not occur, and the oral mucous membranes are not usually inflamed, although the tonsils may be somewhat swollen and congested and red macules may appear on the palate. Complications following this disease are rare except when the disease occurs in women during the first trimester of pregnancy. In such cases, the offspring has a high incidence of congenital defects such as blindness, deafness, and cardiovascular abnormalities, if miscarriage does not occur.

Occasionally reports in the literature have suggested that rubella affecting women during the first trimester of pregnancy can cause a number of developmental defects, including enamel hypoplasia, a high caries incidence, and delayed eruption of deciduous teeth. However, a study by Grahnen provided some evidence that maternal rubella did not give rise to any clinically detectable defects in either the deciduous or permanent dentition of the offspring.

SMALLPOX

(Variola)

Smallpox is an acute viral disease which, before the discovery of vaccination by Jenner, was epidemic in nature and accounted for literally millions of deaths. For example, in Europe alone at the end of the 18th century, it is estimated that at least 400,000 people died of the disease each year.

The World Health Assembly in 1958 requested the Director General of WHO to study the implications of a global smallpox eradication program, and in 1967, such a program was initiated. During 1967, 131,000 cases of smallpox were reported, although 10–15 million cases are estimated to have occurred in 33 countries with the endemic disease and 14 other countries reporting importations.

On December 9, 1979, the WHO Global Commission for the Certification of Smallpox eradication declared:

- Smallpox eradication has been achieved throughout the world.
- There is no evidence that smallpox will return as an endemic disease.

This was officially endorsed by the World Health Assembly Meeting in Geneva on May 8, 1980, when, in Resolution 33.3, it 'declares solemnly that the world and all its people have won freedom from smallpox ... an unprecedented achievement in the history of public health ...'.

The last known patient in the world with 'wild' or natural smallpox was a hospital cook in Somalia who developed the rash on October 26, 1977. Two other cases did occur in Birmingham, England, in 1978 as a result of a laboratory accident, but there have been no further cases, even though six laboratories throughout the world are known to be maintaining this virus.

Thus, there has been official international acceptance of the fact that, for the first time in history, a disease has been totally eliminated from this planet, an effort to which all future generations should pay tribute. The long eradication campaign is a fascinating documentation of public health officials carrying out a complex program with great technical, financial, and administrative problems. Some of this information has been published by Breman and Arita and provides a fascinating insight into many aspects of this disease.

A discussion of the clinical and oral manifestations of smallpox is still maintained here in as much as all members of the United States overseas military forces still receive smallpox vaccinations, one complication of which is the development of the disease itself. Such vaccinations are still used because of the possibility of germ warfare, since controlled stocks of live virus are still maintained in certain countries.

Clinical Features. Smallpox, after an incubation period of 7–10 days, manifests itself clinically by the occurrence of a high fever, nausea, vomiting, chills, and headache. The patient is extremely ill and may become comatose during this period.

The skin lesions begin as small macules and papules which first appear on the face, but rapidly spread to cover much of the body surface. Within a few days the papules develop into vesicles which themselves eventually become pustular. The pustules are small, elevated, and yellowish green with an inflamed border. They are secondarily infected and occasionally become hemorrhagic, a most serious portent. Desquamation marks the beginning of the healing phase of the disease. Severe pitting or pocking of the skin as a result of pustule formation is a common complication of smallpox.

Oral Manifestations. Ulceration of the oral mucosa and pharynx is rather common, and similar involvement of other mucous membranes such as the trachea, esophagus, and vagina also occurs. Multiple vesicles appear much like the cutaneous lesion but, instead of proceeding to the development of pustules, they rupture and form ulcers of a nonspecific nature. In some cases the tongue is swollen and painful, making swallowing difficult.

Complications. Complications are related to the secondary infection which often occurs. Thus the formation of abscesses and the development of septicemia sometimes occur, as well as respiratory infection, erysipelas and infections of the eye and ear.

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is a disease caused by a virus of the pox group. The lesions, which only occur on the skin or mucosal surfaces, are often considered tumor like in nature because of the typical localized epithelial proliferation caused by the virus.

Clinical Features. The infection is more common in children and young adults and manifests itself as single, or more frequently, multiple discrete elevated nodules, usually occurring on the arms and legs, trunk and face, particularly the eyelids. However, it is now recognized that the disease can be sexually transmitted, and lesions of the genitalia and pubo-abdominal area also occur with some frequency.

These lesions are hemispheric in shape, usually about 5 mm in diameter with a central umbilication which may be keratinized, and are normal or slightly red in color. The disease appears to be spread by autoinoculation, by direct contact with an infected individual or by fomites with a reported incubation period of 14–50 days. Lack of inflammation and necrosis differentiates these proliferative lesions from other poxvirus lesions. Lesions can occur anywhere in the body, other than palm and soles, and may be associated with eczematous rash. HIV-infected individuals are more prone to these lesions. Linear distribution of these lesions suggests that autoinoculation of virus occurs due to scratching. Lesions in HIV-infected patients are atypical in manifestations. Lesions are multiple and grow to a large size resembling carcinomas. The virus replicates in the stratum spinosum and forms inclusion bodies which are characteristic, and pathognomonic of poxvirus infection called Cowdry type A inclusion bodies. Most of the lesions heal spontaneously in about 30–60 days and the infection may rarely persist for more than two or three years.

Oral Manifestations. Mucous membrane involvement, particularly the oral cavity, is not common. Cases have been reported; however, such as that of Barsh. Oral lesions, which occur most frequently on the lips, tongue and buccal mucosa, are similar to those on the skin.

Histologic Features. The lesion is quite characteristic, showing thickening and down growth of the epithelium with the formation of large eosinophilic intracytoplasmic inclusion bodies known as Henderson-Paterson inclusions or simply molluscum bodies, measuring approximately 25 μ in diameter. These bodies characteristically accumulate in the crater formed by the distinctive central umbilication of the dome-shaped lesion.

Diagnosis. Smears are prepared from lesions scraping or its contents and stained with pap stain, Giemsa or Gram stain, to demonstrate molluscum bodies.

Treatment. The lesions of molluscum contagiosum have been treated by surgical excision or by topical application of a wide variety of drugs such as podophyllin or cantharidin. There is some evidence that immunosuppressive drugs may evoke eruption of lesions.

CONDYLOMA ACUMINATUM

(Verruca acuminata, venereal wart)

Condyloma acuminatum is an infectious disease caused by a virus which belongs to the same group of human papillomaviruses (HPV) as those associated with common and plantar warts, flat warts, cervical flat warts, pityriasis-like lesions in patients with epidermodysplasia verruciformis and juvenile laryngeal papillomas.

Etiology. Human papillomaviruses are DNA virus that belongs to the family *Papovaviridae*. More than 50 serotypes of HPV are recognized and they are species specific and have not been propagated in tissue culture or in experimental animals. However HPV type 1, 6, 11, 16, 40, and 83 have been produced in human tissues implanted in immunodeficient mice. Condyloma acuminatum is caused by HPV type 6, a11, a30, b42, 43, 45, 46b 51, b54, 55, and 70.

The virus of anal, genital, and presumably oral condyloma acuminatum is HPV-6.

Epidemiology. It is one of the most common sexually transmitted diseases in the world. Incidence among children and adults is high, but low in early childhood. It reaches its peak between 12–16 years of age and then declines sharply to the age of 20 or more. Transmission is mainly by close contact with infected persons, autoinoculation, and orogenital sexual practice.

Pathogenesis. Once inoculated in the epithelium, the virus replicates and is transcribed in the basal cells. Virions are assembled in the cytoplasm and released along with the desquamated cells. This process is associated with the proliferation of all layers except basal cells and produces acanthosis,

hyperparakeratosis and hyperorthokeratosis. Koilocytes are large vacuolization of cells in and below the granular layer with basophilic inclusion bodies composed of viral particles and eosinophilic inclusions.

Clinical Features. This transmissible and autoinoculable viral disease presents as soft pink nodules which proliferate and coalesce rapidly to form diffuse papillomatous clusters of varying size. They occur most frequently on the anogenital skin or other warm, moist intertriginous areas.

Oral Manifestations. Oral lesions of condyloma acuminatum have been reported by Knapp and Uohara, as well as by Doyle and his associates and by Swan and his colleagues. These lesions have appeared as small, multiple, white or pink nodules which enlarge, proliferate and coalesce, or as papillomatous, bulbous masses scattered over or diffusely involving the tongue, especially the dorsum, buccal mucosa, palate, gingiva, or alveolar ridge.

Histologic Features. The papillomatous projections making up the verrucoid lesion generally show a parakeratotic surface with marked underlying acanthosis. Vacuolated cells in the spinous layer are common, as are numerous mitotic figures. In some instances, the epithelial changes are sufficiently disturbing to be mistaken for carcinoma. The supporting connective tissue is usually edematous, with dilated capillaries and a chronic inflammatory cell infiltrate. A case of oral condyloma acuminatum has been studied with both the light microscope and electron microscope by Shafer and his associates, who found intranuclear viral inclusions in the lesional epithelial cells.

Treatment. Surgical excision is usually used to eradicate the lesions, although topical podophyllin has also been used.

CHICKENPOX
(Varicella)

Chickenpox is an acute, ubiquitous, extremely contagious disease usually occurring in children, and is characterized by an exanthematous vesicular rash. It is most common in the winter and spring months.

Etiology. Varicella zoster virus is a DNA virus, which causes two distinct lesions known as chickenpox, a primary lesion and a reactivated lesion known as herpes zoster. The incubation period is approximately two weeks. It has been stated by Sabin that the virus causing this disease is one of the most contagious and sooner or later infects everyone in the world. It rather closely resembles smallpox, but is far less severe. The virus is the same as that which causes herpes zoster, and the lesions of the two diseases have many features in common. The relationship between these two diseases is discussed under herpes zoster. The mode of transmission is by airborne droplets or direct contact with infected lesions, with the probable portal of entry being the respiratory tract.

Clinical Features. The disease is characterized by the prodromal occurrence of headache, nasopharyngitis, and anorexia, followed by maculopapular or vesicular eruptions (dew drops) of the skin and low-grade fever. These eruptions usually begin on the trunk and spread to involve the face and extremities. They occur in successive crops so that many vesicles in different stages of formation or resorption may be found. The lesions of the skin eventually rupture, form a superficial crust and heal by desquamation. A charecterstic feature in all the stages of the disease is occurrence of the papules, vesicles and crusts are seen at a time in same area. The disease runs its clinical course in a week to 10 days, seldom leaving any after effects. Occasionally, secondary infection of the vesicles results in the formation of pustules, which may leave small pitting scars upon healing.

Oral Manifestations. Small blister-like lesions occasionally involve the oral mucosa, chiefly the buccal mucosa, tongue, gingiva, and palate, as well as the mucosa of the pharynx (Fig. 6-8). The mucosal lesions, initially slightly raised vesicles with a surrounding erythema, rupture soon after formation and form small eroded ulcers with a red margin, closely resembling aphthous lesions. These lesions are not particularly painful. Typical cases have been reported by Badger.

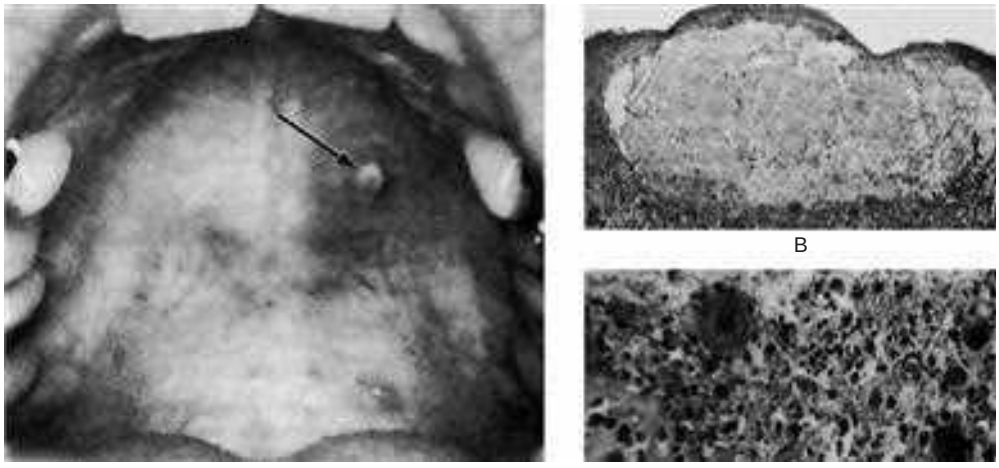

Figure 6-8. Chickenpox.
A single intraoral vesicle formed in association with the typical skin lesions **(A)**. A vesicular lesion **(B)** showing typical viral inclusion bodies **(C)** *(A, Courtesy of Dr Stephen F Dachi).*

Complications. Secondary infection is common and caused by *Streptococcus* or *Staphylococcus*. CNS involvement leads to encephalitis, transverse myelitis, Guillain-Barre syndrome, and Reye's syndrome. Other complications include pneumonia, myocarditis, nephritis, arthritis, and bleeding diatheses. Renal and hepatic involvement can also occur. Perinatal infections are fatal.

HERPES ZOSTER

(Shingles, zona)

Herpes zoster is an acute infectious viral disease of an extremely painful and incapacitating nature which is characterized by inflammation of dorsal root ganglia, or extra-medullary cranial nerve ganglia, associated with vesicular eruptions of the skin or mucous membranes in areas supplied by the affected sensory nerves. The virus causing this disease is the same as that of varicella, or chickenpox (the V-Z virus), and occasionally the two diseases are clinically nearly indistinguishable. Similar eosinophilic intranuclear inclusion bodies, indicative of viral infection, occur in both diseases. It is now believed that herpes zoster is caused by reactivation of the latent V-Z virus which had been acquired during a previous attack of chickenpox. In essence, a primary infection by the V-Z virus results clinically in chickenpox, while a recurrent infection results clinically in herpes zoster. The fact that herpes zoster is sporadic in occurrence whereas varicella is seasonal further supports the belief that herpes zoster is not a result of a primary exogenous infection.

Clinical Features. The disease is most common in adult life and affects males and females with equal frequency. Although rare, it does occur in children. In 576 cases of herpes zoster in patients of all ages, 31(5.4%) were in children under 15 years of age, according to Rogers and Tindall, but in this age group the disease has a very benign clinical course.

Initially, the adult patient exhibits fever, a general malaise, and pain and tenderness along the course of the involved sensory nerves, usually unilaterally. Often the trunk is affected. Within a few days the patient has a linear papular or vesicular eruption of the skin or mucosa supplied by the affected nerves. It is typically unilateral and dermatomic in distribution. After rupture of the vesicles, healing commences, although secondary infection may intervene and slow the process considerably. Occasionally, herpes zoster may resemble the lesions of herpes simplex, but the two diseases can be separated since the zoster virus cannot be transmitted to animals, e.g. the rabbit cornea, as can the simplex virus.

The triggering factors initiating the onset of an attack of herpes zoster are varied and may include trauma, development of malignancy or tumor involvement of dorsal root ganglia, local X-ray radiation or immunosuppressive therapy. It is a common infection in immunocompromised patients and those with certain malignancies, including Hodgkin's disease and the malignant lymphomas, and can be life-threatening if the viscera become involved. However, many attacks begin for no apparent reason, and these have often been attributed to a decrease in host resistance due to age.

Oral Manifestations. Herpes zoster may involve the face by infection of the trigeminal nerve (Fig. 6-9). This usually consists of unilateral involvement of skin areas supplied by either the ophthalmic, maxillary or mandibular nerves. Lesions of the oral mucosa are fairly common, and extremely painful vesicles may be found on the buccal mucosa, tongue, uvula, pharynx, and larynx (Fig. 6-10). These generally rupture to leave areas of erosion. One of the characteristic clinical features of the disease involving the face or oral cavity is the unilaterality of the lesions. Typically, when large, the lesions will extend up to the midline and stop abruptly.

A special form of zoster infection of the geniculate ganglion, with the involvement of the external ear and oral mucosa, has been termed Hunt's syndrome (James Ramsay Hunt's syndrome). The clinical manifestations include facial paralysis as well as pain of the external auditory meatus and pinna of the ear. In addition, vesicular eruptions occur in the oral cavity and oropharynx with hoarseness, tinnitus, vertigo and occasional other disturbances.

Diagnosis. Herpes zoster can frequently be recognized by the characteristic distribution of the lesions, although there may be a similarity to the lesions of herpes simplex infection. Skin lesions and oral lesions in particular may be easily identified as viral diseases by cytologic smears and the finding of characteristic multinucleated giant cells (Tzanck test) and intranuclear inclusions. However, this does not differentiate between herpes zoster and herpes simplex. This can only be done by fluorescent antibody staining techniques, viral culture or serologic diagnosis.

Treatment. The newer antiviral drugs are now under intensive clinical testing for potential effectiveness in treatment of herpes zoster. The preliminary results appear very promising.

MUMPS

(Epidemic parotitis)

Mumps is an acute contagious viral infection characterized chiefly by unilateral or bilateral swelling of the salivary glands, usually the parotid. The submaxillary and sublingual glands are occasionally involved, but seldom without parotid involvement also. Other than salivary glands, it may also involve nerves meninges, pancreas and gonads. Although it is usually a disease of childhood, mumps may also affect adults, and in such cases there is a greater tendency for complications to develop. Mumps has an incubation period of two to three weeks.

Epidemiology. The incubation period varies from 14–18 days with the extreme of one to four weeks. Mumps is transmitted through the respiratory route. It can be isolated from the saliva of the infected patients either seven days before the onset of parotitis or nine days after its onset. Most cases were unrecognized because of the absence of parotid swelling. As the disease is contagious before the onset of parotitis,

Figure 6-9. Herpes zoster involving face and oral mucosa.

Figure 6-10. Herpes zoster involving the buccal mucosa.

isolation of patient is not possible to prevent the infection. Once infected, patients develop a lifelong immunity against the disease but recurrence is also reported.

Pathogenesis. Once transmitted through droplet nuclei or saliva or fomites, it starts replicating in the respiratory epithelium. It spreads to local lymph nodes and subsequently develops viremia. The affected area shows perivascular and interstitial mononuclear cell infiltrates with edema. Necrosis of acinar and epithelial duct cells are seen in salivary glands and in the germinal epithelium of seminiferous tubules.

Clinical Features. The disease is usually preceded by the onset of headache, chills, moderate fever, vomiting, and pain below the ear. These symptoms are followed by a firm, somewhat rubbery or elastic swelling of the salivary glands, frequently elevating the ear, which usually lasts about one week. This salivary gland involvement produces pain upon mastication. Bilateral parotid involvement occurs in about 70% of the cases. Pain and tenderness may be severe during the rapid phase of parotid enlargement and swelling reaches its maximum in about three days; it remains at its peak for two to three days and then gradually subsides. The submandibular gland may also involve separately or in conjunction with the parotid gland. The involvement of the sublingual gland is

rare. Presternal edema may be present in a few cases due to pressure on the lymphatics in the neck. It is also reported that the papilla of the opening of the parotid duct on the buccal mucosa is often puffy and reddened.

Differential Diagnosis. It should be differentiated from other parotid swelling caused by influenza, parainfluenza 1 and 3, Coxsackie, HIV, and cytomegalovirus, Sjögren's syndrome, pleomorphic adenoma, etc.

Diagnosis. Virus can be isolated from saliva and throat swabs two days before or seven days after the onset of parotitis and from CSF. It can also be confirmed by the complement fixation test, hemagglutination inhibition or ELISA. Serum amylase is elevated in both parotitis and pancreatitis.

Complications. Other organs of the body may be affected as a complication of the disease. These include the testes, ovaries, pancreas, mammary glands, and occasionally the prostate, epididymis, and heart. When mumps involves the adult male, orchitis is a great danger and ensues in approximately 20% of cases. This orchitis is usually unilateral, but occasionally complete sterility results. The involvement of the pancreas producing an acute pancreatitis often causes an elevation in serum lipase. Serum amylase is also elevated but this is regardless of pancreatic involvement. Meningoencephalitis, deafness, and mastoiditis are also occasional complications. Rare complications like nerve deafness, facial paralysis, cerebral ataxia, and encephalitis have also been reported. When occurs in the first trimester of pregnancy it results in abortion.

The disease, though discomforting and often producing an acutely distressing condition, is seldom fatal.

> The availability of live attenuated mumps virus vaccine, first licensed in 1968, has resulted in a marked decline in the incidence of the disease, with a corresponding decrease in cases of meningitis and encephalitis. Unfortunately, the vaccine is not protective to individuals already exposed to the virus and who are in the incubation state of the disease.

Prognosis. An overall prognosis is good in uncomplicated cases. Death occurs due to CNS or cardiac involvement.

Treatment. Treatment is conservative; maintaining hydration and alimentation. Prevention is by means of vaccination.

NONSPECIFIC 'MUMPS'

There are several 'nonspecific' conditions characterized by enlargement of one or more of the major salivary glands that are not related etiologically to epidemic parotitis, or true mumps, but yet may produce considerable difficulty in diagnosis and differential separation from true mumps of viral origin. Banks has summarized a variety of these in his classification (Table 6-2) and discussion of parotid swellings. Although not all of these are of specific microbial origin, some of the more common conditions which have clinical and occasional microscopic resemblance to epidemic parotitis, or mumps. These include: (1) chronic nonspecific sialadenitis, (2) acute postoperative parotitis ('surgical mumps', retrograde sialadenitis), (3) nutritional 'mumps', (4) chemical 'mumps', and (5) miscellaneous.

Table 6-2: Classification of parotid swellings

1. Developmental
   - (a) Polycystic disease of the parotid gland
   - (b) Adenomatoid hyperplasia
   - (c) Lymphoepithelial cysts
2. Infectious and inflammatory
   - (a) Bacterial
     - (i) Acute suppurative parotitis
     - (ii) Recurrent subacute parotitis
     - (iii) Chronic nonspecific parotitis
     - (iv) Chronic specific parotitis
       1. Tuberculosis
       2. Actinomycosis
   - (b) Viral
     - (i) Mumps
     - (ii) Cytomegalic sialadenitis
     - (iii) HIV associated salivary gland disease
     - (iv) EBV infection
     - (v) Coxsackie A
     - (vi) Echo virus infection
     - (vii) Parainfluenza type 1, 3 infections
3. Obstructive and traumatic lesions
   - (a) Retention cysts (salivary duct cyst)
   - (b) Sialolithiasis
   - (c) Congenital atresia
4. Allergic and immunologic disorders
   - (a) Allergic sialadenitis
   - (b) Sjögren's syndrome
   - (c) Sarcoidosis
   - (d) Uveoparotid fever
5. Metabolic and hormonal disorders (sialosis or sialadenosis)
   - (a) Hormonal
     - (i) Diabetes mellitus
     - (ii) Catecholamine excess
     - (iii) Acromegaly
   - (b) Mulnutrition
   - (c) Drug induced
   - (d) Dysenzymatic
     - (i) Alcoholic cirrhosis
     - (ii) Pancretogenic sialadenosis
     - (iii) Nephrogenic sialadenosis
     - (iv) Obesity
6. Ageing
   - (a) Oncocytosis
7. Neoplastic
   - (a) Benign tumors
   - (b) Malignant tumors
8. Miscellaneous
   - (a) Pneumoparotitis

Chronic Nonspecific Sialadenitis

Nonspecific chronic sialadenitis is an insidious inflammatory disease of the major salivary glands characterized by intermittent swelling of the glands which may lead to the development of clinically obvious fibrous masses. It is most common in adults, particularly males. A similar, and perhaps related, condition

has been reported by Katzen and du Plessis under the term 'recurrent parotitis' in children. They observed that the disease usually subsided spontaneously at puberty although David and O'Connell reported that it may extend into adult life. Brook has published an excellent review of this recurrent suppurative parotitis in children.

The most frequent cause of chronic sialadenitis is the occurrence of salivary duct calculi (q.v.) with subsequent pyogenic bacterial infection. However, any condition which may result in salivary duct occlusion, such as tumors, foreign bodies or scar formation may result in this form of the disease.

If the etiologic factor is removed, there is generally subsidence of the clinical manifestations of the disease. If untreated, the salivary gland may be replaced by fibrous tissue, which may be tumor like in its extent.

Acute Postoperative Parotitis

This condition has a long and interesting history that has been reviewed by Schwartz and coworkers. It is believed to be the result of a retrograde infection (one reaching the parotid gland by microorganisms ascending the parotid duct) in debilitated patients suffering from dehydration, suppression of salivary secretion, vomiting and/or mouth-breathing, after a surgical procedure. Thus it is felt that xerostomia, or dry mouth, is one of the most important factors, since the stagnation of salivary flow would allow the ascension of microorganisms through the duct into the gland.

The microorganisms involved are usually *Staphylococcus aureus, Staphylococcus pyogenes, Streptococcus viridans* and pneumococci.

The majority of patients involved are adults, of middle age or older. Bilateral parotid gland involvement is common and the clinical signs and symptoms generally occur between the second and 20th postoperative days. Any type of surgical procedure may be followed by the appearance of this condition, not just a local procedure in the area of the salivary glands, although the exact mechanism is not known.

The onset of the disease is rapid and is frequently accompanied by severe pain and rapid swelling of the parotid gland. The overlying skin may be reddened, and the associated edema may involve the cheek, periorbital area, and neck. Trismus is present, as is a low-grade fever with headache, malaise, and leukocytosis. A purulent discharge may be expressed from the parotid duct by digital pressure along the duct toward its orifice. Treatment of this condition is generally the administration of antibiotics.

Nutritional 'Mumps'

Numerous investigators have reported a chronic, asymptomatic, bilateral enlargement of the parotid and/or submandibular glands occurring endemically in populations suffering from malnutrition. The dietary factors specifically involved have not been identified, but the lesions occur most frequently in patients with multiple signs of nutritional deficiency such as hypoproteinemia, anemia, angular cheilosis, pellagroid pigmentation of the hands and face, and general underweight. A relation to either vitamin A or C deficiency has not been demonstrated.

The condition is progressive one, but relatively slow to develop. It appears to be somewhat more common in young and middle-aged adults.

Histologic studies indicate that salivary gland involvement is essentially noninflammatory. The enlargement of the salivary glands in the acute phase of the condition is due to hypertrophy of the individual acinar cells, but in the chronic phase, to a replacement of normal gland parenchyma with fat. There is apparently little interference with normal salivary gland function.

A clinically identical form of parotid swelling has been reported by Borsanyi and Blanchard in a series of patients suffering from Laennec's hepatic cirrhosis with a history of chronic alcoholism. This form of salivary gland disease is undoubtedly only one manifestation of the 'nutritional mumps' discussed by Sandstead and his group.

Chemical 'Mumps'

Bilateral swelling of the salivary glands occasionally accompanies the administration of either inorganic or organic iodine, and this has frequently been referred to as 'iodine mumps.' This condition has been reviewed by Carter, who pointed out that this probably represents an iodine idiosyncrasy reaction. A similar form of salivary gland swelling has been reported by Albright and his coworkers to follow administration of triiodothyronine in the treatment of myxedema. These findings are of special interest in view of the long series of studies of Shafer and Muhler that have conclusively shown a close relation between the thyroid and salivary glands.

Another example of chemically induced experimental salivary gland swelling has been that following administration of isoproterenol to rats, reported by Selye and his group. In their studies the salivary glands increased approximately five times their normal size within 17 days after the initiation of drug administration. In this case the glandular enlargement is due to a true hypertrophy of acinar cells.

Miscellaneous Factors. There are numerous other situations in which salivary gland swelling may occur, and many of these have been discussed by Pearson and are described in more detail in other sections of this text. For example, salivary gland swelling is common in Sjögren's syndrome, Mikulicz's disease or benign lymphoepithelial lesion, salivary duct calculus, and allergic phenomena. In addition, swelling of the salivary glands was reported by Dobreff in 1936 to follow hypofunction of pancreatic islets and by Racine in 1939 to occur as a premenstrual phenomenon.

Fibrocystic disease (mucoviscidosis) of the pancreas is a hereditary defect of the secretory mechanism of most of the exocrine glands in the body, including the salivary glands. Bilateral enlargement of the submaxillary glands has been reported by Barbero and Sibinga in 92% of a group of 106

children with fibrocystic disease as contrasted to similar enlargement in only 2% of a group of 300 normal children. At necropsy, these submaxillary glands from patients with fibrocystic disease were two to three times heavier than normal. These investigations suggested that cystic fibrosis is an important cause of chronic submaxillary gland enlargement in the pediatric age group.

Sarcoidosis has been reported by Greenberg and his associates to have caused enlargement of the parotid gland in 6% of a series of 388 patients with this disease. The enlargement was bilateral in 83% of the cases, and unilateral in 17%.

Nevertheless, as in nearly every nonspecific condition of such an etiologically diverse nature, there is always an idiopathic group in which even careful evaluation of clinical, microscopic, and laboratory findings fail to reveal the cause of the disease, and such is the case in noninfectious 'mumps,' a certain percentage of these cases cannot be explained.

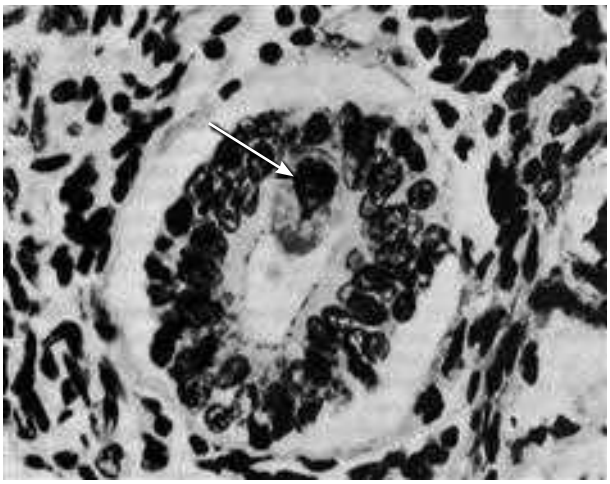

Figure 6-11. Cytomegalic inclusion disease.
The arrow points to the typical inclusion body in the parotid ductal epithelium *(Courtesy of Dr Charles A Waldron).*

CYTOMEGALIC INCLUSION DISEASE

(Salivary gland virus disease)

Salivary gland inclusion disease is a viral infection of interest since routine postmortem examinations have revealed that a considerable proportion of infants who die exhibit this disease, regardless of the cause of their death. Although it is frequently an inapparent infection, it is a cause of fetal encephalitis and may produce irreversible damage to the central nervous system. Smith and Vellios reported that in the majority of cases, the patients are less than two years of age although the disease has been reported in a few adults. Some cases, reviewed by Amromin, have occurred widely disseminated in adults. There are no particular signs or symptoms of this disease, although some infants have been reported to have manifested hepatosplenomegaly, hemolytic anemia, and a hemorrhagic tendency. It may be an incidental autopsy finding in patients who have died of blood dyscrasias, liver damage, pertussis, purpura, and other diseases. Transplacental infection may occur even without visible evidence of infection in the mother. In fact, approximately 50% of women in the childbearing group are seropositive for complement fixing antibodies to this virus, while approximately 4% of pregnant women excrete the virus in the urine. Occasional infants without an established diagnosis of generalized cytomegalic inclusion disease survive, although there may be some retardation of mental and motor development. In a review of cytomegalovirus as a major cause of birth defects, Marx has stated that it is the most common viral cause of mental retardation, surpassing even rubella virus.

Intranuclear and cytoplasmic inclusions in the cells of the salivary glands are a constant feature, while similar inclusions frequently occur in the kidneys, liver, pancreas, lungs, adrenals, intestine, brain, and occasionally other organs. The diagnosis is frequently established in living infants by examination of urinary sediment and the demonstration of the inclusion bodies here. These inclusions have a distinctive morphologic appearance and are pathognomonic of the disease (Fig. 6-11).

There is evidence to suggest that disturbances of cellular metabolism such as those occurring in certain vitamin deficiencies may predispose to the viral infection or may possibly activate an existing subclinical infection. The widespread distribution of the virus is apparent from the fact that over 80% of adults possess serum antibody against the virus. It is also now recognized, as reported by Cangir and Sullivan, that dissemination of the latent disease may occur in leukemia patients receiving antimetabolite therapy and in organ transplantation patients or others receiving immunosuppressant drugs and subject to opportunistic infection.

Other interesting manifestations of this virus include:

- Cytomegalovirus mononucleosis, which may be very difficult to distinguish from infectious mononucleosis, since the clinical characteristics of the two may be nearly identical.
- Its association with Kaposi's sarcoma in the acquired cellular immunodeficiency syndrome (q.v.).

POLIOMYELITIS

(Infantile paralysis)

Poliomyelitis, at one time, was a very serious viral disease which has been almost totally eliminated, particularly the paralyzing form, as a result of the widespread use of the Salk and Sabin vaccines. Prior to this, poliomyelitis was of some significance in dentistry because of scattered reports which suggested that the exposed dental pulp might act as a portal of entry into the body for the virus. This no longer appears to be of any clinical significance.

CHIKUNGUNYA

Chikungunya fever is a mosquito borne illness of humans caused by chikugunya virus. It belongs to Arboviruses (arthropod-borne viruses), which are viruses of vertebrates biologically transmitted by hematophagous insect vectors. They are world wide in distribution but are more numerous in tropical regions. In India, over 40 arboviruses have been detected, of which more than 10 are known to produce human disease. Chikungunya is believed to have originated in Africa and was subsequently introduced in Asia where it is transmitted from human to human mainly by *Aedes aegypti* and, to a lesser extent by *Ae. albopictus* through an urban transmission cycle.

After inoculation, primary viral multiplication occurs in lymphoid and myeloid cells. The virus then spreads to the targeted organs and immune system starts functioning at this stage leading to the activation of both humoral and cellular immunity. This response of the body leads to the clinical features of the disease.

Clinical Features. Patients become symptomatic after the incubation period of 4–7 days. The infection is of acute onset with variable clinical features. This disease is characterized by the clinical triad of 'fever, rashes and arthralgia'. Chikungunya is a Makonde word meaning 'the one which bends up' referring to the posture of the affected patient acquired due to excruciating pain in the joints.

Severe headache, chills and rigors, nausea and vomiting may present along with fever. The fever may disappear to return in one or two days giving it the name of 'saddle back fever. The occurrence of polyarthralgia along with myalgia, is a typical feature of the illness. The joint pain is frightening in severity, completely immobilizing many patients. The joint becomes very painful to touch. Different joints of the same patient may be involved at different times.

Oral Manifestations. The maculopapular rashes and gingival hemorrhages are uncommon signs although more frequent in children. But in India and other Asian countries cases with gingival bleeding were reported. Rashes occur mainly on trunks or extensor surface of the limbs and are itching in nature.

The probable diagnosis of chikungunya fever can be made on the basis of presence of the virus in community, and a clinical triad of fever, rashes and arthralgia.

Diagnosis. The virus produces neutralizing and hemagglutination inhibiting (HI) antibodies and that helps in making serological diagnosis. Reverse transcriptase polymerase chain reaction (RT-PCR) is confirmatory for the identification of chikungunya virus. IgM capture ELISA is the most sensitive serologic assay, and is necessary to distinguish the disease from dengue.

Treatment and Prognosis. The disease is considered to be self-limiting and benign in nature. The available literature does not report mortality due to this virus. There is no specific antiviral therapy available for chikungunya and treatment is mostly, supportive one. Symptoms may be treated with analgesics and antipyretics.

ORAL MANIFESTATIONS OF HIV INFECTION

Acquired immunodeficiency syndrome (AIDS) is caused by the human immunodeficiency virus (HIV) and is characterized by immunosuppression, which leads to a spectrum of clinical manifestations that include opportunistic infections, secondary neoplasms, and neurologic manifestations. Two genetically distinct populations of viruses known to cause AIDS are HIV-1 and HIV-2. HIV- 1 is the most common type responsible for AIDS in central Africa and the rest of the world, and HIV-2 in west Africa and India.

EPIDEMIOLOGY

Estimates at the end of 2007 indicate that there are 33 million people living wih HIV infection, 2.7 million have new infection and 2.0 million have succumbed to the disease. 96% of the infected are in low and middle income countries. The demographic features of the spread of HIV in Asia is somewhat different from that in other parts of the world, as the infection was first seen in intravenous drug users (IDUs) in Thailand and Burma in contrast to groups indulging in high-risk sexual behavior in the western countries. Globally, South and South-east Asian countries follow South Africa in terms of the total number of people living with the disease (UNAIDS).

India

The evidence of HIV infection was first documented in Chennai in southern India in 1986. The heterosexual route is the predominant mode of transmission, followed by intravenous drug use. India's prevalence estimates are based on sentinel surveillance conducted at public sites, according to the National AIDS Control Organization (NACO). Nationwide, an annual HIV sentinel surveillance was first organized in 1994, at 55 sentinel sites, which grew to 1134 HIV sentinel sites across the country, in 2007. Coverage and outreach of the HIV sentinel sites has been improving each year (Table 6-3).

The Annual Round of HIV Sentinel Surveillance, 2003, was conducted in 455 sentinel sites in all Indian states and union territories. These included: 271 sites at antenatal clinics (as proxy for the general population), 166 sites in clinics for sexually transmitted diseases, 13 sites among injecting drug users, three sites for men having sex with men and two sites for commercial sex workers. In 2004, the number of sentinel sites increased to 1134. Data from NACO indicate that India stands third in the number of people living with HIV/AIDS, with 23.9 million people living with the infection and a prevalence of 0.31 percent in the adult population.

Table 6-3: Coverage and outreach of the HIV sentinel sites

Year	2000	2001	2002	2003	2007
No. of sites	232	320	384	455	1134

HUMAN IMMUNODEFICIENCY VIRUS

The human immunodeficiency virus is a nononcogenic human retrovirus that belongs to the lentivirus group type III. The virion is an icosahedral structure that contains numerous external spikes formed by two major envelope proteins, the external gp120 and the transmembrane gp41. The core protein p17 is found outside the viral nucleoid and forms the matrix of the virion. The HIV glycoprotein antireceptors (GP-41 and GP-120) make a snug attachment of their specific receptors on a human cell membrane. These receptors are CD4, which are typically found on T4 lymphocytes and other white blood cells. A coreceptor called CCR-5 (fusin) permits docking with the host cell and fusion with the cell membrane leading to the formation of syncytia.

Mode of HIV Transmission. Sexual transmission is the predominant mode of infection worldwide, accounting for more than 75% of all cases of HIV transmission. It is also transmitted through infected body fluids such as blood and blood products, and breast milk. HIV has been demonstrated in oral fluids, but their infectivity appears to be reduced. So, saliva is not a significant route of transmission of HIV infection. Infection can be transmitted vertically from mother to the child.

Pathogenesis of HIV Infection. The two major targets of HIV infections are the immune system and the central nervous system. A characteristic feature of AIDS is the profound immunosuppression of cell mediated immunity. After gaining entry into the host, either through exposure to blood, body fluids, or sexual activity, the first step in virus infection involves binding of the virion to the surface of a target cell. This is mediated by binding of the envelope gp120 to the CD4 surface protein found on most helper T cells. After binding, the virus becomes internalized into the host cell where it becomes uncoated. The viral RNA is then reverse transcribed into linear double-stranded viral DNA in the cytoplasm of infected cells by the reverse transcriptase and then transported to the nucleus, where it is first 'circularized' and then integrated into the host cell. The integrated viral DNA is transcribed into full length RNA by the host cell. These RNA transcripts can either be packaged within virus particles, to serve as the genome of progeny virus, or they can serve as mRNA for the synthesis of viral gene products.

HIV first infects macrophages where it multiplies and is shed, infecting lymphocytes and other cells that possess the CD4 receptor site. The most significant of these are the T4 (helper) cells that coordinate the immune responses to most infections. Following the infection, the virus often enters a dormant stage lasting for 2–15 years.

When HIV is transmitted, fusion with CD4 cells occurs rapidly, and within a few days the virus migrates to regional lymph nodes, and then enters the circulation. This results in widespread dissemination to the brain and the lymphatic system, causing the 'primary HIV infection' or the 'seroconversion syndrome.'

The most common signs and symptoms of acute infection include fever, fatigue, maculopapular rash, headache, lymphadenopathy, pharyngitis, myalgia, arthralgia, aseptic meningitis, retrorbital pain, weight loss, depression, gastrointestinal distress, night sweats, and oral or genital ulcers. The acute illness may last from a few days to more than 10 weeks, but the duration is usually less than 13 days. The severity and the duration of the illness may have prognostic implication; severe and prolonged symptoms are correlated with rapid disease progression.

After infection, there is a rapid rise in plasma viremia, often to levels in excess of 1 million viral RNA molecules per milliliter. After the initial rise in plasma viremia, there is a marked reduction from the peak viremia to a steady-state level of viral replication. The decrease in the viral load during acute HIV-1 infection is probably due to virus specific immune responses that limit viral replication. There is also a correlation between cytotoxic T-lymphocyte responses to the envelope protein and the reduction in plasma viral RNA. In addition, soluble factors produced by CD8 cells inhibit HIV-1 replication in the early stages of acute infection and may thus contribute to the reduction of the viral load.

Within 6–12 weeks, antibodies to HIV are detectable in the blood, and enzyme linked immunosorbent assay (ELISA) and Western blot testing can document seroconversion. At this time, patients are confirmed as HIV positive. The time between viral infection and seroconversion is referred to as the 'window period.' During this period, HIV is present in body fluids and can be transmitted, but the HIV serology may be nonreactive. The disease subsequently progresses to 'asymptomatic chronic infection with or without persistent generalized lymphadenopathy' (PGL). PGL consists of lymphadenopathy for a duration of more than three months and involves two or more extrainguinal sites. Though the immune function is normal during this phase, viral replication occurs at a rapid rate resulting in the destruction of the CD4 cells. At this time, the lymphatic tissue serves as the major reservoir for HIV, the follicular dendritic cells filter and trap free virus and infected CD4 cells, and the viral burden in peripheral blood mononuclear cells is relatively low. With progressive disease, the lymph node architecture is disrupted, and more HIV is released. As more viruses are generated and released, more CD4 cells are destroyed, leading to decreased immune function and disease progression.

Clinical Features. The clinical features of HIV infection, therefore, range from asymptomatic infection to severe clinical illness and AIDS. The time for the onset of symptoms varies from five to six months to few years, and may be influenced by the source of HIV infection, patient's age, gender, drug habits, immunogenetics, and other factors. In 1993, the Centers for Disease Control (CDC) revised their classification system proposed in 1986 and expanded the surveillance case definition for AIDS among adolescents and adult.

Patients generally remain asymptomatic until their CD4 cell count falls below 500 cells/mm^3, at which time the patient enters the 'symptomatic HIV infection' previously known

Table 6-4: 1993 revised classification system for HIV infection and expanded AIDS surveillance case definition for adolescents and adults

CD4+T-cell categories	Clinical categories		
	(A) Asymptomatic acute (primary) HIV or PGL	(B) Symptomatic not (A) or (C)	(C) AIDS-indicator conditions
≥500/mm^3	A1	B1	C1
200–499/mm^3	A2	B2	C2
<200/mm^3 (AIDS indicator T-cell count)	A3	B3	C3

Source: http://hivinsite.ucsf.edu

as the 'AIDS related complex' and more recently referred to as 'Stage B,' according to the 1993 CDC classification, which is characterized by the development of opportunistic infections. As HIV continues to replicate, the CD4 cell count dramatically decreases. AIDS is diagnosed when the CD4 cell count falls below 200 cells/mm^3 or when one of the AIDS defining illnesses is documented (Table 6-4). Eventually, the immune function ceases, resulting in advanced HIV infection, characterized by a CD4 cell count <50 cells/mm^3, overwhelming opportunistic infections, and death. Without antiretroviral therapy, the progression of HIV from transmission to death is approximately 10–12 years.

Oral Lesions in HIV Infection. Oral lesions are often clearly visible and several can be diagnosed accurately on clinical features alone. In those cases where HIV status is unknown and where HIV testing is difficult, certain oral lesions provide a strong indication of the presence of HIV infection. Oral lesions that are associated with this disease are important, as they not only affect the quality of life of the patient but also are useful markers of disease progression and immunosuppression. They are strongly associated with immunosuppression, as measured by CD4 cell counts, and are modestly associated with a high viral burden. Thus oropharyngeal lesions feature in all classifications (CDC 1986, CDC 1993) (Table 6-5), staging, and prognosis. Oral lesions have also been advocated and are used as entry criteria and end points for prophylaxis therapy and vaccine trials.

In 1995, European Commission (EC) Clearinghouse on oral problems related to HIV infection and the WHO Collaborating Center on oral manifestations of the immunodeficiency virus released the following classification:

- Presumptive criteria: Relate to the initial clinical appearance of the lesion.
- Definitive criteria: They are the result of special investigations for absolute diagnosis.

These two added criteria give the diagnostic criteria of the oral manifestations of HIV infection.

Oral Candidiasis

Oral candidiasis is the most common intraoral opportunistic fungal infection strongly associated with HIV infection. It has been reported that oral/esophageal candidiasis, in HIV-infected patients, may herald the development of full-blown AIDS within two years.

Table 6-5: Revised classification of HIV infection (1993)

Group 1:	Lesions strongly associated with HIV infection Candidiasis Erythematous Pseudomembranous Hairy leukoplakia Kaposi's sarcoma Non-Hodgkin's lymphoma Periodontal disease Linear gingival erythema Necrotizing ulcerative gingivitis Necrotizing ulcerative periodontitis
Group 2:	Lesions less commonly associated with HIV infection Bacterial infections *Mycobacterium avium–intercellulare* *Mycobacterium tuberculosis* Melanotic hyperpigmentation Necrotizing ulcerative stomatitis
Group 3:	Lesions seen in HIV infection Bacterial infections *Actinomyces israelii* *Escherichia coli* *Klebsiella pneumoniae* Cat-scratch disease Drug reactions (ulcerative, erythema multiforme, Lichenoid reaction, toxic epidermolysis) Epithelioid (bacillary) angiomatosis Fungal infections other than candidiasis *Cryptococcus neoformans* *Geotrichum candidum* *Histoplasma capsulatum* Mucormycosis (zygomycosis) *Aspergillus flavus* Neurologic disturbances Facial palsy Trigeminal neuralgia Recurrent aphthous stomatitis (RAS) Viral infections CMV Molluscum contagiosum

The four clinical patterns seen are:

Pseudomembranous Candidiasis. This clinically appears as white to yellowish white plaques which can be easily scraped off, exposing red areas. The lesions are usually extensive, involving more than one site in the oral cavity. It may also extend to involve the oropharynx and esophagus.

Erythematous Candidiasis. This is clinically seen as red lesions, which are commonly located on the dorsum of the tongue, palate, and buccal mucosa. Tongue lesions are also referred to as central papillary atrophy.

Hyperplastic Candidiasis (Fig. 6-12). These lesions are characterized by white plaques which cannot be removed by scraping. Diagnosis can be confirmed by biopsy, which demonstrates the fungal hyphae in the keratinized layers of the epithelium. This lesion can be differentiated from other oral

Figure 6-12. Hyperplastic candidiasis involving the tongue.

Figure 6-13. Angular cheilitis.

white lesions as these respond to topical or systemic antifungal therapy mixed infection of *Candidia albicans* and Staphylococcus or candida alone.

Angular Cheilitis (Fig. 6-13). Erythema and/or fissuring and/or scaling of the angles of the mouth clinically characterize this lesion. Microbiologically, the lesion can be due to mixed infection of *Candida albicans* and *Staphylococcus aureus* or Staphylococcus or Candida alone.

Diagnosis. Candidiasis is diagnosed by its clinical appearance, PAS staining for candidal hyphae, of biopsied tissue or smears from lesion, or culturing the organism on Sabouraud's agar.

Candidiasis can be effectively treated by topical application of antifungal agents nystatin or clotrimazole. The systemic antifungals used are fluconazole or itraconazole. Though the systemic azoles produce longer disease free intervals, they are more frequently associated with drug interactions and drug resistance.

Periodontal Lesions

Periodontitis in HIV-positive patients is influenced by age, smoking, viral load, and microorganisms such as *Fusobacterium nucleatum, Prevotella intermedia, and Actinobacillus actinomycetemcomitans.*

HIV-associated periodontal lesions as listed by EC-Clearinghouse (1993) include:

Figure 6-14. Linear gingival erythema.
(Courtesy of Dr R Saravanakumar, Meenakshi Ammal Dental College, Chennai).

- **Linear gingival erythema (LGE)** is a non-plaque induced gingivitis exhibiting a distinct erythematous band of the marginal gingiva with either diffuse or punctuate erythema of the attached gingiva (Fig. 6-14).
- **Necrotizing periodontal diseases** are subclassified as necrotizing ulcerative gingivitis (NUG), necrotizing ulcerative periodontitis (NUP) and necrotizing stomatitis (NS). NUG involves destruction of one or more interdental papillae and is limited to the marginal gingiva. NUP extends beyond the papillae and marginal gingiva causing the loss of the periodontal attachment, and possibly exposing the bone. When the necrosis extends beyond the periodontium into the mucosa and osseous tissue, it results in NS. These three conditions are different stages of the same disease. The only distinction appears to be their severity.
- **Chronic periodontitis** has also been reported with an increased rate of attachment loss or exacerbated periodontitis.

NUG, NUP and NS appear to have the same pathogens as the corresponding diseases in HIV noninfected populations. HIV-related periodontitis seems to be a multifactorial, multimicrobial disease with no single organism being responsible. The disease may be initiated by conventional periodontal pathogens but the progression and tissue destruction depends upon many factors. The most important factors are the overwhelming host response and an increase in secretion of potentially destructive inflammatory mediators. This condition may also allow other opportunistic microorganisms including viruses to become established and cause further destruction.

The progression of the periodontal disease and tissue destruction in the presence of the HIV infection is dependent upon the presence of typical and atypical subgingival microorganisms including viruses, their byproducts and the local inflammatory host response.

HERPES SIMPLEX VIRUS INFECTION

Herpes (Fig. 6-15) labialis is clinically seen as vesicles on the lip and adjacent facial skin which rapidly break down to produce shallow ulcers. Intraoral lesions on the gingiva are referred to as acute herpetic gingivostomatitis. Lesions may extend to involve the palate, pharynx, and tonsils. The lesions present as numerous pinhead sized vesicles, which collapse to form small ulcers exhibiting a red base covered with yellow fibrin. The persistence of active sites of HSV infection for more than one month in a patient with HIV infection is one of the accepted definitions of AIDS. These lesions can be treated by the administration of oral acyclovir.

Herpes Zoster

Herpes zoster virus infection is a recurrent viral infection seen in HIV-infected patients and presents a clinical course, which is more severe in morbidity than that encountered in immunocompetent patients. In AIDS patients herpes zoster begins as a unilateral cluster of vesicles and ulcers in a classical dermatome distribution but subsequently extends beyond the dermatomal boundary and heals by scarring. Oral acyclovir is the drug of choice in the treatment of herpes zoster.

Oral Hairy Leukoplakia

Oral hairy leukoplakia (OHL) was first reported by Greenspan and coworkers in 1984 on the lateral margin of the tongue among young homosexual males. The term hairy leukoplakia was given because of the corrugated surface of the epithelium. Initially this lesion was observed exclusively in male homosexuals. Further reports indicated their prevalence among other risk groups for AIDS (IDUs, transfusion recipients, hemophiliacs) and in certain immunocompromised HIV seronegative patients.

The association of these lesions with Epstein-Barr virus (EBV) has been demonstrated by immunohistochemistry, electron microscopy and *in situ* hybridization. It has been hypothesized that basal epithelial cells of the lateral margin of the tongue normally harbor latent EBV and significant diminution of Langerhans cells by HIV, in the affected site, permits reactivation of EBV with subsequent epithelial hyperplasia. It must be noted that EBV is associated with several forms of lymphoma in HIV-positive patients.

Oral candidiasis and OHL are predictive indicators for subsequent development of AIDS in HIV-seropositive patients. OHL is included under the Group I category of the EC-Clearinghouse revised classification of oral lesions associated with the HIV infection.

Clinical Features. OHL frequently appears bilaterally on the lateral borders of the tongue as painless, faint white vertical streaks or thickened and furrowed areas with a shaggy keratotic surface with vertical striations imparting a corrugated appearance. The floor of the mouth, the buccal mucosa, the tonsillar region, the soft palate, and the posterior portion of pharynx are the other areas involved less frequently.

Histologic Features. Lesion shows features of epithelial hyperplasia with acanthosis and hyperkeratosis, which produce surface corrugations. A remarkable feature of the acanthotic epithelium is the presence of varying numbers of lightly stained, swollen, balloon cells in the upper prickle cell layer. Superficial epithelial cells show dense aggregates of nuclear chromatin material marginated along the nuclear membrane known as nuclear beading. Ultrastructural studies reveal heterochromatin distribution along the inner aspect of nuclear envelope and ground-glass nucleoplasm with an even distribution of EBV particles throughout. Occasional, minor atypical changes including basal cell hyperchromatism and increased number of mitoses are seen. The presence of candidal hyphae in the overlying superficial epithelial cell layers is not an uncommon finding. EBV can be demonstrated by *in situ* hybridization, PCR, or immunohistochemistry.

Management. OHL is usually asymptomatic, but occasional slight soreness, discomfort, and unsightly appearance of the lesion warrant treatment. Since many OHL cases reveal candida, topical antifungal agents like nystatin, and clotrimazole, and systemic agents like ketoconazole and fluconazole are employed. Antiviral agents like acyclovir, desciclovir and ganciclovir, result in clinical improvement. However, discontinuation of therapy results in recurrence of the lesion, if immunosuppression persists.

Figure 6-15. Herpetic ulcer of the palate.

Kaposi's Sarcoma

Kaposi's sarcoma is a multifocal neoplasm of vascular endothelial origin. Human herpes virus type 8 is involved in the pathogenesis of Kaposi's sarcoma. Commonly affected sites include palate, gingiva, tongue, and oropharynx or the skin. The clinical appearance of oral Kaposi's sarcoma can be macular, nodular, or raised and ulcerated, the color of which can range from red to purple. Early lesions tend to be flat, red and asymptomatic, with the color becoming darker as the lesion ages. As lesions progress, they can interfere with the normal functions of the oral cavity and become symptomatic secondary to trauma or infection. Bacillary angiomatosis often mimics Kaposi's sarcoma, but diagnosis can be made from a biopsy from the lesion, examined with the Warthin-Starry

Figure 6-16. Aphthous ulcer in HIV-infected patient.

Figure 6-17. Shiny dome-shaped papules of molluscum contagiosum.

stain. Treatment features intralesional vinblastine or surgical removal. Systemic chemotherapy is indicated for widespread or disseminated form.

Aphthous Ulcers

Aphthous ulcers (Fig. 6-16) present as recurrent, round, shallow, painful ulcers of variable size and duration that are typically found on nonkeratinized oral mucosa. Oral ulcers in HIV-infected patients are large and more extensive. They usually measure more than 2 cm in diameter with regular borders. Aphthous ulcers respond to topical steroids. Though systemic corticosteroids have proved to be beneficial in immunocompetent patients, they are avoided in HIV-infected patients to prevent further immune depression. Chlorhexidine and tetracycline rinses have been reported to be useful in treating herpetiform aphthae.

Oral Squamous Cell Carcinoma

Oral squamous cell carcinoma has been reported in HIV/AIDS patients with the same frequency as in the general population, associated with same risk factors but at a younger age. Impaired immunosurveillance, and an increased chance of human papilloma virus infection are a few suggested causes. The treatment consists of surgical resection, chemotherapy and/or radiotherapy.

Molluscum Contagiosum

Molluscum contagiosum (Fig. 6-17) is an infection of the skin, caused by a pox virus. It presents as shiny, white, and hemispherical skin-colored dome-shaped papules that often demonstrate a central depressed crater. In patients with AIDS, numerous lesions may be present which have no tendency to undergo spontaneous resolution and some grow to a large size. Histopathologically, the epithelium exhibits many large intracytoplasmic inclusions known as molluscum bodies. Cryotherapy is recommended for large and disfiguring lesions.

Thrombocytopenic Purpura

Thrombocytopenic purpura (TP) is a hematologic disorder characterized by a decreased number of circulating blood platelets (less than 150,000 platelets/mm^3 of blood). The reduction may be due to reduced production, increased destruction and sequestration subsequent to splenomegaly. Thrombocytopenic purpura in HIV diseases is characterized by reduced production of platelets due to drugs, malnutrition, immunological alterations, microbial invasion, or due to the course of HIV disease. Oral TP is characterized by pinpoint petechiae following minor trauma and even mastication. Spontaneous gingival hemorrhage is not uncommon. Platelet transfusions and/or corticosteroid therapy may be beneficial, provided the cause is removed.

HIV-associated Salivary Gland Disease

HIV-associated salivary gland disease (HIV SGD) is a heterogeneous group of signs and symptoms that vary from person to person and as the HIV infection progresses in the same individual. About 5% of HIV patients exhibit this condition. The main clinical sign noted in children and in earlier stages of the disease is parotid enlargement, which is bilateral and associated with cervical lymphadenopathy. As HIV progresses, salivary glands are infiltrated with CD8 lymphocytes leading to diffuse infiltrative lymphocytosis syndrome, resulting in salivary gland enlargement, in a few cases. This group of patients is at risk of B cell lymphoma. At the other end of the spectrum of HIV-associated salivary gland disease, qualitative and quantitative xerostomia (reduced salivary secretion) is experienced by most HIV-positive patients. The causes of xerostomia include drugs (antiretrovirals, antifungals, chemotherapeutics, antihistaminics, mood-altering drugs, multivitamins), oral diseases (candidiasis) or as a part of the progression of the HIV disease. The symptoms include dryness of the mouth, predisposition to fungal diseases, dental caries, and infections.

Non-Hodgkin's Lymphoma

In 1984, non-Hodgkin's lymphoma was described in 90 homosexual men with AIDS. Since 1985, aggressive B cell lymphoma has been classified as an AIDS-defining illness and is the second most common cancer associated with HIV. HIV patients are 60 times at risk of non-Hodgkin's lymphoma than the general population and around 3% of HIV-infected people develop lymphomas. A relationship between Epstein-Barr virus infection and non-Hodgkin's lymphoma has been suggested. This lesion tends to present as a large, painful, ulcerated mass on the palate or gingival tissues. Biopsy is necessary for a definitive diagnosis, often with a confirmatory immunohistochemical panel of markers. The treatment of non-Hodgkin's lymphoma is often a combination of chemotherapy and radiation.

Hyperpigmentation

In HIV-infected patients, hyperpigmentation (Fig. 6-18) of the oral mucosa, the skin and nails has been reported. Oral hyperpigmentation may occur suddenly in HIV-infected individuals and has been attributed to several medications including ketoconazole and zidovudine taken by AIDS patients. Adrenocortical destruction has been reported from several infections associated with HIV disease. Hyperpigmentation in HIV-infected individuals may also be due to a direct result of the HIV infection. Diagnosis is made by the clinical appearance of a recent onset, and brown to brownish-black intraoral focal or diffuse macules.

Oral lesions and Highly Active Anti-retroviral Therapy (HAART)

With the introduction of HAART therapy there has been a decrease in the opportunistic infections associated with HIV infection. HAART therapy has been associated with a decrease in the occurrence of oral candidiasis, oral hairy leukoplakia and Kaposi's sarcoma. Interestingly, there have been reports of increase in the occurrence of human papilloma virus (HPV) infection, attributed to the functionally incomplete reconstitution of the immune system.

Human papilloma viruses are small double-stranded DNA viruses, which infect stratified epithelium, of both skin and mucosa. More than 100 types of HPV viruses have been identified, around 60 of which are known to infect the head and neck region. The viruses can cause papillomas or warts and premalignant and malignant lesions of the epithelium.

DIAGNOSIS OF HIV

Virus-based Tests

1. **Viral Culture**. It directly detects the virus and hence is highly specific. It is positive, even during the window period and during the terminal phase when the viral load is high and when the ELISA may be negative. With the availability of PCR, HIV culture is not done routinely any more.
2. **PCR**. Polymerase chain reaction (PCR) has revolutionized the diagnosis and treatment of HIV infection. Two types of PCR are available: PCR for DNA of provirus present in the infected host cells and PCR for HIV RNA from plasma, which detect the free virus present in plasma. PCR can detect as low as 20 copies/ml of plasma and is highly sensitive and specific test. It is very useful for early diagnosis of HIV infection in newborn. Results of PCR are available in 24–48 hours unlike viral culture that takes 2–4 weeks. Quantitative PCR can be done to define the viral load in copies per ml of plasma. This is useful before starting therapy and monitoring response and relapse following antiretroviral drugs. The limitations of PCR are its cost and the need for sophisticated laboratory equipment.
3. **P24 Antigen Detection**. It is detectable during the window period and the late phase of infections when the virus is replicating fast. It is often not detectable at other times as viral replication is low. Hence this test is not sensitive enough to be of use for routine diagnosis. It is useful in blood banks where the P24 antigen, along with ELISA, can shorten the window period of diagnosis to less than two weeks.

A B

Figure 6-18. Hyperpigmentation of tongue (A) and palate (B).

Anti-HIV Antibody Tests

1. **Enzyme Linked Immunosorbent Assay (ELISA)/ Immunofluorescence.** ELISA is the more popular and widely done test. ELISA tests have nearly 99% sensitivity and specificity, especially on repeated testing. These tests are also much cheaper than PCR and culture, and can be done at any center. In the West, it is mandatory to do a Western blot, if the ELISA is positive, before confirming a person as HIV-positive. In India and according to WHO, it is not necessary to do a Western blot if the ELISA is positive. Instead, one should confirm it by repeating one or two more ELISA tests, using different kits on repeated blood samples. So, if two or preferably three ELISA tests are positive, a person is confirmed as HIV infected. One will have to wait 18 months to diagnose HIV infection in a newborn if one uses only ELISA. Hence ELISA cannot help in early diagnosis of HIV infection in the newborn. Similarly, ELISA is negative during the window period, that is, 6–12 weeks following HIV exposure, and sometimes during the last phase of HIV infection due to severe immunodeficiency leading to severe hypogammaglobulinemia. PCR is useful in such cases. Being cheap and easy to do, ELISA is the mainstay of HIV diagnosis in older children and adults in developing countries.
2. **Western Blot Analysis**. This detects specific antibodies and shows them as separate bands on gels. Hence it is more specific than ELISA. It is interpreted as positive if at least two of three bands, i.e. p24, gp41, gp120/160 bands, are positive. If none are positive, it is labeled as negative. If only one band is positive, it is labeled as indeterminate. When the test is indeterminate, one needs to repeat both ELISA and Western blot once or twice after 4–6 weeks until it becomes definitely positive or negative. Like ELISA, Western blot is also negative during the window period, and sometimes in the late phase of HIV infection. It cannot be relied upon for early diagnosis of HIV in newborns, as it detects maternal antibodies for as long as 18 months.

Immunological Tests and Surrogate Markers

CD4+T cell count, CD4+T cell % and CD4/CD8 ratio are tests done to determine immune status. A gradual decline in CD4+T cell count suggests disease progression. CD4+T cell % is more constant whereas absolute CD4 is age dependent. It helps to prognosticate, monitor disease progression and to determine response and relapse following antiretroviral drug therapy.

Salivary Tests

The fluids obtained from the oral cavity are saliva and gingival crevicular fluid. The immunoglobulin content of oral fluids is similar to that of blood, but their levels are lower. However, the use of an HIV IgG antibody capture assay (GAC ELISA), designed specifically for testing oral fluids, has produced encouraging results. A number of studies, including several in developing countries, report that the sensitivity and specificity of these optimized tests lie in the range of 95–100% and 98–100%, respectively.

CHAPTER 7

Mycotic Infections of the Oral Cavity

■ B SIVAPATHASUNDHARAM AND N GURURAJ

CHAPTER OUTLINE

Mycology, the study of fungal infections, has gained remarkable impetus in the past few decades, owing at least in part to the fact that fungal diseases are far more common than was previously suspected. Many erroneous conceptions of this branch of microbiology existed until only recently, but careful scientific investigation of various aspects of mycology, such as epidemiology, pathogenesis, immunology, diagnosis and treatment, has done much to eliminate the confusion. Furthermore, excellent monographs and reviews on certain fungal diseases, such as those on blastomycosis by Witorsch and Utz and by Sarosi and Davies; on coccidioidomycosis by Fiese and by Stevens; on cryptococcosis by Littman and Zimmerman; on histoplasmosis by Sweany and by Goodwin and his colleagues; and on mucormycosis (phycomycosis) by Lehner, have been valuable contributions to our understanding of these conditions.

NORTH AMERICAN BLASTOMYCOSIS

(Gilchrist's disease)

North American blastomycosis is a mycotic infection caused by *Blastomyces dermatitidis* and may occur either in a cutaneous form or in a systemic form involving bones, liver, lungs, subcutaneous tissues, and other organs. Experimental transmission to animals is only haphazardly successful and cannot be used as an aid in diagnosis, although spontaneous infection in dogs is quite common. The source of the infection in human beings is unknown, although affected persons commonly work or spend a great deal of time outdoors. It is becoming an important medical problem, particularly in central United States as has been pointed out by Furcolow and his associates.

Clinical Features. North American blastomycosis is far more common in men than in women and typically occurs in middle age. Skin lesions usually begin as small red papules which gradually increase in size and form tiny miliary abscesses or pustules which may ulcerate to discharge the pus through a tiny sinus. Crateriform lesions are typical and these often exhibit indurated and elevated borders (Figs. 7-1, 7-2). The infection commonly spreads through the subcutaneous tissues and becomes disseminated through the blood stream. The systemic disease is characterized by fever, sudden weight loss, and in cases of lung involvement, a productive cough associated with other symptoms typical of pulmonary tuberculosis.

Oral Manifestations. Lesions of the oral cavity have been reported occurring in blastomycosis and may resemble those of actinomycosis, although abscess formation is not usually as prominent. Tiny ulcers may be the chief feature. The oral infection may be either the primary lesion or secondary to lesions elsewhere in the body. In an extensive discussion of this disease, Witorsch and Utz have reported that 25% of their group of patients had oral or nasal mucosal lesions. Bell and his coworkers have also pointed out that the oral lesions, which may be the first apparent manifestation of the disease, are probably more common than has been thought. In two

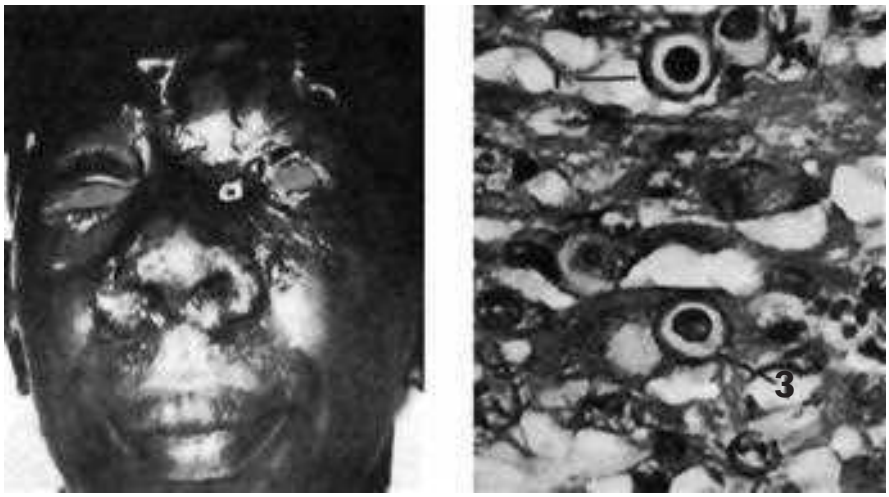
(A) Early lesion. **(B)**, Advanced lesion *(Courtesy of Dr Stephen F Dachi).*



A B

Figure 7-2. North American blastomycosis.
(A) Advanced North American blastomycosis of the face. **(B)** Photomicrograph of granulomatous lesion of blastomycosis, showing typical yeast like organisms with doubly refractile capsule (1) *(A, Courtesy of Dr Wilbur C Moorman).*

cases reported by Page and his associates, the oral lesions bore enough resemblance to epidermoid carcinoma to warrant it as a consideration in the differential diagnosis.

Histologic Features. The microscopic features of North American blastomycosis are similar to those of other chronic granulomatous infections. The inflamed connective tissue shows occasional giant cells and macrophages and the typical round organisms, often budding, which appear to have a doubly refractile capsule (Fig. 7-2). The organisms, usually measuring between 5μ and 15μ in diameter, are common within giant cells. Microabscesses are frequently found. If the lesions are not ulcerated, overlying pseudoepitheliomatous hyperplasia may be prominent.

SOUTH AMERICAN BLASTOMYCOSIS
(Lutz's disease, Paracoccidioidomycosis)

South American blastomycosis is related to the North American form of the disease and is caused by infection with *Blastomyces (Paracoccidioides) brasiliensis*. The systemic lesions are similar to those of North American blastomycosis.

Oral Manifestations. Bogliolo reported that the organisms may enter the body through the periodontal tissues and subsequently reach the regional lymph nodes, producing a severe lymphadenopathy. He has demonstrated the organisms in both the periodontal membrane and in a periapical granuloma and has cultivated them from these sites. The microorganisms

also have been shown to penetrate the tissues and establish infection after extraction of teeth, producing papillary lesions of the oral mucosa. Widespread oral ulceration is also a common finding.

The chief difference between North American and South American blastomycosis is in the size of the causative organisms. The fungus in the South American form of the disease varies between approximately 10μ and 60μ in diameter, being considerably larger than that of the North American disease.

HISTOPLASMOSIS

(Darling's disease)

Histoplasmosis is a generalized fungal infection caused by the organism *Histoplasma capsulatum*. It is widespread in its distribution and endemic in the Mississippi Valley and Northeastern United States, where up to 75% of the population have had a primary but subclinical infection. It is usually acquired by inhalation of dust containing spores of the fungus, the contamination probably occurring from excreta of birds such as pigeons, starlings, and blackbirds. It is classified clinically into acute primary pulmonary, chronic pulmonary and disseminated forms. In the disseminated forms, the infection spreads to extra pulmonary sites including oral cavity.

Oral lesions are present in a high percentage of cases. Reports of 73 cases have been reviewed by Weed and Parkhill, which found that 33% of the cases had oral lesions as part of the presenting complaint.

Clinical Features. The disease is characterized by a chronic low-grade fever, productive cough, splenomegaly, hepatomegaly and lymphadenopathy, since the organisms have a special predilection for the reticuloendothelial system and chiefly involve the spleen, liver, lymph nodes, and bone marrow. Anemia and leukopenia may also be present. The infection by this organism may be extremely mild, manifesting only local lesions such as subcutaneous nodules or suppurative arthritis, and may produce no more serious effects than a positive histoplasmin skin reaction or calcified pulmonary nodules similar to those seen in tuberculosis. Histoplasmosis often terminates fatally; however, particularly the generalized form.

Oral Manifestations. The oral lesions of histoplasmosis have been reviewed by Levy and by Stiff. They appear as nodular, ulcerative or vegetative lesions on the buccal mucosa, gingiva, tongue, palate, or lips (Fig. 7-3). The ulcerated areas are usually covered by a nonspecific gray membrane which is indurated with raised and rolled out borders resembling carcinoma. The organisms may be demonstrated in tissue sections in many, but not all cases. Thus it is wise in suspected cases to preserve a piece of tissue at the time of biopsy for microbiologic examination. The organism may be readily isolated by inoculating the emulsified tissue onto blood agar containing penicillin and streptomycin. Occasionally cases have been mistaken for carcinoma or even Vincent's infection, while the lymphadenopathy has suggested Hodgkin's disease.

Histologic Features. Histoplasmosis appears basically to be a granulomatous infection which affects chiefly the reticuloendothelial system. Thus the organisms are found in large numbers in phagocytic cells and appear as tiny intracellular structures measuring little more than 1μ in diameter (Fig. 7-3).

Treatment. Pulmonary histoplasmosis usually, resolves spontaneously, while severe forms of the disease are usually treated by amphotericin B.

COCCIDIOIDOMYCOSIS

(Valley fever, San Joaquin valley fever)

Coccidioidomycosis is now recognized as a relatively common fungal disease and endemic chiefly in the Southwestern portion of the United States, Arizona, California, Nevada, New Mexico, Texas, and Utah. It is also known to occur in Mexico, Central and South America, and occasionally Europe. In those areas where the disease is endemic, the vast majority of the population has at one time or another been infected by the organism, but usually this has been a subclinical infection. The disease appears to be transmitted to man and animals by inhalation of dust contaminated by the spores of the causative organism, *Coccidioides immitis*. This organism develops from an arthrospore into a nonbudding spherule, measuring between 10μ and 80μ in diameter, which is packed with endospores measuring approximately 5μ in diameter. When the spherules rupture, the endospores which are set free then develop into full-size spherules

Clinical Features. There are two basic forms of the disease: primary nondisseminated and progressive disseminated coccidioidomycosis. In primary coccidioidomycosis, patients generally develop manifestations suggestive of a respiratory disease such as cough, pleural pain, headache, and anorexia. In addition, about 20% of the patients develop skin lesions, either erythema nodosum or erythema multiforme. This form of the disease is self-limiting and runs its course within 10-14 days. In a small percentage of cases, pulmonary cavitation, calcified nodules or pulmonary fibrosis may remain.

In the **disseminated** form of the disease that occurs in only about 1% of the cases, there is a mortality rate of approximately 50%. The disease usually runs a rapid course and the dissemination extends from the lung to various viscera, bones, joints, skin, and to the central nervous system where meningitis is the most frequent cause of death. The dissemination to bone results in osteomyelitis in 10–50% of cases.

Oral Manifestations. Lesions of the head and neck, including the oral cavity, occur with some frequency as has been pointed out by Frauenfelder and Schwartz. The lesions of the oral mucosa and skin are proliferative granulomatous and ulcerated lesions that are nonspecific in their clinical appearance. These lesions tend to heal by hyalinization and scar. Marked chronicity is often a feature of these lesions. Lytic lesions of the jaws may also occur and such a case has been reported by Igo and his associates.

Figure 7-3. Histoplasmosis.
Lesions involving tongue **(A, C)** and palate **(B)**. The photomicrograph **(D)** of the bone marrow biopsy shows *Histoplasma capsulatum* within macrophages (*A and B, Courtesy of WJ Bruins Slot: Arch Dermatol, 76: 4, 1957, and C, of Dr Charles Newman).*

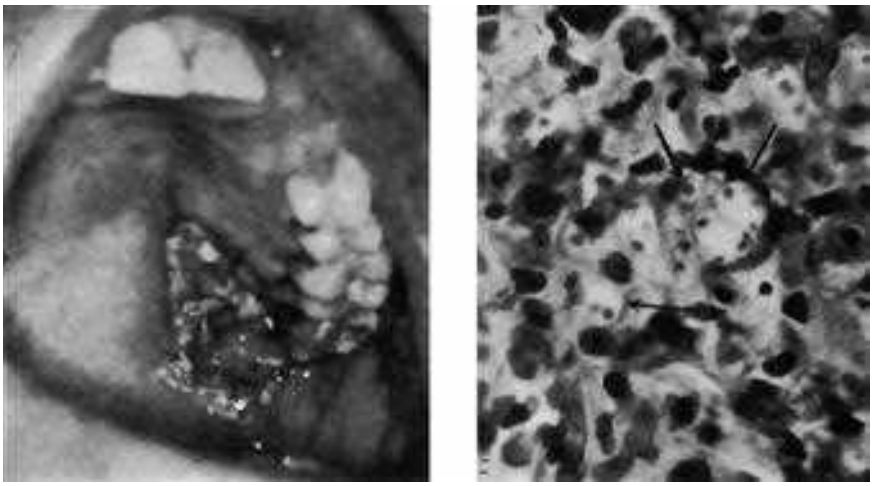
Histologic Features. The tissue reaction in coccidioidomycosis is similar to that of many specific infectious granulomas. Large mononuclear cells, lymphocytes and plasma cells predominate, although epithelioid cells are not usually seen. Foci of coagulation necrosis are often found in the center of the small granulomas, and multinucleated giant cells are scattered throughout the lesion. The organisms themselves are often found within the cytoplasm of the giant cells as well as lying free in the tissue. In tissue sections, the organisms will be found to vary greatly in size and generally show no budding. The endospores within the large spherules can usually be identified without difficulty.

Treatment. Amphotericin B has been found to provide effective chemotherapeutic control of the disease.

CRYPTOCOCCOSIS

(Torulosis, European blastomycosis)

Cryptococcosis is a chronic fungal infection caused by *Cryptococcus neoformans (Torula histolytica)* and *Cryptococcus bacillispora*, and may present widespread lesions in the skin, oral mucosa, subcutaneous tissues, lungs, joints, and particularly the meninges. The organisms are widespread and frequently found on the skin of healthy persons; for this reason, the exact mechanism of infection is not known. The organisms appear to be harbored by pigeons, but the actual infection of the human probably results from inhalation of airborne microorganisms. Since it is often an opportunistic infection, the disease has increased in incidence as immunosuppression has become more prevalent.



A B

Figure 7-4. Cryptococcosis.
The large ulcer of the palatal mucosa **(A)** contained the typical organisms **(B)**, and these were subsequently cultured *(Courtesy of Dr Charles W Newman. From CW Newman and D Rosenbaum: Oral cryptococcus. J Periodontol, 33: 266, 1962).*

Clinical Features. The first evidence of infection by these organisms is the presence of skin lesions from which blood stream dissemination to other parts of the body frequently occurs. Nevertheless, some authorities consider the respiratory tract colonization or visceral lesions to be the primary site, the skin lesions occurring secondarily. The skin lesions appear as multiple brown papules which ultimately ulcerate; the clinical picture is not specific. Most studies indicate a slight predilection for occurrence in middle-aged males.

The lesions of the lungs produce symptoms of a nonspecific pneumonitis, while the meningeal lesions produce a variety of neurologic signs and symptoms generally associated with increased intracranial pressure.

Cryptococcosis has been repeatedly reported in patients already suffering from some form of malignant lymphoma, evidence of the opportunistic nature of the disease.

Oral Manifestations. Occasional cases of oral cryptococcosis, almost invariably occurring in patients with other visceral or cutaneous lesions have been reported. One of these reports was that of Newman and Rosenbaum, in which the oral lesions were the first evidence of the infection. Interestingly, their patient was also suffering from chronic lymphatic leukemia.

The oral lesions appear as simply nonspecific single or multiple ulcers, which in a patient known to have leukemia, may be mistaken for the widespread ulceration often seen in leukemic patients as a result of their inability to react to a mild, nonspecific bacterial infection (Fig. 7-4A).

Histologic Features. The causative organism is a gram-positive, budding, yeast-like cell with an extremely thick, gelatinous capsule. The *Cryptococcus* measures 5–20μ in diameter, and in tissue sections, appears as a small organism with a large clear halo, sometimes described as 'tissue microcyst' (Fig. 7-4B). The capsule is colored intensely with the periodic acid-Schiff (PAS) stain, and the organisms may be cultured on Sabouraud's glucose agar.

The tissue reaction is essentially a granulomatous one of the tuberculoid type, but focal necrosis is often absent and epithelioid cell proliferation is minimal. Multinucleated giant cells are common as the organisms with their characteristic halos are found singly or in groups scattered throughout the granuloma.

Treatment and Prognosis. The use of amphotericin B has been found to give excellent results. The ultimate prognosis of the patient is variable; however, and especially dependent upon the sites of involvement.

CANDIDIASIS
(Candidosis, moniliasis, thrush)

Candidiasis is caused by a yeast-like fungus, *Candida (Monilia) albicans.* Although other species, such as *C. tropicalis, C. parapsilosis, C. stellatoidea, and C. krusei. C. guilliermondii, C. dubliniensis,* and *C. glabrata* may also be involved.

Candida exists in three forms namely, pseudohyphae, yeast, and chlamydospore forms. It reproduces by asexual budding and forms pseudohyphae. These species grow rapidly at 25–37°C. In general, *candida* species differ from one another but can be identified by the formation of pseudohyphae or by biochemical test.

It has been shown repeatedly that this microorganism is a relatively common inhabitant of the oral cavity, gastrointestinal tract, and vagina of clinically normal persons. When the favorable condition develops, the organism transforms into pathogenic form, that is yeast form transformed into hyphae. Thus it appears that the mere presence of the fungus is not sufficient to produce the disease. There must be actual penetration of the tissues, although such invasion is usually superficial and occurs only under certain circumstances. This disease is said to be the most opportunistic infection in the world. Its occurrence has increased remarkably since the prevalent use of antibiotics, which destroy the normally inhibitory bacterial flora and immunosuppressive drugs, particularly corticosteroids

Predisposing factors

- Acute and chronic diseases like tuberculosis, diabetes mellitus, and anemia
- Myxedema, hypoparathyroidism, and Addison's disease
- Immunodeficiency like AIDS
- Nutritional deficiency like Fe, vitamin A and vitamin B_6 deficiencies, etc.
- Prolonged hospitalization for chronic illness and debilitating diseases
- Prolonged use of antibiotics, corticosteroids, and cytotoxic drugs
- Radiation therapy
- Use of intravenous tubes, catheters, heart valves and poorly maintained dentures, heavy smoking
- Old age, infancy, and pregnancy
- Xerostomia. The protective antifungal proteins present in the saliva like histatins and calprotectin are absent in patients with xerostomia

Immunopathogenesis of Candidiasis. Many specific and nonspecific factors have a role in the development of candidiasis. Various anticandidal factors and antiadherence factors also play a major role in its development. Salivary IgA affects the adherence of *Candida* to mucosal cells. T cells and neutrophils also play a role in preventing and clearing the infection. Other factors of less significant role are complement, transferrin, lactoferrin, vitamins A, C, and serum antibody.

and cytotoxic drugs. This is the chief cause of this disease in patients with leukemia, lymphoma or other tumors. In addition to affecting the oral cavity, monilial infection frequently involves the skin as well as the gastrointestinal tract, vaginal tract, urinary tract, and lungs. Vaginal colonization appears to be increased by diabetes, pregnancy, and oral contraceptive agents. The incidence of oral candidiasis has increased after the advent of human immunodeficiency virus. It is reported that more than 90% of the HIV infected individuals develop oral candidiasis during some part of their disease (Ellepola ANB and Samaranayake LP, 2000). Oral candidiasis, usually remains a localized disease, but on occasion it may show extension to the pharynx or even to the lungs, often with a fatal outcome.

Clinical Features. It has a variety of clinical manifestations, making the diagnosis sometimes difficult. Candidal infection may range from mild superficial mucosal involvement to severe, fatal disseminated form seen in immunocompromised individuals. The classification proposed by Samaranayake in 1991 and modified by Axéll et al, in 1997 divides candidiasis into two major categories namely: (1) primary oral candidiasis (infection exclusively confined to oral and perioral tissues), and (2) secondary oral candidiasis (oral lesions as a manifestation of systemic mucocutaneous candidiasis).

Oral Manifestations. Oral lesions in different forms of candidiasis may have a different appearance and must be discussed separately (Table 7-1).

Table 7-1: Classification of oral candidiasis [as proposed by Samaranayake (1991) and modified by Axell et al (1997)]

Primary oral candidiasis	Secondary oral candidiasis
Acute forms Pseudomembranous Erythematous	Oral manifestations of systemic mucocutaneous candidiasis as a result of diseases such as a thymic aplasia and candidiasis endocrinopathy syndrome
Chronic forms Hyperplastic Nodular Plaque like Erythematous Pseudomembranous	
Candida-associated lesions Denture stomatitis Angular cheilitis Median rhomboid glossitis	
Keratinized primary lesions superinfected with Candida Leukoplakia Lichen planus Lupus erythematosus	

Pseudomembranous Candidiasis

It is also known as thrush and is one of the most common forms of the candidiasis. It may occur at any age, but is especially prone to occur in the debilitated or the chronically ill patients or in infants. Occurrence of this lesion in a healthy individual indicates the presence of immune suppression especially HIV infection. It also occurs in patients receiving systemic corticosteroid therapy. The oral lesions are characterized by the appearance of soft, white, slightly elevated plaques most frequently occurring on the buccal mucosa and tongue, but also seen on the palate, gingiva, and floor of the mouth (Figs. 7-5, 7-6 A). The plaques, which have often been described grossly as resembling milk curds, consist chiefly of tangled masses of fungal hyphae with intermingled desquamated epithelium, keratin, fibrin, necrotic debris, leukocytes, and bacteria. The white plaque can usually be wiped away with a gauze, leaving either a relatively normal appearing mucosa or an erythematous area. In severe cases, the entire oral cavity may be involved. Concomitant involvement of oral cavity and esophagus is common in HIV patients.

Erythematous Candidiasis

Also known as **antibiotic sore mouth,** includes central papillary atrophy of the tongue and **cheilocandidiasis**. It usually occurs as a sequela to a course of broad spectrum antibiotics, corticosteroids or any disease which suppresses the immune system, more commonly HIV disease. The lesions in this form of the disease appear red or erythematous rather than white, thus resembling the pseudomembranous type in which the white membrane has been wiped off. The redness is due to increased vascularity. It is distinguished from erythroplakia by its diffuse border wherein erythroplakia the borders are sharp and well demarcated. It too may occur at any site. It is the only

variety of oral candidiasis, which is consistently painful. Central papillary atrophy of the tongue is an asymptomatic, symmetric erythematous lesion of the dorsal aspect in the posterior region. The erythematous appearance occurs due to the loss of filiform papillae. A strong relationship exists between this lesion and chronic smoking and *C. albicans*.

Chronic Hyperplastic Candidiasis
(Candidal leukoplakia)

This is often spoken of as the 'leukoplakia' type of candidiasis. The oral lesions consist of firm, white persistent plaques, usually on the lips, tongue, and cheeks and appear similar to leukoplakia (Fig. 7-6B). These lesions may be homogeneous or speckled (nodular) and persists for periods of years. In this regard, Roed-Petersen and his associates have reported a high incidence of *Candida* organisms present in the lesions of a series of 226 patients with true leukoplakia. In addition, they found a definite relationship between the presence of the organisms and the occurrence of cytologic epithelial atypia in the biopsied lesions of leukoplakia. Cawson and Binnie have presented data which indicate a definite relationship between chronic candidiasis and oral epidermoid carcinoma, basing this relationship on the finding that chronic candidiasis itself is a cause of leukoplakia and thus must be regarded as having possible premalignant potential. These lesions resolve completely following antifungal therapy.

Some cases of chronic hyperplastic candidiasis are associated with iron and folate deficiency and defective cell mediated immunity. There are few keratotic lesions which may be superimposed by candidal infection. These include leukoplakia, lichen planus and lupus erythematosus. They may appear similar to chronic hyperplastic candidiasis clinically but may not regress with antifungal treatment as does the chronic hyperplastic candidiasis.

CANDIDA-ASSOCIATED LESIONS

Denture Stomatitis
(Chronic atrophic candidiasis)

Denture stomatitis is now considered to be synonymous with the condition better known as **denture sore mouth**, a diffuse erythema and edema of the denture-bearing area, often occurring with angular cheilitis. Usually asymptomatic except for the soreness and the presenting complaint may be angular stomatitis. Mandibular mucosa is rarely affected. There is no apparent age limit and some studies show women are affected more frequently than men.

Denture-related candidiasis may be the most common form of the oral disease. For example, in a study reported by Holbrook and Rodgers, they found that in nearly two-thirds of a group of 100 patients with candidiasis, dentures were the one 'disorder' or situation predisposing or traceable to the development of the infection.

Other lesions under this category namely angular stomatitis and median rhomboid glossitis are discussed elsewhere.

SECONDARY ORAL CANDIDIASIS

Chronic Mucocutaneous Candidiasis

Chronic mucocutaneous candidiasis is a group of different forms of the infection, some of which may have multiple features in common; although they can usually be separated as entities. Oral manifestations occur in numerous forms of candidiasis and these have been categorized most conveniently by Lehner, whose slightly modified classification is shown in Table 7-1, and includes the various forms of chronic mucocutaneous candidiasis. In general, chronic mucocutaneous candidiasis is characterized by chronic candidal involvement of the skin, scalp, nails, and mucous membranes. As a group, the patients exhibit varying abnormalities in their immune system — impaired cell-mediated immunity, isolated IgA deficiency, and reduced serum candidacidal activity — and they are usually resistant to the common forms of treatment. Chronic familial mucocutaneous candidiasis is an inherited disorder, probably an autosomal recessive characteristic, which occurs early in life, usually before the age of five years and has an equal gender distribution. Oral lesions occur in these children.

Chronic Localized Mucocutaneous Candidiasis

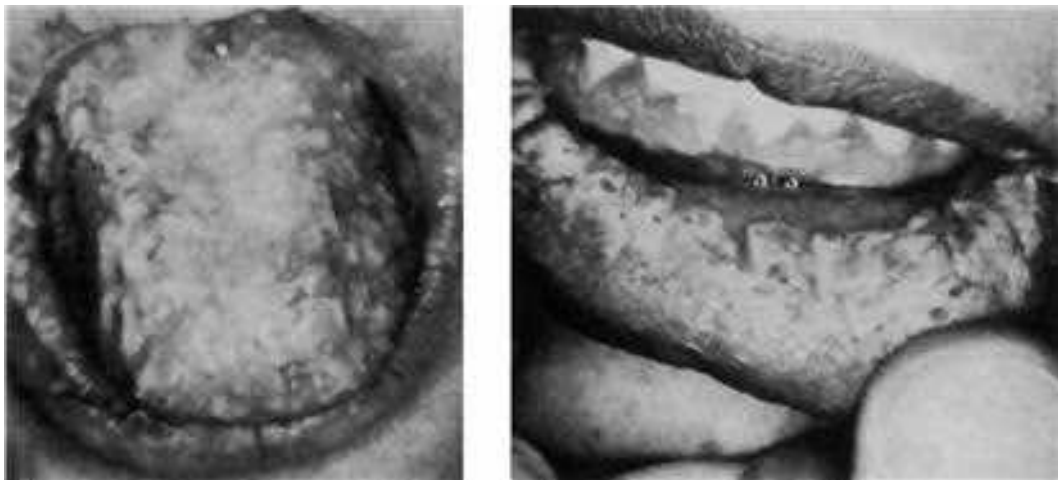
Chronic localized mucocutaneous candidiasis is a severe form of the disease also occurring early in life, but there is no genetic transmission. There is widespread skin involvement and granulomatous and horny masses on the face and scalp. There is an increased incidence of other fungal and bacterial infections. The mouth is the common primary site for the typical white plaques, and nail involvement is usually present.

Candidiasis Endocrinopathy Syndrome

Candidiasis endocrinopathy syndrome is also a genetically transmitted condition characterized by *Candida* infection of the skin, scalp, nails, and mucous membranes, classically the oral cavity, in association with either hypoadrenalism (Addison's disease), hypoparathyroidism, hypothyroidism, ovarian insufficiency or diabetes mellitus. It is recognized that the endocrine manifestations, which may be multiple, may not appear clinically for several years after the appearance of the thrush in the children. The oral findings in the autoimmune polyendocrinopathy-candidiasis syndrome, including the common finding of enamel hypoplasia have been discussed by Myllarniemi and Perheentupa.

Chronic Diffuse Mucocutaneous Candidiasis

Chronic diffuse mucocutaneous candidiasis is the least common form of the disease and appears to be of late onset, since all patients reported by Lehner were over 55 years of age. They exhibit extensive raised crusty sheets involving the limbs, groin, face, scalp and shoulders as well as mouth and nails. There is no familial history and usually the patients have no other abnormality.



A B

Figure 7-7. Oral candidiasis in chronic localized mucocutaneous type (A), and in candidiasis endocrinopathy syndrome (diabetes) type (B).

Id Reaction. It is a hypersensitivity reaction to candidal antigen, which manifests as vesicular and papular rash on the skin of patients with chronic candidiasis.

Chronic mucocutaneous candidiasis presents oral lesions in all forms of the disease. In general, their clinical appearance is similar to the lesions described in chronic hyperplastic candidiasis and occur in the same intraoral locations (Fig. 7-7).

Histologic Features. Fragments of the plaque material may be smeared on a microscopic slide, macerated with 20% potassium hydroxide and examined for the typical hyphae (Fig. 7-6C, D). In addition, the organisms may be cultured in a variety of media, including blood agar, cornmeal agar and Sabouraud's broth, to aid in establishing the diagnosis.

Histologic sections of a biopsy from a lesion of oral candidiasis show the presence of the yeast cells and hyphae or mycelia in the superficial and deeper layers of involved epithelium (Fig. 7-8B). These are more easily visualized if the sections are stained with PAS or methenamine silver, since the organisms are positive in both instances. Chlamydospores are seldom seen on oral smears or histologic sections.

Treatment. The development of new specific antifungal agents such as nystatin has been beneficial in the treatment of candidiasis. Suspensions of nystatin, held in contact with the oral lesions, have been successfully used in even chronic and severe cases of the disease. The use of tablets of the fungicide, prepared specifically for the treatment of intestinal thrush, are of little value in managing oral lesions, since the drug must make intimate contact with the organisms in order to be effective. Other drugs of value are clotrimazole, amphotericin B, and miconazole.

It has been found that occasional cases of candidiasis have remained refractory to treatment by nystatin. These have frequently been associated with one of the endocrinopathies just described in connection with immunologic abnormalities.

GEOTRICHOSIS

Geotrichosis is a fungal disease similar to candidiasis in its clinical features, but caused by organisms of the Geotrichum species.

Clinical Features. The most common lesions are those of the lungs and oral mucosa, although cutaneous and intestinal tract lesions occur on occasion. The lung involvement produces symptoms of pneumonitis or bronchitis but the organisms can be detected in the sputum.

Oral Manifestations. The oral lesions are identical to those of candidiasis or thrush, being a white, velvety, patch-like covering of the oral mucosa, isolated or diffuse in distribution. The differentiation is made only by microscopic examination and/or culture of the organisms.

The development of the disease also parallels that of candidiasis, being seen frequently in debilitated persons or as a secondary type of infection.

Histologic Features. The organisms are small, rectangular-shaped spores measuring approximately 4 by 8μ, often with rounded ends. The tissue reaction is a nonspecific, acute inflammatory one.

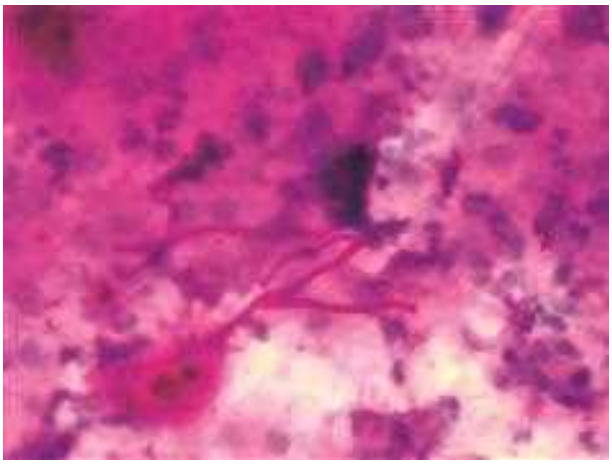
Treatment. Treatment is nonspecific, and there are insufficient data on the effects on geotrichosis of drugs used in treating candidiasis.

PHYCOMYCOSIS

(Mucormycosis, zygomycosis)

Phycomycosis is a fungal infection caused by the order mucorales. Zygomycosis refers to the infection caused by both the order of fungus *Mucorales* and *Entomophthorales*. It is worldwide in distribution and the organisms normally occur in soil, manure,

A B



C

Figure 7-8. (A and B) Chronic atrophic candidiasis in denture wearing patients. (C) Candidal hyphae are seen in a background of epithelial cells (PAS stain) *(Courtesy of Dr Ravindra Shetty, Dr G Sriram, Dr Vaishali Natu, Department of Oral Pathology, Nair Dental College, Mumbai, and Dr N Gururaj, Department of Oral Pathology, CSI Dental College, Madurai)*

fruits, and in decaying matter. These organisms are present in the nasal passages and oral cavities of normal persons.

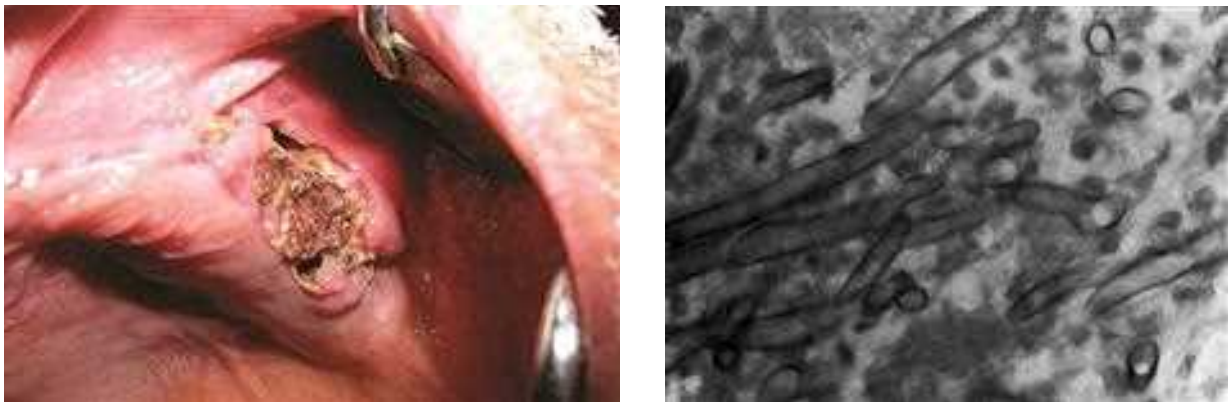
A thorough review of this disease was published by Hutter, and by Lehner, and the craniofacial or rhinocerebral form discussed by Green and his coworkers as well as Landau and Newcomer, Taylor and his associates. This is an opportunistic infection associated with debilitation and is becoming more frequently recognized as a secondary occurrence in cancer patients, especially those with any of the malignant lymphomas and in patients having renal failure, organ transplant, AIDS, and cirrhosis. It is also especially common in patients with diabetes mellitus, especially those with diabetic ketoacidosis; fully 75% of the patients with the rhinocerebral form of mucormycosis have the ketoacidosis. As might be expected, immunosuppressed patients are prone to develop this infection as well as patients with burns or open wounds. Cases have also been reported after administration of steroids and chemotherapeutic antimetabolites.

This disease may actually be caused by numerous Phycomycetes organisms of the Eumycetes (true fungi) class characterized by lack of septation (coenocytic). The three most important types causing infection in man are *Rhizopus*, *Mucor* and *Absidia*.

Clinical Features. Two main types of phycomycosis infection occur in human beings: (1) superficial and (2) visceral, although it is sometimes also classified as localized and disseminated. The superficial infection includes involvement of the external ear, the fingernails, and the skin. The visceral forms of phycomycosis are of three main types: (a) pulmonary, (b) gastrointestinal, and (c) rhinocerebral. Although all forms of phycomycosis are important, the rhinocerebral is of greatest interest to the dental profession, and only this variety will be discussed here.

Infections of the head by these organisms are characterized by the classical syndrome of uncontrolled diabetes, cellulitis, ophthalmoplegia and meningoencephalitis. The infection apparently enters the tissues through the nasal mucosa and extends to the paranasal sinuses, pharynx, palate, orbit, and brain.

One early clinical manifestation of the disease is the appearance of a reddish-black nasal turbinate and septum with



A B

Figure 7-9 (A,B). Mucormycosis involving the maxillary antrum.
(Courtesy to Dr Neelakandan RS, Department of Oral and Maxillofacial Surgery, Meenakshi Ammal Dental College, Chennai).

a nasal discharge. The necrosis may extend to the paranasal sinuses and orbital cavity, with the development of sinus tracts and sloughing of tissue.

Cases of phycomycosis involving the maxillary sinus may present clinically as a mass in the maxilla, resembling carcinoma of the antrum, and radiographs may support the latter diagnosis (Fig. 7-9A). Typical cases have been reported by Green and his associates, by Berger and his coworkers, and by Cruickshank and his colleagues. Surgical exploration; however, will reveal only masses of necrotic tissue in which the organisms can be demonstrated histologically. This involvement may occur at any age, cases having been reported in infants as well as adults.

Histologic Features. The tissue involved by this infection shows a variable amount of necrosis, some of which may be related to infarction brought about by thrombi consisting of the organisms. This fungus has an apparent predilection for blood vessels; it is able to penetrate their walls and thereby produce thrombosis.

The organisms appear as large, nonseptate hyphae with branching at obtuse angles (Fig. 7-9B). Round or ovoid sporangia are also frequently seen in the tissue section. The organisms can be cultured. Hisopathologically mucormycosis should be differentiated from aspergillosis in which the former has an acute angulating branched hyphae of smaller width and latter has septate branched hyphae. A special stain like Grocott's silver methenamine stain may use to confirm the diagnosis

The majority of reported cases of phycomycosis have been diagnosed only at the time of autopsy. In recent years; however, numerous cases of even fulminating head and neck infection by this organism have been diagnosed, treated, and cured. The current survival rate for rhinocerebral disease in patients with no systemic disease is about 75%; with diabetes, about 60%; and with other underlying diseases, about 20%. Pulmonary disease is almost uniformly fatal.

Treatment and Prognosis. Treatment of the disease consists of control of the predisposing factors such as diabetes, surgical excision if the lesion is localized, and administration of amphotericin B, since it is the only drug with proven efficacy.

SPOROTRICHOSIS

Sporotrichosis is a fungal infection caused by *Sporotrichum schenckii* in which the portal of entry is not entirely understood. It has been reported to occur after:

- Exposure to a wide variety of animals, both domestic and wild.
- Accidental injury from the thorns of some plants or bushes.
- Accidental laboratory or clinical inoculation of hospital workers.

Clinical Features. The most common lesions of sporotrichosis involve the skin, subcutaneous tissues and oral, nasal and pharyngeal mucosa, although disseminated visceral involvement occasionally occurs. The skin lesions, often described as sporotrichotic 'chancres,' appear at the site of inoculation as firm, red to purple nodules, which soon ulcerate. Neighboring nodules with regional lymphadenopathy generally develop soon, and both these subcutaneous nodules and involved lymph nodes may also ulcerate and drain.

Oral Manifestations. Nonspecific ulceration of the oral, nasal and pharyngeal mucosa also occurs in this disease, usually associated with regional lymphadenopathy. The lesions are described as healing by soft, pliable scars even though the organisms may still be present in the tissues.

Histologic Features. The fungus is a small, ovoid branching organism with septate hyphae, showing budding forms. It is only 3–5μ in diameter and because of the small size, is seldom recognized in the routine tissue sections. However it can be cultured on Sabouraud's medium.

The tissue reaction is a granulomatous one with epithelioid cells, multinucleated giant cells of the Langhans type and lymphocytes, often surrounding a central area of purulent or caseous necrosis. Polymorphonuclear leukocytes are prominent in some cases. Asteroid bodies radiate formations around the fungal spores in tissues are commonly found in this disease as reported by Lurie. Pseudoepitheliomatous hyperplasia of

the overlying epithelium of skin or mucosal lesions is also almost invariably present.

Treatment and Prognosis. There is no specific treatment for the disease, most antibiotics being ineffective, but the prognosis is generally good, although chronic repetitive remissions and relapses are common. The chronic pulmonary form of the disease is often fatal.

RHINOSPORIDIOSIS

Rhinosporidiosis is a chronic granulomatous disease caused by a fungus called *Rhinosporidium seeberi*, which affects chiefly the oropharynx and nasopharynx as well as the larynx, skin, eyes, and genital mucosa. The mode of infection is not known. This infection is common in India and Sri Lanka.

Clinical Features. Nasal mucosa is the most common site involved. Lesions appear as small verrucae or warts, which ultimately become pedunculated. Genital lesions resemble condylomas.

Oral Manifestations. The oronasopharyngeal lesions are often accompanied by a mucoid discharge and appear as soft red polypoid growths of a tumor like nature, which spread to the pharynx and larynx. The lesions are vascular and bleed readily. Though any intraoral site may be involved, soft palate appears to be the most frequent site. The oral lesions have been reviewed by Ramanathan and his coworkers. In addition, an unusual case involving the parotid duct has been reported by Topazian.

Histologic Features. The organisms appear as sporangia containing large numbers of round or ovoid endospores, each approximately 5–7μ in diameter. In either smear preparations or tissue sections, these sporangia are characteristic in appearance. The surrounding tissue reaction itself is a nonspecific one consisting of a vascular granulation tissue with focal abscess formation and occasional multinucleated giant cells. Both acute and chronic inflammatory cells are present in variable number (Fig. 7-10).

Treatment. Surgical removal of the growths is recommended as treatment of choice.

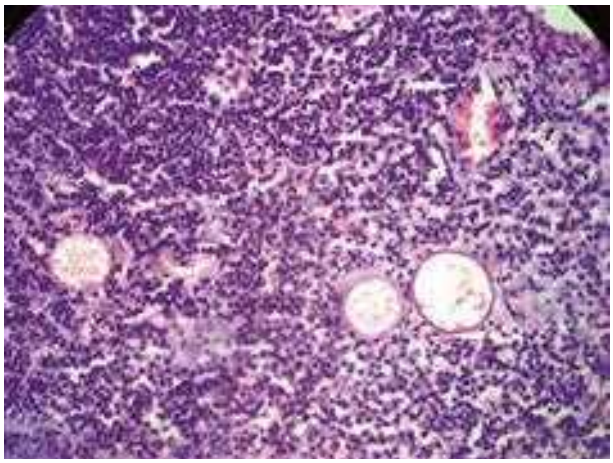


Fig. 7-10. Rhinosporidiosis.
Vascular granulation tissue with sporangia containing endospores *(Courtesy of Dr G Sriram, Meenakshi Ammal Dental College, Chennai).*

Parasitic Infections

There is a considerable variety of protozoal and helminthic parasitic diseases which occasionally manifest oral involvement. The protozoa are unicellular animals which are usually divided into two subphyla: the Plasmodroma—protozoa which move by means of pseudopodia or flagella—and the *Ciliophora*—protozoa which move by means of cilia.

Of the more common protozoal diseases, it is recognized that the following may involve oral structures in some fashion: trypanosomiasis (**Chagas' disease**), leishmaniasis, trichomoniasis and toxoplasmosis.

Helminthic Diseases

The helminths are multicellular parasitic worms, often referred to as metazoa, and are generally divided into two phyla, the Nemathelminthes or roundworms and the Platyhelminthes or flatworms. Of the nemathelminthes, those belonging to the class Nematoda (roundworms) are of medical importance, while of the platyhelminthes, those belonging to the Cestoda class (tapeworms) and the Trematoda class (flukes) are important.

These diseases may also involve oral structures with perhaps an even greater frequency than the protozoal diseases. Of the more common helminthic diseases, the following may manifest oral involvement: cysticercosis, trichinosis (trichiniasis), schistosomiasis (bilharziasis), echinococcus disease (hydatid disease), ascariasis, strongyloidiasis, and myiasis.

The entire field of parasitology is becoming increasingly important since some parasitic infections, once restricted to certain parts of the world are becoming worldwide in their distribution as a result of travel and military entanglements in countries which are parasite reservoirs. Nevertheless, the relative infrequency with which parasitic oral problems are encountered precludes a discussion of the individual diseases here.

CYSTICERCOSIS

Cysticercosis is an infestation caused by Cysticercus. Cysticercus (Gr. Kystis: bladder + kerkos: tail) is a larval form of certain Taenia species. Among various species, the larval form of tape worm, the **Taenia solium** i.e. **Cysticercus cellulosae** (a larval form of T. solium) infests human beings who serve as either definitive or as intermediate hosts of the adult tapeworm.

Consumption of inadequately cooked pork is the primary cause since pigs serve as intermediate hosts. The other causes include consumption of fecally contaminated vegetables, food or water, as well as self-contamination by reflux from the intestine into the stomach or by contaminated hands.

Intraorally, cysticercosis commonly involves lips, cheeks, and tongue. Cysticercosis involving the masseter muscle has been reported by B Dilip Kumar, Bindi Dave, and SM Meghana. Most cases present as a solitary or multiple, painless, well circumscribed, fluctuant swellings, and often mimic mucoceles.

Fig. 7-11. Cysticercosis.
(Courtesy of Dr Ranganathan K, Saraswathi TR, Umaram N. Know this field, J Oral Maxillo Pathol, 8:86, 2004).

Microscopically, cysticercosis appears as a fibrous capsule surrounding a Cysticercus (Fig. 7-11). The bladder wall of larva appears as lightly eosinophilic wavy membrane with multiple tiny ovoid nuclei in the fibrillary stroma beneath. The host reaction to a viable cyst is often minimal. When a cyst dies spontaneously or following chemotherapy, there is usually more inflammation. Local eosinophilia, granulation tissue, and a granulomatous reaction follow. The dead parasite disintegrates and often gets calcified within a residual fibrous scar.

ORAL MYIASIS

Oral Myiasis (Gr. Myia: fly) is defined as a condition in which the soft tissue of different parts of the oral cavity are invaded by the parasitic larvae of flies (Moshref, Ansari and Loftfi, 2008). These larvae commonly known as **maggots**, are of two winged flies, the Diptera. Myiasis occurs mainly in the tropics and is associated with poor personal hygiene. Usually the female fly infests ova in open wounds, dead tissue, or in the natural body cavities, such as ear, nostrils, and oral cavity. The flies lay over 500 eggs directly on diseased tissue. These eggs hatch and the larvae get their nourishment from the soft tissue.

Oral myasis is relatively a rare condition but cases have been reported in gingiva, palate, and extracted wounds. Antunes AA et al (2011) presented a series of 10 cases of oral and maxillofacial myasis and reviewd the literature.

The usual presenting symptoms are painful growth with ulceration and itching due to crawling movement of the larvae (Fig. 7-12). The treatment is aimed at removal of larvae from the affected area and flushing the area with normal saline or antiseptics.

CHAPTER 8

Diseases of the Periodontium

■ B SIVAPATHASUNDHARAM

CHAPTER OUTLINE

Diseases of periodontium comprise of a group of heterogeneous disorders, and majority of them are caused by bacteria. Periodontal diseases have been known since antiquity. Skulls of some ancient cave dwellers show evidence of chronic periodontal disease, while an acute form now known as acute necrotizing ulcerative gingivitis, or 'Vincent's infection,' was reported as early as 400 BC in soldiers in the Greek army of Xenophon. Man suffers to a greater extent from periodontal disturbances than lower animals.

Though there are many distinct types, chronic diseases of the periodontal tissues exist, chronic plaque associated gingivitis and periodontitis are most common. Inflammation confined only to the marginal gingiva is known as gingivitis. Once it extends to involve the connective tissue attachment and alveolar bone loss, it is called periodontitis. Chronic periodontitis causes more teeth loss than any other disease for adults does. Classification of the various periodontal diseases is difficult, because in nearly every case the condition begins as a minor localized disturbance, which unless adequately treated, may gradually progress until the alveolar bone is resorbed and the tooth is exfoliated. Also, a variety of local irritating factors and underlying systemic situations may alter the progress of the disease. The various resulting pathologic conditions are generally similar regardless of the etiologic factors involved. In other words, the reaction to injury that occurs in the gingiva and the supporting tissues of the teeth is usually a chronic inflammatory response. Histologic studies of the periodontium seldom indicate the type of irritant causing the disease or suggest a specific method of therapy.

THE HEALTHY PERIODONTIUM

The periodontium (peri—around, odonto—tooth) or 'the attachment apparatus' includes the following tissues: (1) the gingiva, (2) the periodontal ligament, (3) the root cementum, (4) the alveolar bone. Its main function is to attach the tooth to jaw bone and to maintain the integrity of the masticatory system.

GINGIVA

A healthy gingiva is a part of the masticatory mucosa covering the alveolar process and surrounds the cervical portion of the tooth by snugly fitting into each interproximal space between the teeth (Fig. 8-1A).

Gingiva is anatomically differentiated into two parts; the free gingiva and the attached gingiva. The color of the gingiva is coral pink and it has a stippled 'orange peel' surface. In children, the gingiva is not stippled and appears redder and more delicate. The attached gingiva and the central portion of the interdental papillae are stippled but not the marginal gingiva. Stippling is a form of adaptive specialization or reinforcement for the function. So, reduction or loss of stippling is a common sign of gingival disease. Microscopically gingival epithelium is stratified squamous and parakeratinized except in the gingival sulcus and interdental area where it is nonkeratinized.

In the coronal direction, the gingiva terminates in the free gingival margin with a scalloped outline. In the apical direction it is separated from the loose, darker red alveolar mucosa, by a border termed as mucogingival junction or mucogingival line.

A B

Figure 8-1. Healthy gingiva (A) and healthy alveolar bone (B) in the young adult.

The free gingiva extends apically from the gingival margin to the free gingival groove at the level of the cementoenamel junction (CEJ). The free gingival margin is rounded and is located approximately 1.5–2 mm coronal to the CEJ. It comprises buccal or labial and lingual or palatal aspects and the interdental gingiva. The interdental gingiva also called as interdental papillae has a shape in conformity with the outline of the proximal interdental contact surfaces, as a concavity or a small depression called 'col', (a term used by mountaineers to describe a depression between two peaks) which is covered by non-keratinized epithelium. The col lies between the buccal and lingual papillae and is covered with a vestigial structure consisting of the epithelial remnants of the enamel organs of the two adjacent teeth.

Fish believes that a clinically healthy col is gradually replaced by stratified squamous epithelium unless interrupted by inflammation. According to him, a clinically healthy col covered with enamel epithelium is found only in adolescents or very young adults. If the col becomes inflamed or irritated from aggressive scaling at an early age, it might develop an infrabony pocket, since the col is a vulnerable area of the periodontium.

The attached gingiva is firmly attached to the underlying alveolar bone to form a tough mucoperiosteum and to the cementum by the connective fibers and extends apically to the mucogingival junction.

Differences between the oral epithelium, sulcular epithelium and the junctional epithelium

- Junctional epithelium cell size is relative to the tissue volume, larger than in the oral epithelium
- Intercellular spaces of the junctional epithelium are, relative to the tissue volume, comparatively wider than in the oral epithelium
- The number of desmosomes is more in the oral epithelium than in the junctional epithelium

The epithelium of the free gingiva is microscopically differentiated as oral epithelium, facing the oral cavity, sulcular epithelium, which faces the tooth, and the junctional epithelium between the gingiva and the tooth.

The most coronal portion of the attachment apparatus is called the 'epithelial attachment' or 'epithelial cuff.' This is a band of modified stratified squamous epithelium (normally about 0.2 mm. in vertical dimension) wrapped around the neck of the erupted tooth in the adult. This epithelium is continuous with the epithelium lining the gingival crevice (crevicular epithelium). The attached epithelium, like all other surface epithelium throughout the body, is continuously replaced by multiplication of the basal cells to compensate for the desquamation of the surface cells. This epithelium has relatively high turnover rate. Whether this band is organically attached to the tooth or not is controversial, but the nature of its attachment does not seem to be as important as the fact that the epithelium is present at the site where the tooth extrudes into the oral cavity and that when healthy it forms an effective seal, protecting the underlying connective tissues. The epithelium in this area, whether attached firmly or lightly, is an external cover for the oral cavity, which is resistant to the invasion of irritants and bacteria into the underlying connective tissues. It is a continuous, living, protective device around the neck of the tooth.

Lamina Propria

The connective tissue (lamina propria) components of the gingiva consist of collagen fibers (60%), fibroblasts (5%), vessels and nerves (35%). They are embedded in amorphous ground substances. Cells of the connective tissue include fibroblasts, mast cells, macrophages and the inflammatory cells.

The connective tissue fibers produced by the fibroblast are collagen fibers, reticulin fibers, oxytalan fibers and the elastic fibers. The collagen fibers of the gingiva are oriented in bundles and run in specific direction. Accordingly they are divided into the following groups:

1. **Circular fibers,** these fiber bundles are contained in the free gingiva and encircle the tooth in a cuff or ring-like fashion.

Gingival fluid (sulcular fluid)

Gingival fluid is present at the gingival sulcus in minute amounts. It is not considered as secretion. It is a fluid that exudates and increases during inflammation. Gingival crevicular fluid is a complex mixture of substances derived from serum, leukocytes, cells of the tissues of periodontium, and microbial flora inhabiting the marginal gingiva or the sulcus (pocket). It also contains significant amounts of antibodies, cytokines, enzymes, and tissue degradation products. The amount of gingival fluid is less in healthy sulcus. Gingival fluid helps to cleanse material from the sulcus, and the presence of plasma proteins may improve adhesion of the epithelium to the tooth, thereby maintaining the structure of junctional epithelium. By its antimicrobial property it defends the periodontium.

Defense mechanisms of gingiva

Nature of the gingival epithelium (i.e. the degree of keratinization, permeability, etc.), presence of leukocytes, salivary components, and gingival crevicular fluid guard the periodontal tissues against the various microbial threats.

Gingival crevicular fluid exhibits both cell mediated and humoral immune responses in healthy and diseased periodontal state by having cytokines. Interferon-α in gingival crevicular fluid inhibits the bone resorption activity of interleukin-1β in periodontal diseases.

Leukocytes, predominantly polymorphonuclear leukoctyes (PMN) are present in the healthy gingival sulci. Apart from PMN a smaller amount of B lymphocytes, T lymphocytes, and mononuclear phagocytes are also present. They have phagocytic and killing property and prevent the extension of plaque and bacterial toxins into the gingival sulcus.

Saliva contains antibodies, enzymes, other antibacterial substances, and leukocytes, which protect the oral tissues by its cleansing, buffering, and antibacterial property. It exerts influence on initiation, progression, and maturation of bacterial plaque.

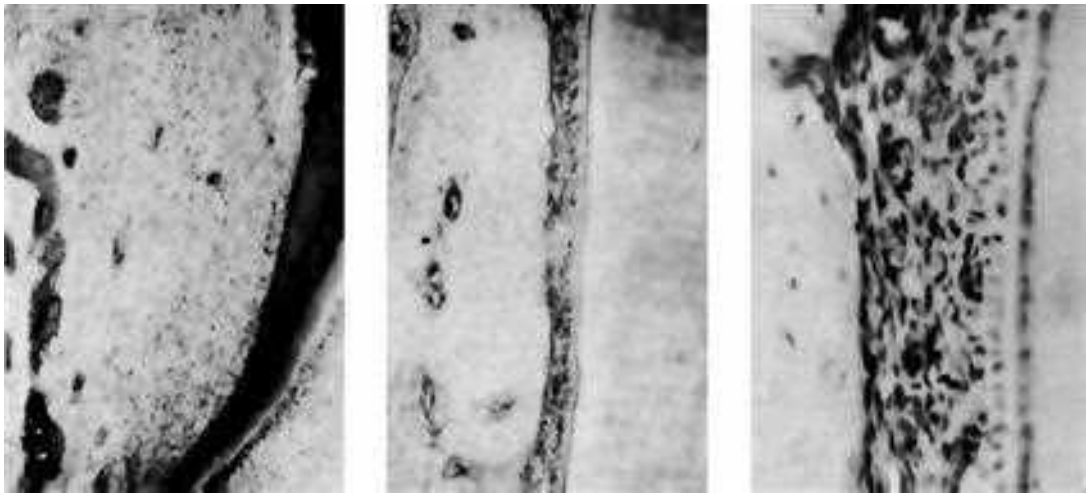
2. **Dentogingival fibers** are embedded in the cementum and project in a fan-like configuration into the free gingival tissue.
3. **Dentoperiosteal fibers** are also embedded in the cementum as dentogingival fibers, but run apically and terminate at the periosteum of the alveolar crest.
4. **Alveologingival fibers** extend from the crest of the alveolar bone to the lamina propria of the gingiva.
5. **Transseptal fibers,** these fibers run straight across the interdental septum and are seen embedded in the cementum of the adjacent teeth.

Periodontal Ligament

The periodontal ligament is a soft, richly vascular, dense fibrous connective tissue and is attached to the cementum on one end and alveoloar bone on the other end and occupies the space between the root cementum and the alveolar bone proper. The embedded portion of the periodontal ligament fibers is known as Sharpey's fibers and the diameters of these fibers are smaller in the cementum than in the alveolar bone proper.

Periodontal ligament is made up of collagen fibers, oxytalan fibers, fibroblasts, amorphous ground substance, and interstitial tissue. Cells of the periodontal ligament include cementoblasts, osteoblasts, osteoclasts and epithelial remnants of Malassez (Figs. 8-2, 8-3). The shape of the periodontal ligament space is of an hourglass-like which is narrowest at the mid-root level. And width of the periodontal ligament ranges from 0.2 to 0.4mm.The mobility of the tooth is largely determined by the width, height and quality of the periodontal ligament.

The principal fibers of the periodontal ligament are collagenous bundles, with a wavy course in longitudinal



A B C

Figure 8-2. Normal immature periodontium.
The unoriented periodontal fibers of a developing tooth are illustrated in **(A)**. The periodontal ligament of an unerupted tooth is shown under low magnification in **(B)** and high magnification in **(C)**.

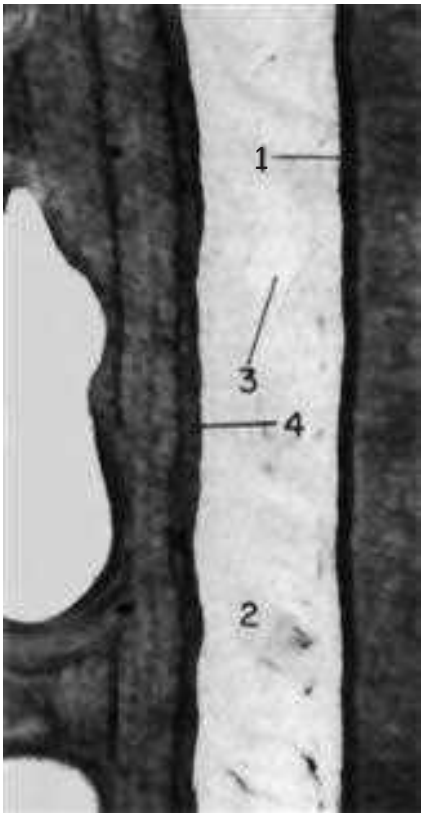


Figure 8-3. Normal mature periodontium.
Note the thin layer of cementum (1), the periodontal fibers (2), the large and empty capillaries (3), and alveolar bone (4).

sections. The principal fibers of the periodontal ligament are broadly grouped into:

1. **Alveolar crest group.** This group of fibres radiate from the crest of the alveolar process and attach to the cervical part of the cementum
2. **Horizontal group.** This group of fibers run at right angles to the long axis of the tooth from cementum to the alveolar bone.
3. **Oblique group.** These are the largest group of fibers extending from the cementum in the coronal direction obliquely to the bone.
4. **Apical group.** Apical fibers run from the cementum to the bone in an irregular manner at the apical portion of the tooth socket.
5. **Interradicular group.** This group of fibers which extend from the interradicular cementum of multi-rooted teeth to the crest of the interradicular bone.

The principal fibers of the periodontal ligament always develop conjunction with the eruption of the teeth.

The collagen fibers hold the tooth in position, suspend it in the alveolus, and transform occlusal pressures to tensile forces on the alveolar bone. Although these fibers are not elastic fibers, they are wavy in arrangement, and straighten under occlusal pressure. Sicher has stated that although fiber bundles extend from cementum to bone, the individual fibers do not. The fibers from the cementum and the bone are connected by an intermediate group of interlacing fibers in the middle of the periodontal ligament. The periodontal ligament also contains elastic fibres, associated with the blood vessels and the oxytalan fibers.

Oxytalan fibers are so named because they are acid-resistant, in contrast to collagen fibers and may be related to elastic fibers. An increase in the number of large oxytalan fibers in the transseptal region of periodontal ligaments supporting teeth, which serve as abutments for fixed bridges, suggests that they may be stress related. A concentration of these fibers is also observed to be inferior to the epithelial attachment, irrespective of its location on the tooth. Although oxytalan fibers may persist for a short time after the collagen fibers have been destroyed in periodontal disease, they ultimately disappear as well, and there is no evidence that they deter the progress of a periodontal lesion.

The functions of the periodontal ligament are the tooth anchorage, fibrous tissue development and maintenance, calcified tissue development and maintenance, nutritive and metabolite transport, and innervation.

The tooth is suspended in its position by the unique attachment (gomphosis) formed by strong connective fibers. Thus the functional arrangement is such that physiologic force from any direction will result in tension in the fiber groups and not compression on the bone or fiber groups.

The cells of the periodontal ligament are the fibroblast, osteoblast, cementoblasts, osteoclasts, nerve fibers, and the epithelial cells. The clusters of the epithelial cells are called as the epithelial cell rests of Malassez, a remnant of the Hertwig's epithelial root sheath.

The epithelial rests are found in all people, but apparently their total number decreases with age. They vary in size from small resting types of larger proliferative masses of epithelial cells. Some are calcified and persist as cementicles. The majority of epithelial rests are located in the cervical area of the teeth at all ages except during the first and second decades, at which time the greatest number is found in the apical area. Reeve and Wentz have suggested that the greater persistence of epithelial rests in the cervical area may be correlated with and influenced by the constant inflammatory reaction present in the area of the gingival sulcus.

Root Cementum

Cementum is a mineralized tissue covering the root surfaces of the tooth. It does not contain blood or lymph vessels or nerves. The different forms of cementum are the cellular, acellular, and afibrillar cementum. The functions of the cementum are to attach the fibers of the periodontal ligament to the root and to repair of the damaged root surface. Cementum of erupted and unerupted teeth undergoes resorption and repair (Fig.8-4). Cementum resorption may be idiopathic or may be caused by local conditions such as occlusal trauma, orthodontic tooth movement, pressure from cysts and tumours, teeth without antagonists, embedded teeth, replanted and transplanted teeth, and tooth with periapical and periodontal diseases. Systemic conditions such as hypothyroidism, calcium deficiency, and

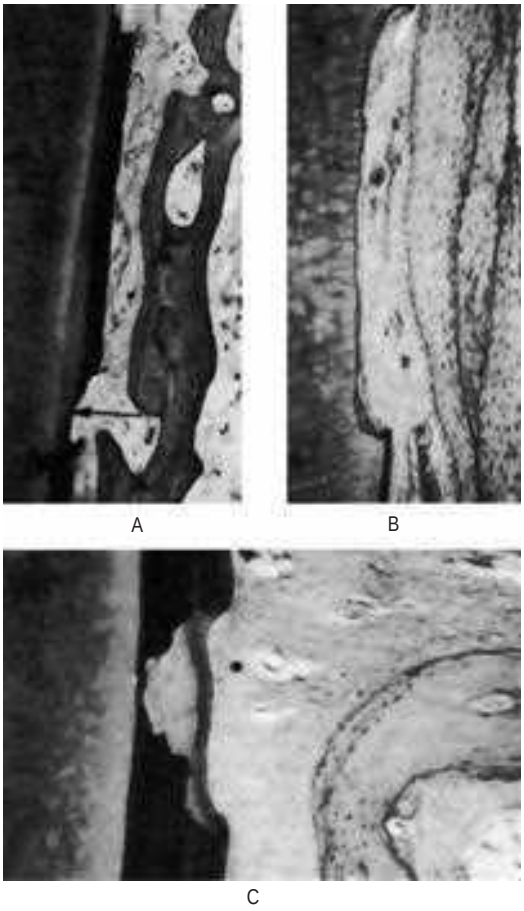

Figure 8-4. Resorption of cementum.
(A and B), Focal microscopic resorption of cementum is common. **(C)** Repair of an area of resorption is evident.

Paget's disease may predispose or induce cemental resorption. Bimstein E and coworkers have examined cemental surface under light microscope and found that teeth from children with leukocyte adhesion deficiency, Down's syndrome, and aggressive periodontitis have narrower cementum areas and concluded that these cemental anomalies may facilitate the establishment and progress of periodontitis in children. In another study by Bimstein and coworkers on histologic characteristics of root surfaces of primary teeth from children with prepubertal periodontitis revealed bacteria inside dentin tubules or covering cementum, a cuticle, or resorbed dentin; normal, wider than normal, or hypoplastic cementum; resorption lacunae with various depths; aplastic root resorption; alternate resorption and repair; and active repair.

Alveolar Bone

Alveolar process is the part of the maxilla and the mandible containing the sockets, which protects and supports the tooth. The main function is to distribute and resorb forces generated by mastication. Radiographs show that the alveolar bone has a definite cribriform plate with uniform trabeculae and it extends to a definite point between the teeth (Fig. 8-1B)

Isolated areas in which the root is denuded of bone and the root surface is covered by periosteum and overlying gingiva are termed as fenestrations. In fenestrations the marginal bone is intact. When such denuded areas extend through the marginal bone the defect is termed as dehiscence.

The layer of bone into which the principal fibers of the periodontal ligament are inserted is termed as 'Bundle bone'. Alveolar bone is constantly renewed as a response to functional demands. Thus the periodontium is a site of continuous readaptation due to its function. The rate of this replacement is unknown, but is probably variable and related, in part at least to the physical forces applied to the periodontal ligament.

DEPOSITS ON TEETH

The organic coverings of tooth enamel are divided into two types: (1) anatomic structures, and (2) acquired pellicle. The anatomic covering, formed during the developmental and eruptive stages, is known as Nasmyth's membrane or enamel cuticle, and remnants of this membrane persist throughout the life of the tooth.

Pellicle

The acquired pellicle is a thin deposit, which may form shortly after eruption on the exposed surface of teeth. It is usually invisible and is probably of no pathologic significance. It is reformed within minutes of polishing. It is fully formed in 30 minutes and reaches its mature thickness of 0.1–0.8 microns within 24 hours. It is free of bacteria and completely covers the tooth surface.

The pellicle has been thoroughly investigated by Meckle, by Leach and Saxton, and by Sonju and Rolla, utilizing electron microscopy, electron histochemistry, optical histochemistry, and chemistry. They found that the brownish stained, smooth, structureless deposits, in contradistinction to plaque, did not stain with basic fuchsin. The brown pigment forms due to the presence of tannins in the pellicle. The pellicle frequently penetrates into the enamel, especially on the proximal surfaces of the teeth. The histochemistry and the electron histochemistry indicated that pellicles are of salivary origin. The histochemistry of the pellicle was found to be practically identical with that of dried salivary films on glass. In addition, similar structures were formed *in vitro* by incubating enamel in saliva. The acquired pellicles were composed of mucoproteins or glycoproteins similar to those found in saliva and contained some lipid material. Primary amino acid groups and 1:2 glycol groups were also demonstrated by both electron histochemistry and chemical analysis. Bacterial enzymatic degradation of salivary glycoproteins did not take place, either because the material was rapidly deposited before bacterial enzyme action could occur or because the stereo-chemical structure of the glycoproteins enabled them to resist enzymatic degradation. A persistent extraneous calcification was always observed in pellicle from the lingual surfaces of lower anterior teeth, but was of such small magnitude that it could not be resolved by light microscopy.

Dental Stains

Pigmented deposits on the tooth surface are called dental stains or extrinsic stains. The oral cavity is subjected to many types of exogenous and endogenous substances that stain teeth. And since the oral flora in many cases contains chromogenic microorganisms, stained deposits are common on the teeth. The stains that are incorporated into tooth structure are known as intrinsic stains and are seen in porphyria, erythroblastosis fetalis and tetracycline therapy (Fig. 8-5A).

Stain from Smoking. As a result of the collection of tobacco tars and resins, a yellowish-brown to black deposit forms on the tooth surfaces of persons who smoke often (Fig. 8-5B). This stain varying from a light brown, powdery deposit in the person who smokes an occasional cigarette to a dense black tarry deposit in heavy smokers. The deposit is harmless to the teeth, although it should be removed because of its objectionable appearance and may act as a nidus for calculus or have a mild, irritating effect on the gingiva. If the dentin is exposed, as in older patients by attrition, the staining may be severe.

A

B

Figure 8-5. (A) Intrinsic stain in congenital erythropoietic porphyria (erythrodontia). (B) Tobacco stain.
(Courtesy to Dr. Rashmi Santosh Kumar, Kamineni Institute of Dental Sciences, Narketpalli, Andhra Pradesh).

Brown Stain. This is a thin, brown, delicate pellicle-like structure that occurs on the teeth and is thought to be composed of salivary mucin. Its occurrence on those surfaces of teeth that are closely adjacent to the orifices of the salivary gland ducts tends to confirm its relation to saliva.

A delicate pigmented dental plaque, called the mesenteric line by some, was described by Pickerill to be a plaque of brown or black dots that coalesce to form a thin, dark line on the enamel at the cervical margin of the tooth. Pickerill, F Bibby and Shourie noted that the presence of this line is often associated with a relative freedom from dental caries.

Black Stain. A thin, black deposit that forms in some patients, both children and adults, on the teeth, is usually in a narrow line or band, just above the free gingiva. It is not associated with smoking. This black stain may be caused by chromogenic microorganisms, although none has been identified or cultured from adult stains. The black stain on primary teeth is associated with a low incidence of dental caries. Slots in 1974 demonstrated that the microflora of black stain was dominated by *Actinomyces* species and showed that they could produce black pigment in culture.

Green Stain. In some persons, mostly children, there is usually a heavy gray-green stain especially prominent on the gingival third of the maxillary anterior teeth. This stain appears to be soft or 'furry' and is difficult to remove, suggesting its association with the enamel cuticle. Sometimes a green stain covers a decalcified area of the enamel. No chromogenic microorganism, which could cause this green stain, has been identified, although it has been assumed that such an organism is the cause. It has also been suggested that coloration of remnants of Nasmyth's membrane, possibly by blood pigments, may be responsible for the stain.

Orange Stain. Occasionally, a light, thin deposit of a material of brick red or orange color is seen on teeth. The cause of this stain is not known, but it is also believed to be due to pigment-producing microorganisms. This stain can be easily removed, is of no apparent significance and may or may not recur.

CALCULUS

In some children and most adults, varying amounts of a hard, stone-like concretion form on the surfaces of teeth or prosthetic appliances (Figs. 8-6, 8-7, 8-8). These deposits are called 'calculus', 'odontolithiasis', or 'tartar.' Calculus is mineralised dental plaque.

Mandel considers calculus formation to be a triphasic process, consisting of cuticle or pellicle deposition, bacterial colonization and plaque maturation, and mineralization, although all three steps may not always be essential. Frank and Brendel have indicated that bacteria can be attached directly to enamel without a cuticular intermediary. Theilade and his coworkers have shown that calcareous deposits can occur in germ-free animals. Nevertheless, the usual process in man is probably a triphasic one.

Calculus is deposited as a soft, rather 'greasy' material, which gradually hardens by deposition of mineral salts in the

Figure 8-6. Supragingival calculus on lingual surface of lower anterior teeth.

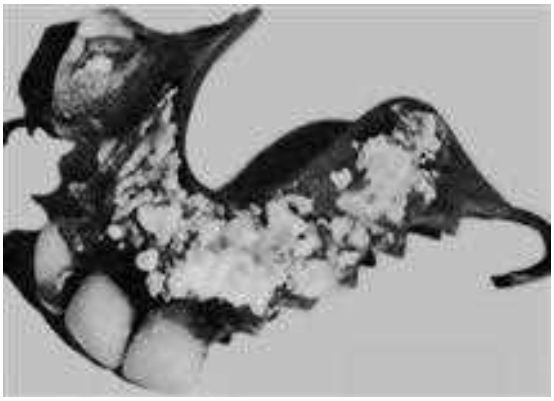

Figure 8-7. Calculus deposited on ill-fitting removable partial denture.

A

B

Figure 8-8. (A, B) Calculus.

organic interstices, until it becomes hard. It varies in color, from yellow to dark brown or black, depending upon the amount of stain present on or within the deposit.

Distribution of Calculus. Calculus is classified or divided into two general types according to its location. Deposits above the gingiva on the exposed coronal surfaces of the teeth are spoken of as **supragingival calculus,** while those covered by the free gingiva are **called subgingival calculus**. The subgingival calculus is generally much harder, denser, less extensive, flatter, more brittle, and darker in color while the supragingival calculus is white or whitish yellow in color and hard with clay-like consistency. Supragingival calculus can be easily detached from the tooth. Many investigators believe that both types of calculus result from a deposit of inorganic substances into bacterial plaque from saliva and that their physical difference is dependent only upon their environment. Many deposits include both types of calculus; one shading into the other, so any actual division is indistinguishable. Others believe that saliva does not penetrate the gingival crevice and that the source of the inorganic salts in calculus is the blood or tissue fluid from the gingival tissues.

The greatest accumulations of calculus, both supragingival and subgingival, occur on those surfaces of the teeth that are closest to the orifices of the major salivary gland ducts. Thus the lingual surfaces of the mandibular anterior teeth opposite the submandibular and sublingual gland openings and the buccal surfaces of the maxillary molars opposite the parotid duct opening are the common sites of deposition of calculus (Fig. 8-9). It may be localized in its distribution or generalized over many tooth surfaces.

Incidence of Calculus Deposition. Careful clinical observations have indicated that calculus is deposited at irregular intervals throughout life. Patients will sometimes demonstrate a rapid deposition for a short time and then no deposition of calculus for days or weeks.

Although there have been few epidemiological studies on the incidence of calculus, several indices to evaluate the quantity of calculus have been developed. The Simplified Calculus Index of Greene and Vermillion and the Probe Method of Calculus Assessment of Volpe and his coworkers were developed to measure the quantity of calculus formed in long-term longitudinal studies, whereas the Calculus Surface Index of Ennever and his coworkers was developed for short-term clinical trials of calculus inhibitory agents. In fact, the WHO proposed in 1978 that since plaque and gingivitis were so closely correlated, it was unnecessary to assess plaque (and presumably calculus) in population studies and field trials.

However, Marshall-Day reported that in a study of persons 13–60 years old, the 19–22-year age group showed an increase in calculus deposition over the younger age group and that there was a further sharp increase in the 31–34-year age group. The incidence of calculus reached a peak of 91% of persons studied in the 56–59-year age group. Of the entire group, 71% of men and 62% of women manifested calculus formation. 26% exhibited supragingival calculus only, with no significant difference between men and women. Persons

A B

with subgingival calculus alone were comparatively few, the incidence being 7% for men and 8% for women. The greater proportion of subjects studied exhibited both types of calculus after 30 years of age. Third National Health and Nutrition Examination Survey revealed that 91.8% of the subjects had detectable calculus and 55.1% had subgingival calculus based on their survey involving 9689 adults in the United States.

Composition of Calculus. Calculus is composed of approximately 75% calcium phosphate, 15–25% water and organic material and the rest calcium carbonate and magnesium phosphate with traces of potassium, sodium, iron, and other elements. When deposits of calculus are washed and analyzed, their basic structure and composition are about the same, regardless of their location. Chemical analyses of calculus varies widely, depending upon the age of the calculus studied, the amount of food debris, and bacterial elements present, and so forth. Calculus consists primarily of calcium phosphate arranged in a hydroxyapatite crystal lattice structure similar to that of bones, enamel, and dentin. The similarity of chemical analyses and physical characteristics of dentin, enamel, cementum, bone, and calculus indicates that removal of calculus from the enamel, cementum or dentin must be done with care, or the dental tissues, especially the cementum, might be damaged.

The organic stroma of the calculus in which the mineral salts are deposited consists of protein polysaccharide complexes, a tangled meshwork of microorganisms, especially gram-positive filamentous types, desquamated epithelial cells and other debris, and white blood cells. Gram-negative filaments and cocci are also present in varying numbers. Mucin has been identified in calculus, as expected from its universal presence in saliva. Mandel and Levy demonstrated a carbohydrate fraction, probably in combination with a protein, and lipid in calculus. Salivary proteins make 5.9–8.2% of the organic component. The composition of subgingival calculus slightly differs from the supragingival calculus. Though the hydroxyapatite content is similar in both types, the magnesium content is more and brushite and octacalcium phosphate is less in subgingival calculus with absence of salivary proteins.

Attachment of Calculus. The manner of attachment of calculus to the tooth surface is an interesting problem, since it is well known that calculus can be scaled from the teeth very easily in some people, but with great difficulty in others. This suggests that calculus has more than one mode of attachment. Acquired pellicle formation has already been discussed. It is important to reiterate McDougall's findings that all plaques on enamel include an acquired cuticle or pellicle. Zander also investigated calculus attachment and observed four types of attachment of the organic calculus matrix to the tooth surface: (1) attachment to the secondary dental cuticle, (2) attachment to microscopic irregularities in the surface of the cementum corresponding to the previous location of Sharpey's fibers, (3) attachment by penetration of microorganisms of the calculus matrix into the cementum, and (4) attachment into areas of cementum resorption. He also found that one piece of calculus seldom got attached by a single mode, but rather by a combination of modes. Calculus embedded deeply into the cementum may appear morphologically similar to cementum and has been referred to as **calculocementum.**

Bacterial Colonization and Plaque Maturation. Many theories have been formulated to explain calculus deposition, but none of them are completely acceptable. No one knows exactly why calculus forms in some persons and not in others, or in the same person at some times but not others.

Numerous studies indicate that the early plaque is composed of a preponderance of coccal microbial forms. As the plaque ages, fusobacteria and filamentous organisms increase in number and, by the second or third week of plaque formation, about half of the organisms in the plaque become filamentous. Gram-positive cocci and rods make up the remainder of the plaque population. The population dynamics of plaque development indicates a progressive decline in aerobic organisms with a concomitant increase in anaerobic organisms.

There is increasing evidence that the various diseases included under the term 'chronic periodontal disease' are in fact different diseases and are associated with distinct microbial organisms. Reports from the laboratories of Socransky and his colleagues, Slots and of Kornman and Loesche and others indicate that there is certain specificity to the combination of bacteria in this subgingival plaque in periodontal diseases like chronic gingivitis, acute necrotizing gingivitis, and juvenile periodontitis. The evidence for microbial specificity of individual periodontal diseases was well presented in a review by Loe in 1981.

There are several reports of microbial differences between clinical forms of periodontal disease. Studies by Tanner and his colleagues showed that the predominant cultivable organisms from periodontitis lesions varied among patients. Their studies were early attempts to distinguish 'pathogens' associated with different clinical features of destructive periodontal disease. Studies of the plaque in various forms of periodontal disease indicate that there are indeed differences not only in clinical and microbial features but also in host responses to microbial complexes. For example, it is possible that *Peptococcus asaccharolyticus* and *Actinobacillus actinomycetemcomitans* play significant etiologic roles in distinctly different destructive forms of periodontal disease.

Plaque Mineralization. The soft dental plaque that is hardened by the precipitation of mineral salts usually starts between the 1st and 14th day of plaque formation. The investigations of Mandel and Levy, as well as Wasserman and his associates, on early developing calculus utilizing histochemical as well as histologic techniques have added to the knowledge of calculus formation. They studied calculus formation by placing contoured strips around lower anterior teeth in patients known to form calculus rapidly. It was noted that the calcifying areas were frequently laminated by alternating dark and light staining bands that produced a concentric ring-like appearance similar to that of pulp stones and urinary calculi. This lamination had been noted by Black in human calculus 70 years earlier.

That bacteria may not be essential for calculus formation was demonstrated by the finding that calcareous deposits developed on the teeth of germ-free animals. Such calcified deposits may be laboratory curiosities and may or may not have relevance to human calculus formation. In any event, the human bacterial plaque does mineralize, but there is no evidence that viable microorganisms are essential for the process.

The major mineral present in calculus is a carbonate apatite similar to that formed in bones and teeth. It is not known why some dental plaques mineralize and others do not. The bulk of the calculus mass consists of mineralized bacteria, and the earliest visible mineral deposition is usually associated with them. Certain microorganisms, such as *Corynebacterium matruchotii* and some strains of *Streptococcus mutans*, can be isolated from plaque, which forms an apatite intracellularly when cultured in a medium rich in calcium phosphate. In addition, dead microbial cells induce apatite formation when suspended in metastable calcium phosphate solutions. This finding suggested to Ennever and his coworkers that some component of the cell functions as a catalyst for apatite nucleation. They isolated such a catalyst from microbial cells and characterized it as a proteolipid, nonpolar protein-acidic phospholipid complex. Bacterial cells do not calcify if the proteolipid has been completely removed. The dental calculus matrix also contains proteolipid, which is essential for its remineralization *in vitro* after it has been decalcified. It is chemically similar to microbial proteolipid. Thus it appeared that proteolipid derived from plaque microbial membranes provided the catalyst for calculus formation. Isolated proteolipid and synthetically prepared analogs have been used to determine the mechanisms of calcification. An essential feature of the mechanism is the initial calcium binding by acidic phospholipids of the complex. The binding is followed by dehydration, which forms a microenvironment in which apatite nuclei are stabilized long enough for crystal growth.

Importance of Calculus. Calculus is always covered with the unmineralized plaque. This unmineralized plaque is the chief irritant and the underlying calculus acts as a significant contributing factor. Calculus is uniformly associated with periodontal diseases. Since it is adherent to the tooth surface, it moves with the tooth during its functions. Subsequently, injuries can occur to the adjacent or overlying gingival tissues that do not move in unison with the teeth. Also, when pressure is placed on the gingiva during mastication, the underlying calculus could irritate the gingival tissues. Thus calculus causes an inflammatory reaction in the gingiva with its overlying mat of microorganisms (Fig. 8-10). Occasionally, supragingival calculus collect in prodigious amounts with little more pathosis present than a superficial inflammation; possibly due to high tissue resistance. Removal of calculus results in rapid clinical improvement.

Prevention of formation of calculus is dependent primarily upon removal by the patient of the fresh, uncalcified deposits with toothbrush and dental floss.

Halitosis

(Oral malodor, fetor oris, fetor ex ore)

Halitosis an unpleasant or foul odor exhaled while breathing or talking. It is one of the most common reasons for seeking dental aid. It is present in all mouth for some time (transient) and some mouth for all time (persistent). Transient halitosis occurs in fasting, eating certain foods such as garlic, onions, fish and the like, obesity, smoking, and alcohol consumption. Because the mouth is dry and inactive during the night, the odor is usually worse upon awakening (morning breath).

Causes of halitosis may be local or extraoral. Among local causes tongue and gingival sulcus are the major sources of oral malodor, which also include retention of food debris on and between the teeth, unclean prostheses and diseased states like chronic periodontitis, dental caries, abscesses, and dry socket.

Extraoral causes of halitosis include respiratory tract infections, hepatic disorders and excretion through breath of

A B

Figure 8-10. Calculus.
The gingival tissues opposite the rough deposits of calculus show inflammation and alterations in the epithelium *(B, Courtesy of Dr JP Weinmann, GW Burnett and Williams and Wilkins Company).*

metabolites. The later includes the sweet odor of diabetes, alcoholic breath, and uremic breath of kidney diseases.

Proteins retained in the mouth are broken down by the anaerobic bacteria into amino acids which in turn is further broken down to produce volatile sulfur compounds namely hydrogen sulfide and methyl mercaptan, which are foul smelling.

The methods of detecting or diagnosing halitosis are organoleptic measurement, sulfide monitoring and gas chromatography.

In some patients no halitosis may be present in spite of their complaint of oral malodor. These non-genuine halitosis patients are either pseudo-halitosis patients or halitophobic. Causes include chemosensory dysfunction like taste or olfactory dysfunction or psychosomatic factor.

CLASSIFICATION OF PERIODONTAL DISEASE

Many classifications of periodontal disease have been proposed. The classification presented here (Table 8-1) is the most accepted and was presented and discussed at the International Workshop for the classification of the periodontal diseases organized by the American Academy of Periodontology in 1999.

GINGIVAL DISEASES

Gingival diseases are broadly classified into dental plaque induced and nonplaque induced. Plaque induced gingival diseases comprise of two categories namely those caused by local factors and those affected by local factors modified by the specific systemic factors of the host.

Table 8-1: Classification of periodontal disease

Gingival diseases Plaque induced gingival disease Nonplaque induced gingival lesions
Chronic periodontitis Localized Generalized
Aggressive periodontitis Localized Generalized
Periodontitis as a manifestation of systemic disease
Necrotizing periodontal disease Necrotizing ulcerative gingivitis (NUG) Necrotizing ulcerative periodontitis (NUP)
Abscesses of periodontium Gingival abscess Periodontal abscess Pericoronal abscess
Periodontitis associated with endodontic lesions Endodotic – periodontal lesion Periodontal – endodontic lesion Combined lesion
Developmental or acquired deformities and conditions Localized tooth related factors that predispose to plaque induced gingival diseases or periodontitis Mucogingival deformities and conditions around teeth Mucogingival deformities and conditions on edentulous ridges
Occlusal trauma

Plaque induced gingival disease is the most common form of gingival disease. This may occur on a periodontium with no attachment loss or on a periodontium with a previous

attachment loss that is stable and not progressing. Plaque induced gingival disease is the result of the interaction of plaque bacteria and defense cells of the host.

This bacteria and host interaction is modified by local and systemic factors. The factors that have been most commonly cited are as follows:

Local factors
1. Microorganisms
2. Calculus
3. Food impaction
4. Faulty or irritating restorations or appliances
5. Mouth breathing
6. Tooth malposition

Systemic factors
1. Nutritional deficiencies
2. Drug action
3. Endocrine changes associated with puberty, pregnancy, menstrual cycle, and diabetes mellitus
4. Allergy
5. Heredity
6. Psychic phenomena
7. Specific granulomatous infections
8. Neutrophil dysfunction
9. Immunopathies

Microorganisms. One must recognize the omnipresence of the many varieties of oral microorganisms that grow as biofilm or plaque, for the most part, on the nonself-cleansing areas of the teeth, particularly below the cervical convexity of the crown and in the cervical areas. Smears of the material taken from the normal gingival sulcus, the gingival sulcus in a case of marginal periodontitis or from the gingival pocket in advanced periodontal disease reveal myriad microorganisms of many different types. Prominent among these will be cocci, various types of bacilli, fusiform organisms, spirochetes, and in advanced periodontitis, amoebas and trichomonads. The normal oral flora is so vast; however, and is made up of so many varieties of microorganisms that it has never been possible to prove conclusively that any one type of microorganism is of greater importance than others as far as periodontal diseases are concerned. The plaque associated with gingivitis and early periodontitis is complex and heterogeneous. However, Slots and coworkers in 1978 demonstrated that in the early stages of gingivitis the *Actinomyces* group of organisms is the dominant genus in the supragingival plaque.

Plaque and plaque-derived endotoxins may act as irritants or antigens in both nonspecific acute inflammatory responses and immune mechanisms of defense. One of the prime functions of the immune response is to activate the inflammatory system. Both the nonspecific acute inflammatory reaction and the immune response are homeostatic mechanisms, each of which usually succeeds in restoring and maintaining homeostasis. The growing weight of evidence suggests that the breakdown in host resistance dental plaque is a result of tissue injury brought about by the immune reaction. When both nonspecific and immunologically mediated inflammatory lesions of the gingiva occur, the lesion is no longer a self-limiting and protective reaction becomes progressively tissue destructive. There are many destructive enzymes released by polymorphonuclear leukocytes (PMNs) and numerous tissue destructive lymphokines and lymphotoxins elaborated by B- or T lymphocytes. Thus, collagenase liberated by both PMNs and lymphocytes, other lysosomal enzyme secretions, lysosomal acid hydrolases (of macrophages), lymphotoxin-mediated cytotoxins, and osteoclast-activating factor (OAF) are all tissue destructive substances released as part of the inflammatory reaction to injury. The subject of host-parasite interactions in gingivitis and periodontitis was reviewed by MacPhee and Cowley in 1981.

Specific microorganisms sometimes cause an inflammatory reaction of the gingiva, although the clinical appearance may be entirely nonspecific. For example, a monilial or a tuberculous infection may affect the gingiva. The herpes simplex virus and the fusospirochetal organisms of necrotizing ulcerative gingivitis may also infect the gingiva. Furthermore, both streptococcal and staphylococcal gingivitis have been described as being due specifically to these organisms. Definite proof of a cause-and-effect relation here is difficult and questionable.

Calculus. Calculus, whether in a supragingival or a subgingival position, causes irritation of the contracting gingival tissue. This irritation is probably caused by the byproducts of the microorganisms, although the mechanical friction resulting from the hard, rough surface of the calculus may also play a role.

Food Impaction and General Oral Neglect. The impaction of food and the accumulation of debris on the teeth because of oral neglect result in gingivitis, through irritation of the gingiva by toxins of microorganisms growing in this medium. The degradation of food debris may also prove irritating to the gingival tissues.

Faulty or Irritating Restorations or Appliances. Faulty restorations may act as irritants to gingival tissues and thereby induce gingivitis. Overhanging margins of proximal restorations may directly irritate the gingiva and in addition allow the collection of food debris and organisms that further injure these tissues. Improperly contoured restorations may also produce gingival irritation by causing food packing or abnormal excursions of food against the gingiva during mastication. Prosthetic or orthodontic appliances impinging on the gingival tissues produce gingivitis as a result of the pressure and of the trapping of food and microorganisms.

Mouth Breathing. Drying of the oral mucous membrane due to mouth breathing, excessive environmental heat, or excessive smoking causes gingival irritation, with accompanying inflammation or sometimes hyperplasia.

Tooth Malposition. Teeth which have erupted or which have been moved out of physiologic occlusion, where they are repeatedly subjected to abnormal forces during mastication, are apparently very susceptible to the development of periodontal

disease. For example, a lower incisor may be 'bucked' out of alignment in the second or third decade of life and suddenly, in its new position, receive much of the occlusal stress of one or two upper anterior teeth. Calculus may be deposited on the lingual surface of such a tooth; the bacteria present attack the tissue around this tooth. As a result the gingival tissues may become inflamed and may recede. Teeth in labial positions have less osseous coverage over their radicular surface and hence are more susceptible to trauma from toothbrushing and other local irritations. Abnormally high frenal attachments also contribute to gingival recession.

Chemical or Drug Application. Many drugs are potentially capable of inducing gingivitis, particularly an acute case of gingivitis, owing to a direct local or systemic irritating action. For example, phenol, silver nitrate, volatile oils, or aspirin, if applied to the gingiva, will provoke an inflammatory reaction. Others, such as dilantin sodium, produce gingival changes when administered systemically. These have been discussed specifically in the Chapter 12 on Physical and Chemical Injuries of the Oral Cavity.

An unusual type of gingivostomatitis termed 'plasma cell gingivitis' (q.v.) first appeared in the United States about 1968. Although a number of etiologic factors such as hypersensitivity, allergy, endocrine disease, specific infection, etc. were proposed, it remained for Kerr and his associates in1971 to identify the most probable causative agent. They found that the disease represented an allergic reaction to some component of chewing gum. When the patients eliminated the use of chewing gum, the tissues returned to normal. The clinical features of the disease were so characteristic that it could be readily recognized as a specific entity, probably with a common etiology.

Nutritional Disturbances. Nutritional imbalance is frequently manifested in changes in the gingiva and deeper underlying periodontium. The effects of nutritional deficiencies on these structures as well as on the oral cavity as a whole have been considered in detail in Chapter 15 on Oral Aspects of Metabolic Disease. It is sufficient to point out that adequate intake, absorption and utilization of the various vitamins, minerals and other foodstuffs are essential to the maintenance of a normal periodontium.

Pregnancy. Many investigators have reported that the gingiva undergoes certain changes during pregnancy which have been termed 'pregnancy gingivitis' (Table 8-2). Among studies of relatively large numbers of pregnant patients, the following may be cited as representative.

The clinical appearance of the gingiva in the pregnant woman varies from an unchanged to a smooth, shiny, deeply reddened marginal gingiva with frequent focal enlargement, and intense hyperemia of the interdental papilla. Occasionally, a single tumor like mass will develop, the 'pregnancy tumor,' which is histologically identical with the pyogenic granuloma (q.v.). Pregnancy induces a hypersensitive response to a mild injury which otherwise would have been innocuous. This gingivitis, clinically nonspecific in appearance, may occur near the end of the first trimester and may regress or even completely disappear at the termination of the pregnancy.

Table 8-2: Incidence of pregnancy gingivitis

Looby (1946): 475 women	(In percentage)
Slight gingivitis	40
Hypertrophic gingivitis	10
Pregnancy tumor	2
Ziskin and Nesse (1946): 416 women	(In percentage)
Pregnancy gingivitis	37.9
Hypertrophic gingivitis	7.0
Raspberry-red gingiva	40.0
Combination	1.8
Maier and Orban (1949): 530 women	(In percentage)
No pathosis	44.6
Mild inflammation	35.9
Moderate inflammation	17.5
Severe inflammation	1.5
Pregnancy tumor	0.5

Diabetes Mellitus. This has been repeatedly reported in association with severe periodontal disease, especially in younger people. It has not been proved that diabetes is a specific cause of severe periodontal disease, since many patients with diabetes have normal periodontal structures. However, in uncontrolled diabetes, many metabolic processes are affected, including those which make up resistance to infection or trauma. For example, a diabetic may suffer from persistent chronic ulcers of the skin of the legs, presumably because resistance is lowered and any minor irritation such as trauma or bacterial infection of the skin will result in injury greater than that in a normal person. Also, the effectiveness of the healing process is decreased, possibly as a result of a disturbance in cellular carbohydrate metabolism. Therefore, considering the periodontium located in the oral cavity with its many factors predisposing to disease, including calculus, bacteria, and trauma, it is not surprising that this structure appears to breakdown more readily in persons with uncontrolled diabetes than in normal people. Controlled experimental animal studies have been performed repeatedly in which the animals were made deficient in insulin production and yet no consistent special periodontal pathosis resulted. Perhaps the local factors were insufficient to overcome the inborn vitality of the periodontium in such cases.

It has been reported by Russell that nearly 40% of a group of 37 diabetics exhibited gingival angiopathy in the form of PAS-positive, diastase-resistant thickening of vessel walls, hyalinization of vessel walls and sometimes luminal obliteration. Similar changes were also found in the periodontal ligament vessels of patients with diabetes mellitus.

Other Endocrine Dysfunctions. Gingivitis is reported to occur with some frequency in puberty as the so-called puberty gingivitis. The gingiva appears hyperemic and edematous. The fact that many adolescents are chronic mouth-breathers as a result of lymphoid hyperplasia of the tonsils and adenoids has suggested that the endocrine basis is relatively unimportant,

while the local irritant (drying of the mucosa because of the mouth breathing) being the actual cause of the condition. Gingivitis associated with menstruation has been reported by many. In addition, a nonspecific gingivitis with gingival bleeding, vicarious menstruation may occur sometimes. This phenomenon is rare.

Psychiatric disturbances appear to have a definite influence upon the severity of periodontal disease. Belting and Gupta reported that the severity of periodontal disease was significantly greater in psychiatric patients than in a controlled group of patients. Significant differences in severity were noted even when such variable factors as amounts of calculus, brushing frequency and bruxism were held constant in the two groups. The severity of periodontal disease increased significantly as the degree of anxiety increased. It was also noted that the severity of periodontal disease decreased significantly in both normal and psychiatric groups as the educational level of the patient increased.

Incidence. Numerous studies have been devoted to ascertaining the incidence or prevalence of gingival disease. It is generally accepted that periodontal disease is worldwide in distribution and that there is no age group (except in very young infants) in which it does not occur. Although all races are affected, there is some difference in incidence between different races and different countries.

Marshall-Day and his associates studied the incidence of periodontal disease in a group of 1,279 persons ranging in age from 13–65 years residing in the Boston, Massachusetts. Their investigations revealed that the incidence of gingivitis was extremely high even in the early age groups, ranging from 80% at age 13–15, to 95% at age 60. An interestingly significant reduction in incidence of gingival disease to 62% occurred in the late teens and early 20s. It was suggested that this reduction was associated with the end of puberty and/or social factors, where the adolescents placed a greater emphasis on oral hygiene and esthetics than they had previously. In 10 of the 13 different age groups, men were affected more frequently than women; the overall average being 88% for males and 80% for females.

Clinical Features. Acute gingivitis is painful uncommon lesion with sudden onset and shorter duration. Specific forms of acute gingivitis will be discussed separately, and the present considerations will be limited to the most common form of gingival disease, the chronic gingivitis.

In gingivitis the inflammation is limited only to the gingiva without underlying attachment loss. It may be localized or generalized. Beginning of periodontitis is marked by the spreading of inflammatory process from the gingiva to the underlying periodontal tissues. Although all forms of periodontitis are preceded with gingivitis, it is not necessarily progress to periodontitis all the time.

Gingivitis sometimes involves only the marginal gingiva, known as marginal gingivitis or interdental papilla, papillary gingivitis. When hyperemia and swelling of the marginal gingiva are confined to a localized area of the gingiva, the affected area sometimes assumes a crescent shape and has been termed a

Figure 8-11. Traumatic crescent.
The recession and inflamed gingival tissue of the mandibular left central incisor resulted from local irritation and trauma.

Figure 8-12. Traumatic gingival recession.
Gingival recession in a five-year-old girl caused by injury while sucking her finger. Stripping of the gingiva by a fingernail is a common manifestation of a habit that often has a psychogenic background *(Courtesy of Dr Thompson M Lewis: J Periodontol, 33: 353, 1962).*

'traumatic crescent' (Figs. 8-11, 8-12). Diffuse gingivitis affects marginal gingiva, attached gingiva and interdental papilla. The earliest manifestations of chronic gingivitis consist in slight alterations in the color of the free or marginal gingiva from a light to a deeper hue of pink, progressing to red or reddish blue as the hyperemia and inflammatory infiltrate become more intense. Bleeding from the gingival sulcus following even mild irritation such as tooth brushing or probing is also an early feature of gingivitis. Edema, which invariably accompanies the inflammatory response and is an integral part of this as it causes a slight swelling of the gingiva and loss of stippling (Fig. 8-13). Inflammatory swelling of the interdental papillae often produces a somewhat bulbous appearance of these structures. This increase in the size of the gingiva favors the collection of more debris with increased bacterial accumulations, which in turn induce more gingival irritation, thus bringing about a continuing cycle. When there is marked enlargement due to edema and fibrosis as a result of chronic inflammation, the process is called chronic hyperplastic gingivitis.

Suppuration of the gingiva, manifested by the ability to express pus from the gingival sulcus by pressure, may occur in advanced chronic gingivitis.

Radiographic Features. Chronic gingivitis, in which the inflammation is limited strictly to the gingiva, does not manifest

Figure 8-13. Gingivitis.
The inflammation of the gingiva results in swelling with reduction and eventual loss of normal stippling.

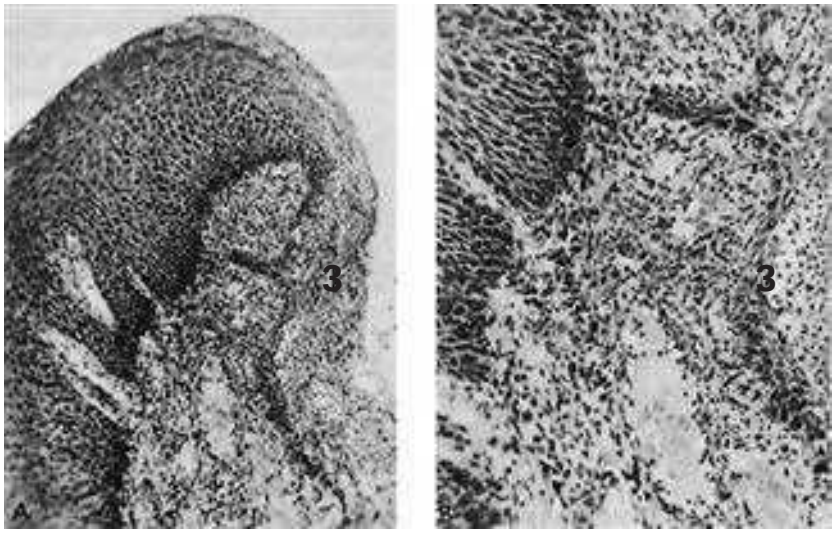
changes in the underlying bone. When bony changes become evident, the condition is termed 'periodontitis'.

Histologic Features. The gingiva in chronic gingivitis reveals infiltration of the connective tissue by varying numbers of lymphocytes, monocytes, and plasma cells. Polymorphonuclear leukocytes are occasionally noted, particularly beneath the crevicular epithelium. The crevicular epithelium is usually nonkeratinized and irregular. It is infiltrated by inflammatory cells and is frequently ulcerated (Fig. 8-14). The capillaries of the connective tissue are usually engorged and sometimes increase in number. Hyperemia, edema, and hemorrhage may be present. The underlying periodontal ligament, except perhaps for those fibers of the free gingival group, is not involved, nor is the crest of the alveolar bone disturbed. The junction of the epithelial attachment to the tooth represents a weak point in the epithelial barrier to the oral environment, and at this point a collection of polymorphonuclear leukocytes and lymphocytes are always found (Fig. 8-15).

Dewar, and Turesky and his associates studied the glycogen content of the granular and spinous layers of the epithelium and found that it increases as the intensity of the underlying inflammation increases. Mast cells containing granules of sulfonated mucopolysaccharide are increased in the inflamed gingiva, but the significance of this finding is not clear. The alkaline phosphatase activity increases somewhat in the inflamed gingiva, since it is present in the inflammatory and endothelial cells, and these are obviously present in larger numbers in chronic gingivitis. No remarkable differences were found in nucleic acid distribution between normal and inflamed gingiva, although the concentration of ribonucleic acid (RNA) was always lower in all cells of the crevicular epithelium and in the marginal epithelium where leukocytic infiltration had occurred.

Histochemical studies of acid phosphatase in normal and inflamed human gingiva have shown that this enzyme is located almost exclusively in the epithelium. There is a greater reaction in the superficial layers (with the exception of the stratum corneum, which is acid phosphatase-free) and a gradual diminution toward the basal cell layer. The reaction is absent or very weak in the epithelial lining of the gingival sulci and periodontal pockets and in the epithelial attachment.

Treatment and Prognosis. Most cases of chronic gingivitis are due to local irritation. If the irritants are removed at this stage, the inflammation with its attendant swelling due to hyperemia, edema, and leukocytic infiltration will disappear within a matter of hours or a few days, leaving



A B

Figure 8-14. Gingivitis.
The gingiva is infiltrated by large number of lymphocytes, plasma cells and polymorphonuclear leukocytes. The crevicular epithelium (1) is invaded by these inflammatory cells and is degenerating (**(A)** Low-power, and **(B)**, high-power photomicrographs).

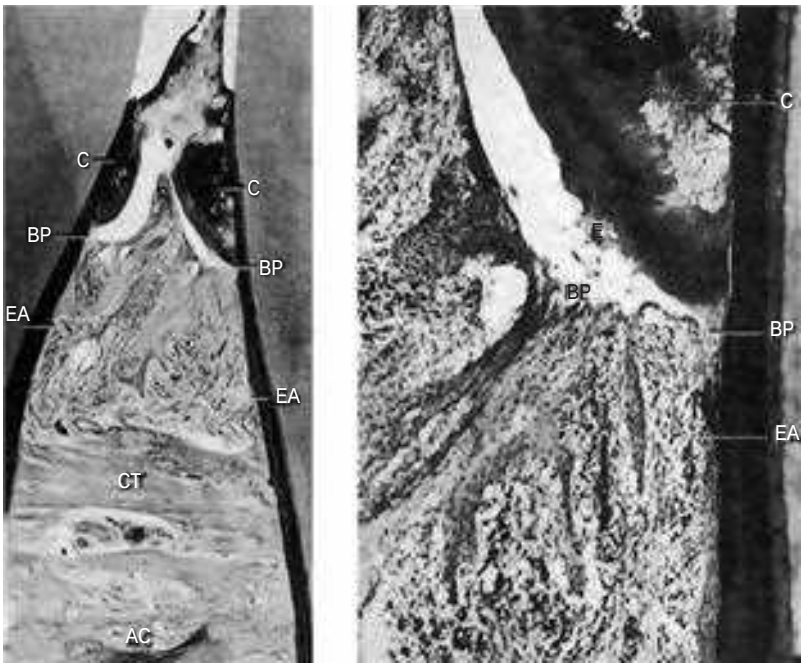


Figure 8-15. Gingivitis.
(A) A photomicrograph of the tissue from interproximal space between two bicuspids. AC marks alveolar crest; CT, transseptal fibers; P, interdental papilla; BP, bottom of pockets; C, calculus: EA, epithelial attachment. Photomicrograph on the right **(B)** shows higher magnification of the bottom of the pocket BP with the calculus C *in situ*. In this case the calculus fills almost the entire pocket. PE, The pocket epithelium, which is broken in some areas; E, the epithelium which is clinging to the calculus; EA, the epithelial attachment alongside the tooth. no permanent damage. The fact that recovery usually follows the removal of irritants emphasizes the need for careful early treatment followed by proper brushing of teeth and frequent prophylaxis. Mechanical removal of plaque can be aided by chemical plaque control measures such as using mouthwashes containing chlorhexidine, listerine or triclosan. If there is poor response to good local therapy, a search should be made for systemic factors, which might be complicating the case.

As in all infections, the immune response plays an important role in delineating the signs and symptoms of the process. Obviously, factors governing leukocyte migration and chemotactic activity influence the host response. If the bacterial plaque does not evoke a positive chemotactic response in the polymorphonuclear leukocytic cells, there will be few, if any, signs of inflammation. On the other hand, if the patient's leukocytes are unable to respond to the 'call of the plaque', either because of a genetic defect or for some other reason, infection and tissue destruction may occur without the inflammatory reaction.

Nonplaque induced gingival diseases may have different etiology and have characteristic clinical presentation. These groups of gingival diseases include specific bacterial, viral, and fungal infections, gingival manifestations of certain dermatoses.

Necrotizing Gingivostomatitis

Necrotizing ulcerative gingivitis, necrotizing ulcerative periodontitis, and necrotizing stomatitis are together termed necrotizing gingivostomatitis and they share many clinical and etiological characteristics. The spectrum of necrotizing gingivostomatitis ranges from necrotizing gingivitis to cancrum oris. Predisposing factors may include emotional stress, immunosuppression, HIV infection, smoking, malnutrition, and pre-existing gingivitis. The diagnosis of necrotizing gingivostomatitis becomes more important in recent years since it serves as a marker for immune deterioration in HIV-seropositive patients. Necrotizing periodontitis shares many of the clinical and etiologic characteristics of necrotizing ulcerative gingivitis in patients with no known systemic disease or immune dysfunction, except that patients with necrotizing periodontitis demonstrate attachment loss.

Necrotizing Ulcerative Gingivitis

(Vincent's infection, trench mouth, acute ulceromembranous gingivitis, phagedenic gingivitis, fusospirochetal gingivitis, acute ulcerative gingivitis)

Necrotizing ulcerative gingivitis is a specific type of gingivitis with characteristic signs and symptoms. The disease manifests both acute and recurrent (subacute) phases; a chronic stage also has been described, but most investigators believe that treating

Figure 8-16. Necrotizing ulcerative gingivitis.
A typically heavy, necrotic membrane covers the gingival tissues of the anterior teeth in this severe case *(Courtesy of Dr Merrill Wheatcroft)*.

chronic necrotizing gingivitis as a separate entity cannot be justified, since it is neither clinically nor histologically specific. This inflammatory condition involves primarily the free gingival margin, the crest of the gingiva, and the interdental papillae (Fig. 8-16). On rare occasions the lesions spread to the soft palate and tonsillar areas, and in such instances the term **Vincent's angina** has been applied. Pain, interdental ulceration, and gingival bleeding are considered to be the diagnostic triad.

Necrotizing ulcerative gingivitis can cause destruction of the supporting tissues of the tooth and is termed as necrotizing ulcerative periodontitis, when bone loss occurs.

Epidemiology. Necrotizing ulcerative gingivitis frequently occurs in an epidemic pattern, sweeping through groups of persons in close contact, especially those living under similar conditions. This was especially apparent during World War I, when the Allied troops suffered severely from the disease. It was here that the term 'trench mouth' originated, since the disease was especially prevalent among the troops in the trenches. Similar sporadic outbreaks also occurred during World War II. Though this condition is relatively uncommon in developed countries nowadays, there has been a global increase associated with HIV infection.

The pattern of the spread of this disease, in many instances, indicated that it was a contagious infection, but this theory is not accepted now. Its occurrence in groups of persons can be explained on the basis of similar predisposing conditions among the members of the group, which may cause gingivitis to develop in each, even though there is no actual contact between them. Necrotizing ulcerative gingivitis may occur at any age, but is reportedly more common among young and middle-aged adults. In developing countries, it is seen almost exclusively in children, related to poverty and malnutrition. Pindborg et al, have reported 232 cases out of 10,000 patients examined in south India, of which 68% were children under 10 years. Malberger diagnosed 50 cases, all in children between one and six years of age among 7,650 patients who attended in an oral surgery clinic in West Africa.

Etiology. It is an endogenous, polymicrobial infection causing destructive inflammation due to the coexistence of several predisposing factors. Most investigators believe that necrotizing ulcerative gingivitis is caused by a *fusiform bacillus* and *Borrelia vincentii*—a spirochete. These organisms may be present in small numbers in the healthy gingival flora. Both microorganisms dominate in this 'fusospirochetal' disease, although other spirochetes, fusiforms, and filamentous organisms are also found. It is likely that a number of factors disturb the host-parasite relationship, facilitating overgrowth of the organisms of the fusospirochaetal complex. Chung et al, found that significant increase in IgG and IgM antibody titers to spirochetes and increased IgG titers to *Bacteroides melaninogenicus* in acute necrotizing ulcerative gingivitis through indirect immunofluorescence and Elisa. Some workers also include vibrio and coccal forms as important agents in the etiology of this disease. The fact that these two microorganisms, the fusiform bacillus and *Borrelia vincentii*, are found in moderate numbers in other oral diseases, including acute herpetic gingivostomatitis, as well as in many apparently healthy mouths, suggests that predisposing factors are essential to the development of the necrotizing ulcerative gingivitis. This is apparent in view of the fact that the disease has never been produced experimentally, in either human beings or animals, simply by oral inoculation of material from lesions in patients with the disease. Fusospirochetal abscesses can be produced in the animals by the subcutaneous injection of gingival exudate, or as reported by Hampp and Mergenhagen, by subcutaneous injection of pure cultures of either *Borrelia vincentii* or *Borrelia buccale*. Rosebury suggested that the subcutaneous tissues are readily susceptible to infection by these microorganisms but that the gingival tissues are relatively resistant because previous contact of the oral tissues with the bacteria had resulted in a local immunity. Some experimental studies showed that *B. intermedius* was responsible for the signs and symptoms of the disease. MacDonald et al, concluded that *Bacteroides melaninogenicus*, a motile gram negative anaerobic bacillus, was the true causative agent of necrotizing ulcerative gingivitis.

Predisposing Factors. Psychological stress plays an important role in the development of necrotizing ulcerative gingivitis, since there is an increased frequency of the disease in people in the military services. Other predisposing factors include immunosuppression, smoking, upper respiratory tract infection, local trauma, poor nutritional status, and poor oral hygiene.

HIV-positive persons suffer from a severe form of necrotizing ulcerative gingivitis as the immune function deteriorates and this progresses to HIV associated periodontitis.

Decreased resistance to infection is one of the most important predisposing factors in the development of necrotizing ulcerative gingivitis. This was apparent during World War I, when the Allied troops living under poor sanitary conditions in the trenches and subsisting on inadequate diets, acquired gingivitis in almost epidemic proportions, suggesting

a contagious disease. According to Schluger, similar outbreaks occurred during and after World War II among soldiers in the field, when poor food, poor oral hygiene and fatigue prevailed.

Stones has reported that the incidence of necrotizing ulcerative gingivitis in Liverpool Dental Hospital (England) shows a significant seasonal variation, the highest incidence occurring between October and February, when respiratory infections and exanthemas are at their peak, and the lowest incidence occurring in July and August. Experimentally, Swenson and Muhler produced fusospirochetal infection in dogs after the administration of Scillaren-B—a mixture of glucosides which lowers tissue-resistance by inducing leukopenia.

Numerous investigators have reported that fusospirochetal infection may be produced more readily in animals deficient in various vitamins. Necrotizing lesions of the oral cavity have been produced in animals deficient in vitamin C and B complex, but it still remains to be proved that the lesions are due to fusospirochetal organisms. In some instances a relation between vitamin deficiency and necrotizing ulcerative gingivitis in humans has been suggested, but the data is conflicting, especially in view of the general inability to alter the course of the disease by administration of vitamins.

Clinical Features. The disease is characterized by the development of painful, hyperemic gingiva and sharply punched-out crater like erosions of the interdental papillae of sudden onset (Fig. 8-16). The ulcerated remnants of the papillae and the free gingiva bleed when touched and generally become covered by a grayish green, necrotic pseudomembrane (Fig. 8-17). The ulceration tends to spread and may eventually involve all gingival margins. It begins rather commonly at a single isolated focus, with a rapid onset. A fetid odor ultimately develops that is extremely unpleasant.

The patient almost always complains of an inability to eat because of the severe gingival pain and the tendency for gingival bleeding. The pain is that of a superficial 'pressure.' The patient usually suffers from headache, malaise, and a low-grade fever. Excessive salivation with the presence of a metallic taste to the saliva is often noted, and regional lymphadenopathy is usually present.

Figure 8-17. Advanced necrotizing ulcerative gingivitis.
Note the presence of a gray necrotic membrane and destruction of the interproximal tissues, particularly in the mandibular anterior region.

In advanced and more serious cases, there may be generalized or systemic manifestations, which may include leukocytosis, gastrointestinal disturbances, and tachycardia. After the necrotizing ulcerative gingivitis is cured, the crests of the interdental papillae, which have been destroyed leaving a hollowed-out area, constitute an area which retains debris and microorganisms and can serve as an 'incubation zone.' Such areas, along with gingival flaps of erupting third molars, are ideal locations for organisms to persist, and in many cases, the recurrence of necrotizing ulcerative gingivitis will begin here.

Bacteriologic Examination. Smears of material from the gingiva in cases of necrotizing ulcerative gingivitis show vast numbers of fusiform bacilli (genus *Fusobacterium* or *Fusiformis*) and an oral spirochete (*Borrelia vincentii*), various other spirochetes, filamentous organisms, vibrios, cocci, desquamated epithelial cells and varying numbers of polymorphonuclear leukocytes (Figs. 8-18, 8-19). The relative numbers of microorganisms present vary with the stage of the disease, secondary invaders being more prominent in the later phases as well as in the subacute form of necrotizing ulcerative gingivitis.

The fusiform bacillus associated with necrotizing ulcerative gingivitis is an elongated rod with tapered ends measuring 5–14 microns in length and 0.5–1.0 microns in diameter. This nonmotile organism is weakly gram-positive, occurs singly or in clusters and can be cultured under anaerobic conditions.

Borrelia vincentii is a gram-negative spirochete with three to six long, loose spirals. It measures approximately 10–15 microns in length, is actively motile and can be cultured anaerobically, although with some difficulty.

The diagnosis of necrotizing ulcerative gingivitis based upon a smear of gingival material is hazardous because of the

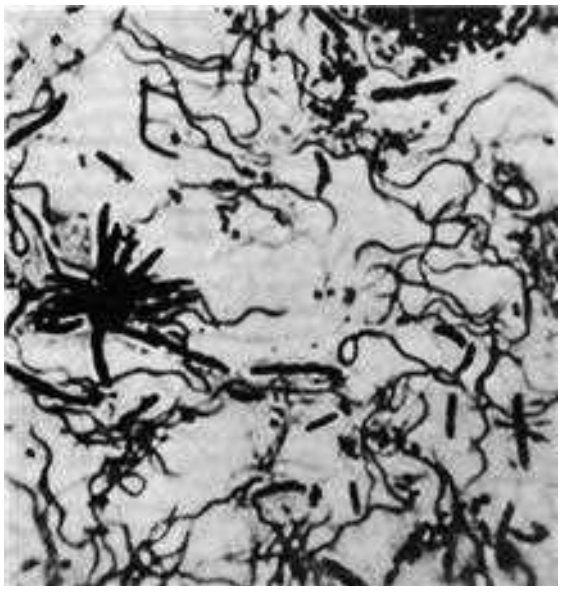

Figure 8-18. Necrotizing ulcerative gingivitis.
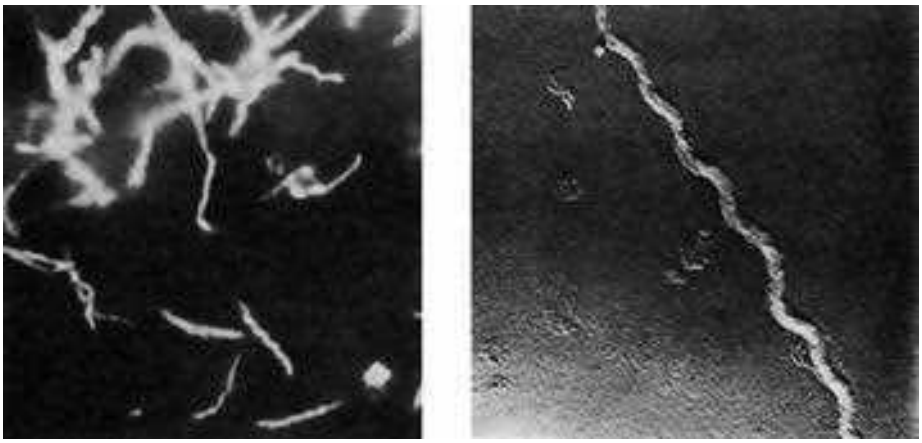
Photomicrograph of a smear from gingival exudate. Note the many spirochetes, fusiform bacteria, and other microorganisms.



A B

Figure 8-19. Oral spirochetes.

nonspecific findings. Although the presence of the disease can often be confirmed when vast numbers of the spirochete and fusiform bacteria are found in the smear, fewer numbers are often seen in smears from 'normal mouths,' cases of acute herpetic gingivostomatitis, simple pericoronitis, marginal gingivitis and chronic gingivitis. Although the bacterial smear may be of value as an aid in diagnosis of atypical cases of necrotizing ulcerative gingivitis, the final diagnosis is a clinical one.

Histologic Features. Microscopic examination of the gingiva in this disease reveals an acute gingivitis with extensive necrosis. The surface epithelium is ulcerated and replaced by a thick fibrinous exudate, or pseudomembrane, containing many polymorphonuclear leukocytes and microorganisms. Even in nonulcerated areas, a common feature noted by most investigators is the general lack of keratinization of the gingival tissues. The connective tissue is infiltrated by dense numbers of polymorphonuclear leukocytes and shows an intense hyperemia. The microscopic picture is an entirely nonspecific one.

There is not a complete consensus among investigators as to the penetration of the gingival tissues by the microorganisms associated with this disease. Vast numbers of both spirochetes and fusiform bacilli are found on the surface of the living tissue in and beneath the necrotic pseudomembrane. Both forms have also been reported as invading viable tissues to variable depths below the surface. It has been suggested that the presence of microorganisms in the tissues is due to surgical artifact. Schaffer, failed to find bacteria penetrating vital tissues under light microscopy. Listgarten, on the other hand, utilizing electron microscopic techniques, was able to identify spirochetes between viable epithelial cells (Fig. 8-20).

Treatment and Prognosis. The treatment of necrotizing ulcerative gingivitis is extremely varied, depending upon

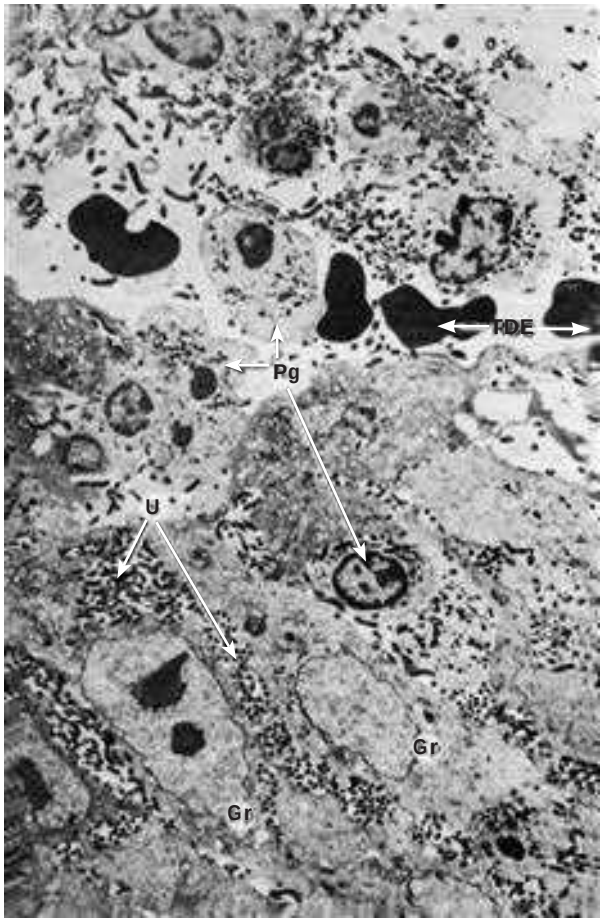

Figure 8-20. Necrotizing ulcerative gingivitis.
Electron microscope photomicrograph illustrates the epithelium adjacent to ulcerated lesion. Neutrophils (Ne), red blood cells (RBC), microorganisms and cellular debris cover the epithelium. Dense masses of large and medium spirochetes (S) and some neutrophils (Ne) distend the space between the epithelial cells (Ep). Note also the cupped-out gingival papillae between the maxillary anterior teeth that might become an incubation zone. Treatment must be continued until such areas are recontoured.

the individual dentist's experience with the disease. Some prefer to treat this condition conservatively, instituting only superficial cleansing of the oral cavity in the early acute stage of the disease with chlorhexidine, diluted hydrogen peroxide or warm saltwater. This is followed by thorough scaling and polishing. Topical anesthetics may be required to reduce the pain during this procedure. In many such cases, prompt regression of the disease results even without medication. Other dentists prefer the use of antibiotics coupled with local treatment.

The usual case of necrotizing ulcerative gingivitis begins to subside in 48 hours with adequate treatment. Sometimes there may be considerable destruction of tissue, involving the interdental papillae and marginal gingiva, and leading to punched-out appearance of the interproximal gingiva and the apparent gingival recession even after the regression of the disease (Fig. 8-21). Recontouring of gingival papillae is usually required; this can be accomplished by proper use of round toothpicks or by gingivoplasty. Treatment cannot be considered complete until the gingival tissue contours almost normal.

Necrotizing ulcerative gingivitis recurs with considerable frequency in patients who have already been treated. Occasional serious sequelae such as gangrenous stomatitis or noma, septicemia and toxemia, and even death have also been reported following this disease.

Desquamative Gingivitis

Desquamative gingivitis is not a disease entity but a clinical term used for many years to describe a unique condition of the gingiva characterized by intense redness and desquamation of the surface epithelium (Fig. 8-22). At one time, this was thought to be a specific degenerative disease of the gingival tissues, although of unknown etiology, and was sometimes also called 'gingivosis'. However, the term 'gingivosis' was first used by Schour and Massler in 1947 to describe a probably

A

B

Figure 8-22. Chronic desquamative gingivitis.

unrelated disease of the gingiva which they found in a group of malnourished Italian children.

McCarthy and his colleagues studied 40 cases of desquamative gingivitis and concluded in 1960 that it was not a specific disease entity but rather a clinical manifestation of several diseases and thus had several etiologies. The term 'desquamative gingivitis' is now used by most workers as a descriptive term for the oral manifestations of any one of a variety of diseases which, once identified, may permit a rational therapeutic approach of value for patient management.

Etiology. McCarthy and his colleagues proposed a classification of desquamative gingivitis based on etiology. They suggested the causative factors to be:

- Certain dermatoses
- Hormonal influences
- Abnormal responses to irritation
- Chronic infections
- Idiopathic.

Subsequent studies such as those of Nisengard and Neiders and of Rogers and his associates have shown that the dermatoses are numerically the most important of the causative factors.

For example, in the study of Nisengard and Neiders, 67 of the 100 patients exhibited immunofluorescent findings suggestive of or diagnostic of a dermatosis.

The most important dermatoses presenting oral findings categorized as a desquamative gingivitis are:

- Cicatricial pemphigoid (benign mucous membrane pemphigoid)
- Pemphigus
- Lichen planus.

Other diseases such as pemphigus vulgaris, epidermolysis bullosa, systemic lupus erythematosus, and linear IgA disease may also have gingival involvement, presenting as desquamative gingivitis. These individual diseases along with their identification by immunofluorescence will be considered with other diseases of the skin in Chapter 19.

Gingival Abscess

Gingival abscess is an acute, localized, and painful lesion of sudden onset. It is caused by sudden forceful penetration of any foreign objects such as a bristle of a toothbrush or an apple core, which carry bacteria deep into the gingival tissue.

Clinical Features. It is usually limited to the marginal gingiva. Initially it appears as reddish swelling with a smooth and shiny surface. Within hours, it becomes fluctuant and exhibits pointing and through which pus discharges.

Histologic Features. Connective tissue shows vascular engorgement, edema and formation of abscess cavity surrounded by a diffused collection of polymorphonuclear leukocytes. The overlying epithelium exhibits secondary changes in the form of intra- and inter-cellular edema, microabscess formation, and sometimes ulceration.

Treatment. Spontaneous rupture is common. The invading foreign material, if any, will be usually expelled along with the pus.

Pericoronitis

Periocoronitis is an inflammatory lesion occurring around the impacted or partially erupted tooth. Incomplete eruption of the tooth provides a large stagnation area for food debris under the gingival flap. This becomes infected easily and results in inflammation of the pericoronal flap. It exhibits chronic inflammation for a long period. If the debris and bacteria are deeply entrapped, an abscess may form which is called a pericoronal abscess. It is a mixed infection and various bacteria of the dental plaque (particularly anaerobes) play a significant role in the development of pericoronitis.

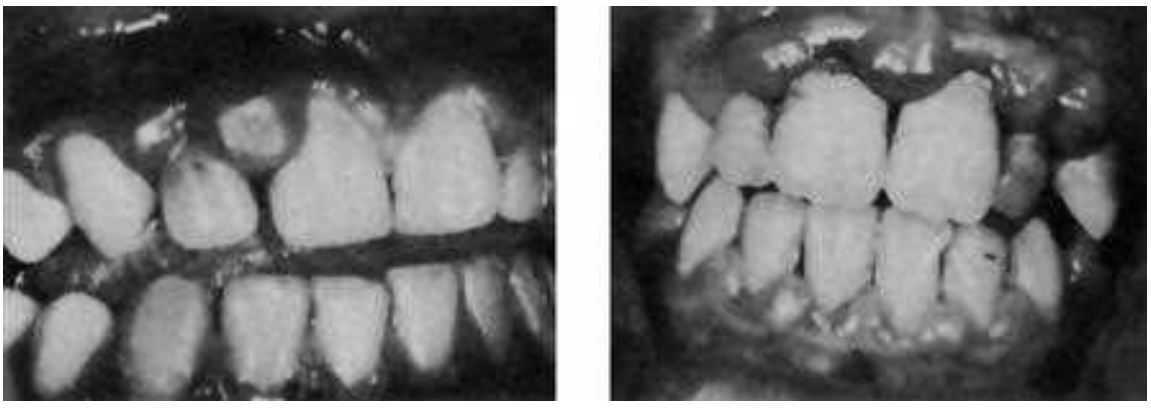
Clinical Features. Mandibular third molar is the commonly involved tooth. Pain and swelling of the pericoronal tissue around the affected tooth, difficulty in chewing, and difficulty in opening the mouth are the usual complaints. Patient may be mildly ill with fever, malaise, and regional lymphadenopathy.

Histologic Features. The epithelium of the pericoronal flap shows hyperplasia, intercellular edema, and leukocytic infiltration. The underlying connective tissue exhibits increased vascularity, dense diffused infiltration with lymphocytes, and plasma cells along with varying number of polymorphonuclear leukocytes.

Management. Entrapped food debris must be removed. When the upper tooth is involved, it should be grounded or extracted if it is malposed. Radiograph helps in assessing the position of the involved tooth. If impacted, the tooth must be removed. And if it is in a favorable position, surgical removal of the pericoronal flap is advocated after acute symptoms subside. The administration of antibiotics helps to relieve the symptoms and prevents the spread of infection to the adjacent tissue spaces.

Gingival Enlargement

The gingival tissues in the healthy adult completely, though barely, fill the interproximal spaces between teeth, beginning near the contact area and extending apically and laterally in a smooth curve. However, there is frequently an increase in the size of the gingiva so that soft tissue overfills the interproximal spaces, balloons out over the teeth and protrudes into the oral cavity. The enlargement of the gingiva may be localized to one papilla or may involve several or all of the gingival papillae throughout the mouth (Fig. 8-23). The enlargement



A B

Figure 8-23. Gingival enlargement.
Focal enlargement involving only two papilla **(A)**, and diffuse enlargement of papillae **(B)**.

is usually more prominent on the labial and buccal surfaces, although it does occasionally develop in the lingual gingiva. It does not involve the vestibular mucosa.

The term 'gingival hyperplasia' was used for a long time for a gross increase in size of gingival tissues, which may result from a number of different conditions. Gingival enlargements are not to be confused with overgrowths of bone, or exostoses, noted occasionally on the alveolar bone, usually at some distance from the gingiva.

Gingival enlargements can be classified based on etiologic factors and pathologic changes as follows:

1. Inflammatory gingival enlargement
2. Drug induced gingival enlargement
3. Enlargement associated with systemic factors
   a. Conditioned enlargement
   b. Enlargements due to systemic diseases
4. Idiopathic gingival enlargement
5. Neoplastic enlargement
6. False enlargement.

Inflammatory enlargement of the gingiva usually results from prolonged chronic inflammation of the gingival tissue. In most cases, the enlargement results because of local irritations such as poor oral hygiene, accumulation of dental calculus or mouth breathing, and represents a variation in host tissue response to dental plaque accumulation.

In inflammatory enlargement, the gingivae are soft, edematous, hyperemic or erythematosus and sensitive to touch. They can bleed easily, and present a glossy, nonstippled surface. Usually gingival enlargements are secondary to other types of enlargements. In such cases, dual etiologic factors should be kept in mind during management (Fig. 8-24). Clinical examination often reveals the nature of the local irritation that causes the enlargement, but the histologic picture is usually nonspecific, showing merely inflammation of the gingiva. The local irritation results in hyperemia, edema and lymphocytic infiltration. Many times the irritation results also in a proliferation of the fibrous connective tissue of the gingiva. The proliferation may be increased by some predisposing systemic factors.

Figure 8-24. Inflammatory gingival enlargement due to local collection of plaque.
(Courtesy of Dr Ajayprakash, Department of Oral Pathology, Kamineni Institute of Dental Sciences, Andhra Pradesh).

Drug-induced Gingival Enlargement. It is now well established that gingival enlargement sometimes occurs as a result of the use of the anticonvulsants, immune suppressants, and calcium channel blockers.

Diphenylhydantoin (dilantin sodium) was the first reported anticonvulsant to produce gingival enlargement. Other hydantoins known to induce gingival enlargement are ethotoin and mephenytoin. Other anticonvulsants such as valproic acid, methsuximide, and succinimides also produce gingival enlargement.

Dilantin sodium induces gingival enlargements in 3–84.5% of the patients receiving the drug. Phenytoin stimulates proliferation of fibroblast-like cell in tissue culture and also decreases the collagen degradation. It occurs most commonly in younger individuals, especially shortly after the institution of dilantin sodium therapy.

Cyclosporine, a potent immunosuppressive agent, has also been reported to produce gingival enlargement in 30% of the patients receiving the drug.

Calcium channel blockers such as nifedipine, nitrendipine, and verapamil also induce gingival enlagement. Nifedipine, the commonly used drug in cardiovascular conditions, induces gingival enlargement in 20% of the cases.

Drug-induced gingival enlargement begins painlessly, involving one or two interdental papillae, which present an increased stippling and ultimately a roughened or pebbled surface with lobulations. The gingival tissues are dense, resilient, and insensitive; they show little or no tendency to bleed (Fig. 8-25).

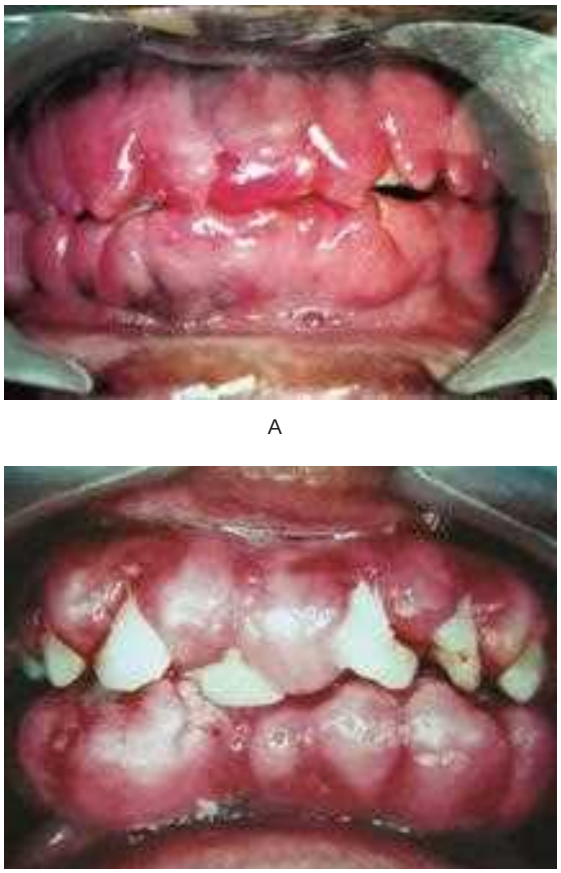
The bulk of the enlargement is due primarily to proliferation of the fibrous connective tissue with numerous fibroblasts. There is a possibility of superimposed chronic inflammation. The enlargement generally presents no difficulties, although it is esthetically objectionable. It may be so severe as to interfere with everyday functions, and for this reason it may be surgically excised. Unfortunately, its recurrence is common. It has been found that careful oral hygiene will result in slower development of the enlargement, and slower recurrence after surgical excision. Some regression of the enlargement may result if the use of the drug is discontinued. Cyclosporine-induced enlargements are more vascularized and have more amounts of plasma cells and extracellular substance.

There is no strict line of demarcation between hyperplasia of connective tissue and benign neoplasia of fibroblasts; indeed, there are several conditions which resemble fibromas but which should not be so designated. Keloid is one such condition, and fibrous enlargement of the gingiva is another.

ENLARGEMENT ASSOCIATED WITH SYSTEMIC FACTORS

CONDITIONED ENLARGEMENT

Conditioned enlargements are caused by the systemic condition of the patient, which exaggerates the usual gingival response to dental plaque. However, bacterial plaque is essential for the



A

B

Figure 8-25. Drug-induced gingival enlargement.
(A) Enlargement of the gingiva in an epileptic patient receiving dilantin sodium. **(B)** Gingival enlargement in a patient receiving nifedipine *(A and B, Courtesy of Dr ND Jayakumar, Saveetha Dental College, Chennai)*.

initiation of this type of enlargement. There are three types of conditioned enlargements: hormonal, nutritional, and allergic.

Hormonal Enlargement

Inflammatory gingival enlargement often occurs at puberty, both in men and women. Some investigators think that this enlargement may result from an endocrine imbalance at this particular stage of the patient's development. Others believe that it may occur, at this age, because oral care is poor, there is local irritation associated with eruption of teeth, and/or nutrition may be inadequate. Thus, the enlargement may be only indirectly associated with an endocrine disturbance.

One also notices a tendency for gingival enlargement of the inflammatory type during pregnancy. This proliferation may be due to disturbed nutrition, poor oral hygiene, or some systemic predisposition toward proliferation. Increased levels of estrogen and progesterone in pregnancy cause change in the vascular permeability, which leads to gingival edema and altered inflammatory response to dental plaque.

The so-called pregnancy gingivitis, more properly spoken of as 'gingivitis in pregnancy', is often associated with isolated gingival proliferation, sometimes so severe that it is referred to as a 'pregnancy tumor,' which is basically a pyogenic granuloma (q.v.). These proliferations resemble those seen in some nonpregnant women who have severe local irritations. Microscopic studies of these gingival lesions reveal increased vascularity, multiplication of fibroblasts, edema, and infiltration of leukocytes into the gingiva.

Nutritional Enlargement

Vitamin C Deficiency. The spongy, bleeding gums of scurvy, vitamin C deficiency (q.v.), have long been recognized as a specific entity. The enlargement of gingiva is generally included in the classic description of scurvy. This enlargement is essentially a conditioned response to bacterial plaque. The combined effect of vitamin C deficiency and inflammation produces this enlargement. Although clinical scurvy is now rare, there are a few occasional cases. Subclinical cases are probably common, since it has been reported that many patients do not include adequate vitamin C in their diets. In such cases, the gingivae become tender, swollen, and edematous. They bleed upon the slightest provocation. Gingival sulci are often filled with partially clotted blood, and the crests of the interdental papillae are red or purple. There is sometimes ulceration and necrosis of the papillae as infection becomes superimposed upon the susceptible tissues. Hemorrhages following slight trauma to other parts of the body are also noted.

Treatment includes improvement of oral hygiene and administration of vitamin C.

Allergic Enlargement

Plasma Cell Gingivitis (Atypical gingivitis, plasma cell gingivostomatitis). This distinct form of gingivitis first reported in the United States, usually arises as a hypersensitive reaction to a component of chewing gum, dentifrices, or some of the dietary components. It commonly presents as a mild marginal gingival enlargement, sometimes extending to involve the attached gingiva.

Clinical Features. This disease is more prevalent in young women. The initial symptom is soreness of the mouth, which is intensified by hot or spicy food. It starts as mild marginal gingival enlargement and extends to attached gingiva, and in severe cases, extends to buccal and vestibular mucosa. Gingiva appears swollen, erythematous, and friable with loss of stippling. The involvement of other oral tissues like the tongue and lips is common. They appear atrophic, dry, and exhibit cracks or fissures.

Histologic Features. The surface epithelium is hyperplastic, shows intracellular edema, and micro abscesses. The underlying connective tissue is densely infiltrated with chronic inflammatory cells, predominantly a polyclonal mixture of plasma cells. There is marked vascular dilatation with severe thinning of epithelium over the connective tissue pegs.

Treatment and Prognosis. Possible allergens should be identified by careful study of the patient's history and eliminated. Topical and systemic steroids give good results.

ENLARGEMENT DUE TO SYSTEMIC DISEASES

Leukemia

Gingival enlargement is often an early finding in acute monocytic, lymphocytic or myelocytic leukemia (q.v.). Leukemic enlargement may be diffused or marginal, localized or generalized. Gingiva appears shiny, bluish red, soft, edematous, easily compressible, tender, and frequently ulcerated. They show no signs of stippling (Fig. 8- 26). The gingivae are usually inflamed, owing to local infection, and occasionally a necrotizing ulcerative gingivitis develops.

Histologic study of this type of gingival enlargement shows that the gingival tissues are packed with immature leukocytes, the specific type depending on the nature of the leukemia. These abnormal white blood cells are unable to perform their defensive function and cannot control the infection at the gingival margin. Capillaries are engorged, and the connective tissue is edematous.

Granulomatous Diseases

Some local and systemic granulomatous diseases may involve the gingiva and present as gingival enlargement. Common diseases in which gingiva is involved are Crohn's disease, sarcoidosis (q.v.), Wegner's granulomatosis (q.v.), and foreign body gingivitis. The latter is caused by the introduction of foreign materials into the sulcular epithelium.

Regional Enteritis
(Crohn's Disease)

Regional enteritis is a slowly progressive disease of unknown etiology. Some of the features suggest an unusual reaction to an extrinsic agent, possibly of infective origin. Atypical mycobacteria have been implicated in some cases. It occurs in persons of all ages, involves both genders equally and is characterized by granulomatous, superficial ulcerations of the intestinal tract with frequent fistulas developing onto body surfaces or viscera, or between intestinal loops. This disease has been reported as having oral manifestations or oral extensions, and 24 such cases have been reviewed by Bernstein and McDonald. The most commonly involved areas are the buccal mucosa, where the lesions present a cobblestone appearance; the vestibule, where linear and hyperplastic folds, which may mimic denture-induced hyperplasia; the lips, which appear diffusely swollen and indurated; the gingiva and alveolar mucosa, which exhibit a granular erythematous swelling; and the palate, where multiple ulcers occur. Glossitis may be seen secondary to malabsorption of vitamin B_{12}. The oral lesions may either precede or follow the appearance of the intestinal lesions, and like those lesions, commonly show periods of quiescence alternating with exacerbations of the process. The microscopic findings of the oral lesions are those of a chronic granulomatous disease, reminiscent of sarcoid.

Figure 8-26. Gingival enlargement due to acute monocytic leukemia.

Microscopically, it consists of fibrosis and a focal dense collection of lymphocytes and plasma cells. Lymph vessels appear dilated. The presence of noncaseating granulomas which are typically small, consisting of macrophages, epithelioid cells, and occasional giant cells are seen. Typical cases have also been reported by Bottomley and his associates and by Eisenbud and his colleagues.

Management. Oral lesions resolve when intestinal Crohn's disease is controlled. The use of oral sulfasalazine or intralesional injection of corticosteroid gives good results.

Idiopathic Gingival Enlargement

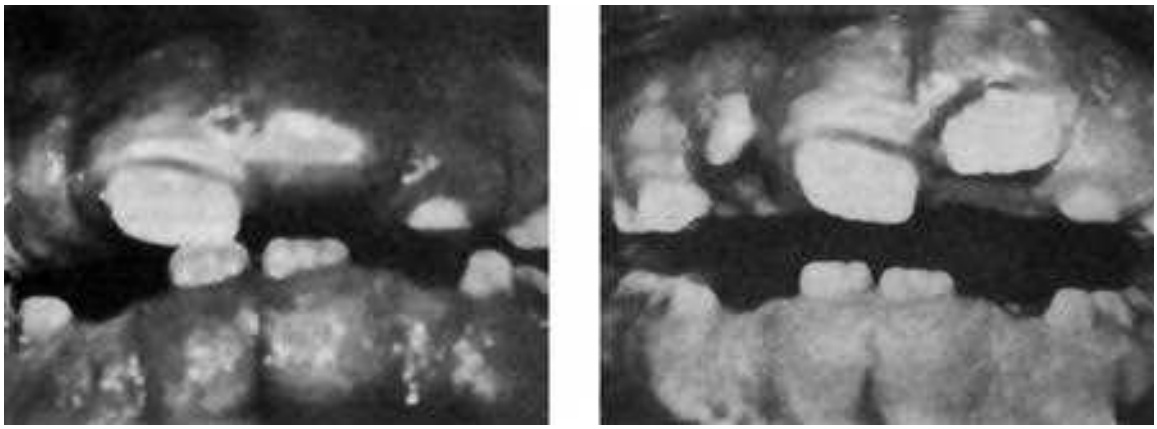
There have been a few cases where the patient's gingival tissues are so diffusely enlarged that the teeth are completely covered. If the enlargement is present before tooth eruption, the dense fibrous tissue may even interfere with or prevent eruption (Fig. 8-27). Other names for this condition are 'fibromatosis' (q.v.), 'fibromatosis gingivae,' 'elephantiasis gingivae,' and 'congenital macrogingiva'. The cause of this developmental enlargement of gingival tissue is not known. It is probably hereditary, being transmitted as an autosomal dominant trait in some instances, since reports have been made of several cases occurring in the same family.

A typical case of idiopathic gingival enlargement presents large masses of firm, dense, resilient, insensitive growth that covers the alveolar ridges and extends over the teeth. It is normal in color, and the patient complains only of the deformity. Often the gingivae are so enlarged that the lips protrude, and the fibrous mat of tissue upon which the patient chews may be 25 mm wide and as much as 15 mm thick.

This enlargement may be detected at an early age and in a few cases even at birth. Teeth do not erupt normally because of the dense fibrous tissue.

Histologic sections of tissue from idiopathic fibrous gingival enlargement show hyperplastic epithelium with elongation of rete ridges and mild hyperkeratosis. The underlying stroma is made up almost entirely of dense bundles of mature fibrous tissue with few young fibroblasts present. Occasionally, some chronic inflammation caused by local irritation may also be present.

Surgical removal of the excess fibrous tissue is the only feasible treatment. The condition may recur afterwards.



A B

Figure 8-27. Fibromatosis gingivae.
Idiopathic fibrous hyperplasia **(A)** before and **(B)** after an incision had been made to allow eruption of the maxillary central incisor. Eventually these teeth assumed a relatively normal position.

Neoplastic enlargements are due to benign and malignant neoplasms involving the gingiva, discussed in Chapter 2 on Benign and Malignant Tumors of the Oral Cavity.

False enlargements occur due to underlying dental or osseous anomalies and are not an abnormality of the gingiva as such.

PERIODONTITIS

Periodontitis is defined as 'an inflammatory disease of the supporting tissues of the tooth caused by specific microorganisms or group of specific microorganisms, resulting in progressive destruction of the periodontal ligament and alveolar bone with pocket formation, recession, or both'. It is classified as chronic, aggressive, and as a manifestation of systemic diseases. The so-called acute periodontitis that results from acute trauma is now termed as occlusal trauma.

Chronic Periodontitis

(Periodontoclasia, pyorrhea, pyorrhea alveolaris, Schmutz pyorrhea)

Chronic periodontitis is the most common form of periodontal disease and is associated with local irritation. This begins as a marginal gingivitis, which usually progresses, if untreated or improperly treated, to chronic periodontitis. This type of periodontitis, sometimes referred to as marginal periodontitis, is most common in the adult, although it is found occasionally in children, especially when oral hygiene is lacking, or in certain cases of malocclusion.

The amount of tissue destruction is consistent with local factors. In the adult, periodontal disease of this type accounts for more than 90% of the cases of periodontal disturbances and is responsible for greater tooth mortality than dental caries. In general, the treatment of this form of periodontal disease, as of all others, is dependent upon the removal of etiologic factors, both local and systemic, the maintenance of good oral hygiene, and the establishment of a stable, harmonious articulation free from traumatic interferences.

Etiology. Gingivitis may precede and develops into a more severe periodontitis, which involves not only the gingiva, but also alveolar bone, cementum, and periodontal ligament. Etiologic factors, in general, are the same as for gingivitis, but are usually more severe or of longer duration.

Local factors such as microbial plaque, calculus, food impactions, and irritating margins of fillings appear to be most important in the development of this common form of periodontal disease. No abnormalities of the immune system seem to appear. Chronic periodontitis is predominantly associated with *Actinobacillus actinomycetemcomitans, Bacteroides forsythus, Porphromonas gingivalis,* and *Prevotella intermedia.* The microflora in advanced periodontitis is characterized by the presence of large numbers of asaccharolytic microorganisms, including *Fusobacterium nucleatum, Bacteroides melaninogenicus, Eikenella corrodens, Bacteroides corrodens,* and *Bacteroides capillosus.* Slots (1977) found that these organisms constituted up to 75% of the isolates from periodontitis pockets.

Incidence. The incidence of periodontal disease is difficult to determine, and figures vary according to the criteria used by the individual investigators. This wide variation in the reported prevalence of periodontal disease is doubtless due to lack of uniformity in methods of assessment used, and of course, to inherent differences in the populations examined.

According to a study by Marshall-Day, chronic periodontal disease occurs rarely before 18 years of age, but increases in incidence so rapidly that after 45 years of age almost all subjects show evidence of localized or generalized bone loss. The incidence of bone loss in men is slightly higher than in women, and of pocket formation increased constantly with age, reaching a peak of 94% at ages 52–55 years. Abnormal tooth mobility was rarely encountered before 25 years of age, but increased sharply from 25% at ages 35–39 to 49% at ages 40–48, with a steady rise to 79% at age 60. Localized or generalized

clinically demonstrable suppuration occurred spontaneously or under digital pressure in almost 40% of subjects at age 40 and approximately 50% in the older age groups. There was also a rapid rise in tooth loss after 35 years of age, so that by 60 years of age, 60% of the teeth had been lost and 26% of patients were completely edentulous.

Immunologic Features. There is considerable evidence indicating that plaque-induced effector mechanisms play a major role in the pathogenesis of inflammatory periodontal disease. Both the cellular and humoral immunologic pathways have been implicated in the destruction of periodontal tissues. Correlations of varying magnitudes have been demonstrated between the clinical severity of periodontal disease and plaque antigen-induced peripheral blood lymphocyte blastogenesis by Ivanyi and Lehner (1971), by Horton and coworkers (1972), and by Mackler and associates (1974). The clinical severities of periodontal disease have also been correlated with salivary IgA concentrations by Orstavik and Brandtzaeg (1975). Robertson and his coworkers (1980) studied the periodontal status of patients with primary immunodeficiencies and compared them with age-matched and plaque-matched individuals. Since most patients with immunodeficiency diseases have a short life span, most of the patients examined were younger than 15 years of age. There were; however, two patients, one 45 years old and the other 16 years old, with IgA deficiency, although low to undetectable levels of IgA were noted in all of the immunodeficient patients studied.

Without exception, immunodeficient patients demonstrated less gingival inflammation than immunocompetent subjects matched in age and plaque index. These results are in accord with studies by Tollefsen and colleagues and by Kardachi and Newcomb of patients receiving immunosuppressant drugs. The diminished levels of gingival inflammation in immunodeficient patients can be explained if there was a qualitative difference in the oral microflora or if there was impairment in the host's ability to react to plaque. Brown and coworkers found very few differences in the microbial composition of dental plaque between the two patient groups reported on by Robertson and his colleagues (1980). However, significantly higher plaque levels of catalase-negative diphtheroids and *Candida sp*. were found in immunodeficient patients, whereas control groups had higher concentrations of *Fusobacterium sp*. They concluded that immunoglobulins have minimal influence on the microbial composition of dental plaque. Therefore, if dental plaque is present and the reaction to it is absent or minimal, there would be lesser chances of periodontal disease. On the other hand, if the immunologic effector mechanisms are responsible for the signs or symptoms of periodontal disease, there would be inflammation and tissue destruction only in patients who are able to mount an immunologic response to the presence of dental plaque. Mackler and his coworkers reported in 1978 that the earlier mild gingivitis lesions contained predominantly thymus (T)-derived lymphocytes, whereas the more advanced lesions contained large numbers of B-lymphocytes and plasma cells. Thus, patients with humoral (B-lymphocyte) immunodeficiencies would be expected to have some gingival inflammation, since many such patients manifest normal T-cell mediated responses. In fact, some of the IgA-deficient patients in Robertson's study did show mild gingivitis, but it was less severe than in the age and plaque-matched controls.

Evidence that the immune response is capable of destroying all periodontal tissues in experimental animals was provided by Levy and his colleagues (1976). When complete (CFA) and incomplete (IFA) Freund's adjuvant was injected into the periodontium of CFA-sensitized marmosets, capuchins, and rhesus monkeys, all animals developed a proliferative granulomatous reaction to the injection site. However, only in CFA-injected animals was there marked destructive periodontitis with considerable bone destruction. The injection of IFA into the periodontium of the same animals resulted in the formation of nondestructive proliferative granulation tissue.

It seems obvious then that the immune response, while often protective, can also be a highly destructive reaction to injury. Page and Schroeder have summarized the histopathology and immunopathology of periodontitis.

There are contradicting reports regarding the genetic polymorphism for cytokines as potential markers for periodontitis. Lopez NJ and coworkers reported positive association of interleukin-1 polymorphism with periodontitis based on a study involving 330 patients with periodontitis and 101 healthy controls. While Sumer AP et al found association of interleukin-10 gene polymorphism and generalized chronic periodontitis, in their study involving 75 Turkish patients with generalized chronic periodontitis and 73 healthy controls.

Cystatin C is a potent inhibitor of lysosomal proteinases and probably one of the most important extracellular inhibitors of cysteine proteases. According to a study done by Sharma A et al (2012), the mean cystatin C concentration in gingival crevicular fluid and serum was highest in periodontitis group and lowest in periodontally healthy group with intermediate concentration in gingivitis group and after periodontal therapy group. With this finding they suggested that cystatin C increases with disease progression to prevent further periodontal degeneration and decreases after treatment due to bone metabolic homeostasis.

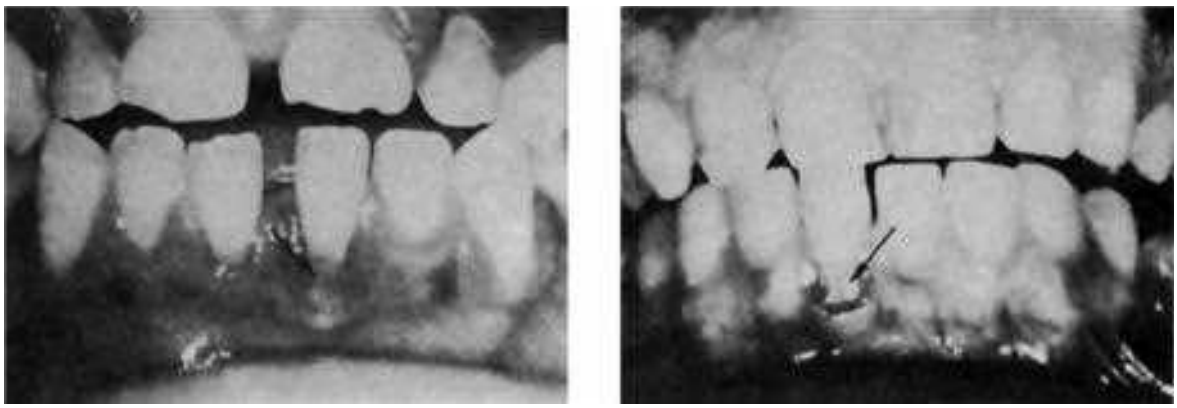
Clinical Features. Periodontitis usually begins as a simple marginal gingivitis, as a reaction to plaque or calculus. An early, and perhaps the first, pathologic finding is a tiny ulceration of the crevicular epithelium. Unless the irritants are removed, more plaque and calculus are deposited with the passage of time, and the marginal gingivitis becomes more severe. The gingiva becomes more inflamed and swollen, and with irritation, the crevicular epithelium suffers ulceration more frequently. It proliferates as a result of the inflammation so that at this stage there is a tendency for the epithelial attachment to extend or 'migrate' apically on the tooth. As it does so, it gets easily detached at its coronal portion. Through this process and because of the increased swelling of the marginal gingiva, the gingival crevice gradually becomes deeper and is classified as an early periodontal pocket (Fig. 8-28). The presence of periodontal pockets measuring more than 3–4 mm indicates the destruction of periodontal ligament and alveolar bone resorption.

Figure 8-28. Developing periodontal pocket.
C labels a firmly attached deposit of subgingival calculus. The arrow indicates a break in the integrity of the epithelial lining of the pathologic pocket. Note the chronic inflammatory reaction in the soft tissue and the scarcity of gingival fibers *(Courtesy of Dr JP Weinmann and Dr GW Burnett, and Williams and Wilkins Company).*

Clinically, the presence of calculus may be detected at this stage. Subgingival calculus may be more readily visualized if the free marginal gingivae are blown-back from the tooth by compressed air. Besides the mild visible swelling and hyperemia of the gingivae there is also a tendency for them to bleed readily; minute 'spontaneous' hemorrhages will often appear if the gingivae are simply rubbed by the examiner in the region of the interdental papillae. An unpleasant, almost foul type of halitosis is also present.

As periodontitis becomes more severe, the teeth become mobile and give off a rather dull sound and hurt when tapped with a metal instrument. Suppurative material and other debris occasionally may be expressed from the pathologic pocket adjacent to a tooth by slight pressure on the gingiva. Compressed air and instrument exploration will reveal that the tissue detachment may be severe. The embrasures may be open because the interdental papillae are deficient. The normal festooning is not apparent, and the gingivae appear 'boggy' because of hyperemia and edema; no stippling is detected, and the gingival tissues are smooth, shiny, and perhaps redder or bluer than normal. The patient may have no subjective symptoms or may complain of a bad taste, bleeding gums, and hypersensitivity of the necks of the teeth due to exposure of cementum as the soft tissues recede. In other words, the patient has a severe chronic gingivitis and an involvement of the deeper portions of the periodontium. This is the stage of severe periodontitis.

Gingival recession is a common phenomenon, particularly in later years in life. In such cases the gingival tissues recede toward the apex, exposing the cementum, sometimes to an alarming degree. Since the cementum is softer than enamel, it is often worn away by a toothbrush and an abrasive dentifrice. Gingival recession can occur more rapidly if there has been rapid alveolar bone loss, due to any cause, since gingival tissue in health will maintain uniform relations with alveolar bone crest. Gingival recession often begins as a thin break in the free gingiva adjacent to the center of a tooth. This is called a Stillman's cleft (Fig. 8-29).



A B

Figure 8-29. Gingival recession (Stillman's cleft).
The recession on the lower anterior teeth is due to poor oral hygiene and an abnormal amount of local irritation **(A and B)**.

Abnormal frequency and direction of tooth brushing, occlusal forces, or a high muscle attachment will sometimes lead to gingival recession. Gingival recession is preceded by alveolar bone loss, but bone loss is not necessarily accompanied by an equal amount of recession.

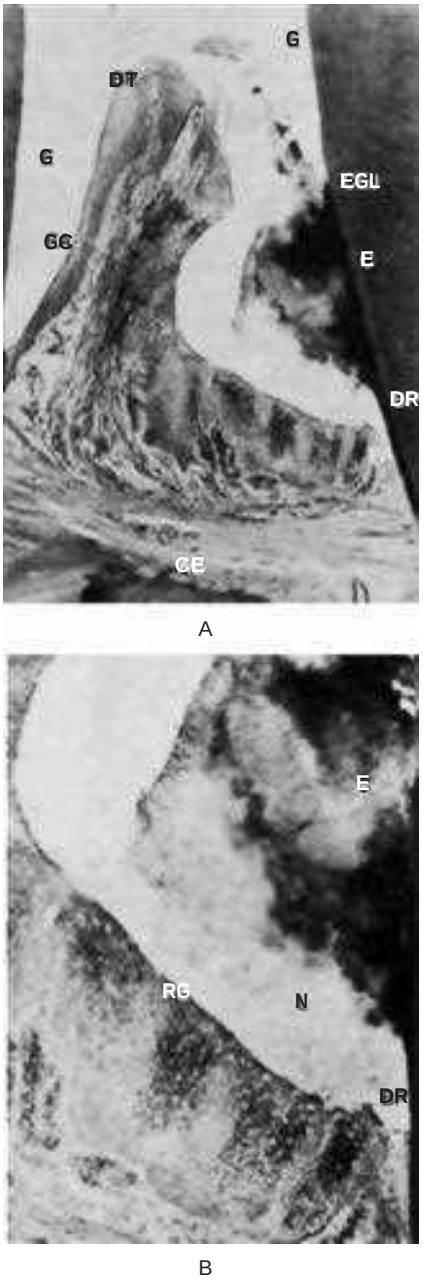


Figure 8-30. Periodontitis, early.

The bottom of the pocket on the third molar is on the enamel (BP_1), whereas it is on the cementum (BP) of the second molar. E, Enamel is lost in decalcification; EA, epithelial attachment; CEJ, cementoenamel junction; C, deposit of calculus; AC, alveolar crest showing resorption. The illustration on the right is a higher magnification of the bottom of the pocket, showing calculus (C) separated from the epithelium (PE), and leukocytes (L), which have migrated from the connective tissue *(Courtesy of Dr B Orban and J Periodontol)*.

Histologic Features. In marginal gingivitis, which is just beginning to undergo transition into early periodontitis, the enlarged free marginal gingiva is densely infiltrated with lymphocytes and plasma cells. The apical border of the inflamed area approaches the crest of the alveolar bone and the crestal fibers of the periodontal ligament (Figs. 8-30, 8-31). The crevicular epithelium shows various degrees of proliferation, and often, tiny ulcerations. One of the early microscopic signs of the encroachment of the inflammatory process on the periodontium is the appearance of the osteoclasts on the surface of the bone crest. They soon appear to lie in the little bays of bone resorption known as Howship's lacunae. The underlying tissues of the periodontium show no changes at this stage. The pathologic process involves the alveolar bone

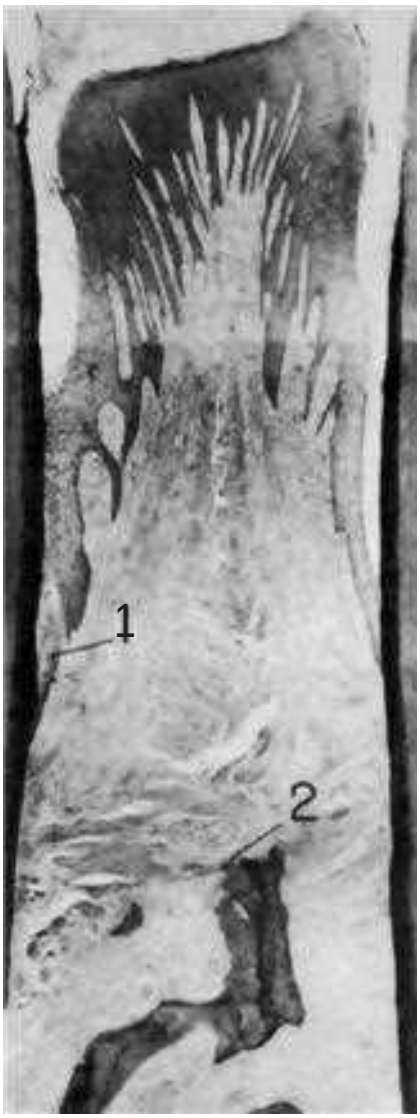

Figure 8-31. Periodontitis, early.

prior to involvement of the periodontal ligament.

The next stage of the progress of the disease is a continuation of the factors just described:

- More plaque is deposited in an apical direction on the tooth
- More irritation of the free gingiva occurs
- The epithelial attachment proliferates apically down onto the cementum of the tooth and shows more ulceration
- The alveolar crest of bone is resorbed further apically
- Principal periodontal ligament fibers become disorganized and detached from the tooth
- A periodontal pocket exists between the free gingiva and the tooth, to depths from 2 mm down, until finally the apex of the tooth is approached.

The deep pocket that exists between the calculus and plaque-covered tooth surface and the epithelial lining of the gingival tissues forms a protective trap for multiplying microorganisms and for leukocytic cellular exudate from the inflamed soft tissue of the pocket wall. The vicious cycle of irritant collection, inflammation and detachment continues, along with periodontal bone resorption in an apical direction (Fig. 8-32).

Classification of Periodontal Pockets. In a normal healthy periodontium, the gingival tissues fit snugly around the teeth, and the gingival crevice approximates zero. In the presence of inflammation; however, the gingival tissues increase in bulk, causing an increase in the depth of the pocket around the teeth. If the pathologic changes are limited to the gingiva, this is called a gingival pocket or pseudopocket. If; however, the base of the pocket has invaded further into the periodontium, it is called a periodontal pocket. The base of the periodontal pocket is on the root of the tooth, and the epithelial attachment is on cementum. Although periodontal disease usually progresses apically and advances at the expense of the horizontal loss of the crest of the alveolar bone, sometimes the depth of the pocket extends apically to the crest of the alveolar bone. Such a pocket, which has bone on its lateral wall, is called an infra-bony pocket, and is the exception rather than the rule, since usually the bottom of the pathologic pocket is level with or coronal to the alveolar crest of bone (supra-bony pocket, Fig. 8-33). The infra-bony pocket may result from food impaction and is frequently found along the tooth that has shifted considerably out of its usual position or has

been subjected to severe occlusal trauma. Infra-bony pockets are classified according to their shape (narrow or broad) and the number of bony walls. According to Goldman and Cohen in a complete discussion of this condition, three-wall infra-bony pockets are commonly observed in the interdental areas where one finds an intact proximal wall as well as buccal and lingual walls of the alveolar process. Two-wall infra-bony pockets may be seen in the interdental areas, with the buccal and lingual walls intact, but the proximal wall destroyed. A 'curtain' of soft tissue remains where the osseous wall has been destroyed. Infra-bony pockets with one osseous wall are occasionally seen in the interdental area.

The type of periodontal pocket present can be determined by careful clinical examination and study of good radiographs. Consideration of the topography and type of infra-bony pocket is important in planning the treatment of periodontal disease. The most favorable type of pocket for reattachment to occur is, of course, the one with three osseous walls. A 'slating fill-in' of bone can occur in a pocket with two bony walls; but when only one wall is present, chances for the formation of additional height of alveolar bone are poor.

Radiographic Features. The earliest change in the periodontal bone is a blunting of the alveolar crest due to the beginning of bone resorption (Fig. 8-34). A straight line can be drawn along the edge of alveolar bone at almost any stage of the disease and the bone loss is said to be horizontal. There is a tendency for cupping out of the interdental alveolar bone. The periodontal ligament space retains its usual thickness, and generally no changes are noted except the superficial bone changes that actually may become extensive (Fig. 8-35). It is of interest that radiographic evidence of alveolar bone changes has been reported in about 12% of cases in which pocket formation does not exist clinically.

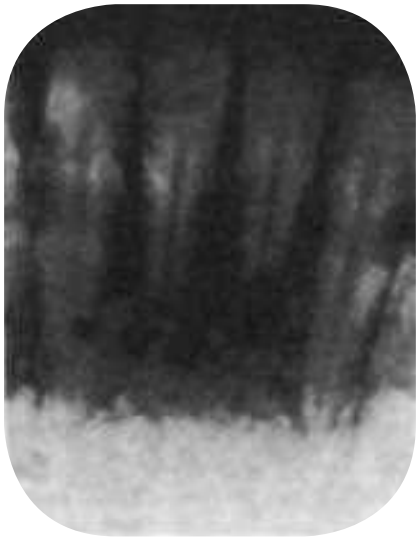

Figure 8-34. Periodontitis, early.

A

B

Figure 8-35. (A) Periodontitis, advanced. (B) Severe form of chronic periodontitis.

Treatment and Prognosis. By careful complete periodontal treatment, the teeth involved by periodontal disease can be saved if the bone loss has not been too extreme, if irritants are removed by scaling and curettage and if pockets are eliminated by gingival recession or by surgical removal of the gingiva (gingivectomy), if osseous deformities are eliminated and the tooth-supporting tissues are recontoured to a normal physiologic architecture, if occlusal forces are balanced, and systemic factors are corrected.

Clinicians for many years have demonstrated that after the successful treatment of periodontitis, pathologic pockets are shallower, even though no tissue was removed. Obviously this loss of pocket depth can be caused either by gingival recession or by reattachment of periodontal ligament to the tooth surface next to the pocket. Actually, both recession and reattachment may occur in the same case. There is usually a shrinkage or recession of the gingival tissues as inflammation and its associated edema and hyperemia is diminished, for as the gingival tissues return to a state of health the normal relation of gingiva to alveolar bone is gradually re-established just above the bone level. The distance from the crest of the

gingiva to the base of the pocket is diminished by the reduction in the size of the gingiva.

The second possible explanation for the shallower pocket after therapy is reattachment. Reattachment may be defined as a re-establishment of fibrous connection of the tooth to the alveolar bone and gingiva by periodontal fibers in an area of cementum which is adjacent to a pathologic pocket. A typical epithelial attachment is described as reforming. The cellular elements that would make reattachment possible are all present in the periodontium; resorption of the bone and rebuilding of new bone with reattachment of new periodontal ligament fibers go on constantly.

Considering this problem from a purely theoretic point of view, if reattachment is to occur, it is necessary that connective tissues remain in contact with the tooth for an appreciable, but as yet undetermined, period of time. Since the cementum lining the pocket is necrotic, cementoclasts must resorb the cementum to a level at which it is viable. Next, cementoblasts must develop to deposit a new layer of cementum which traps ends of connective tissue fibers. Finally, new alveolar bone must be built opposite the newly attached periodontal fibers in response to the stimulus of the periodontal ligament.

Reattachment will not occur as long as inflammation persists in the tissues next to the tooth. Factors interfering with reattachment include the following:

Crevicular epithelium. For reattachment to occur, this epithelium must be curetted away. Since cementum can be deposited only by connective tissue, the presence of epithelium interferes with the reattachment. The fresh bleeding connective tissue surface will form a blood clot in contact with the tooth, which can organize and contribute to reattachment. In certain cases, particularly those with infra-bony pockets, the blood clot is easily protected and healing occurs more easily.

Mobility. During the period of reorganization the tooth must be at least relatively immobile, since motion tends to disturb the healing process and allow any remaining crevicular epithelium to proliferate and reline the pathologic pocket.

Inflammation itself apparently interferes with reattachment, perhaps because cementoblasts cannot develop in areas of inflammation.

Necrotic cementum is also a barrier to reattachment, since new cementum apparently will not be deposited upon cementum that has been in contact with oral fluids and suppuration for an appreciable time.

Other, as yet unknown, factors are also involved. Connective tissue can lie adjacent to cementum for months without being lined by epithelium or establishing a reattachment of the periodontal ligament to tooth.

Provided the condition is not too advanced and therapy is adequate, periodontitis can be arrested, and teeth can be maintained to function almost indefinitely. The inflammatory process gradually subsides; gingival tissues return to normal size, color and contour; the teeth become less mobile, and suppuration and bleeding stops. The depth of the gingival crevice approaches zero, owing to tissue shrinkage or gingivectomy; stippling returns and the case appears normal, even though the gingival tissues and alveolar crest are apical to their original position. In other words, a new steady state is reached, different from the original but compatible with the maintenance of good oral health.

Aggressive Periodontitis

Aggressive periodontitis is a rapidly progressing type of periodontitis that occurs in patients who do not have large accumulations of plaque and calculus. This may be either localized or generalized; replacing the terms localized and generalized juvenile periodontitis and rapidly progressive periodontitis. It has a familial tendency suggesting a genetic predisposition.

This disease appears to be the result of a defect in the immune response rather than plaque and calculus deposition. The disease is specific. Microflora associated with this disease are *Actinobacillus actinomycetemcomitans* and *Porphyromonas gingivalis. P. gingivalis,* and *Bacteriodes forsythus* frequently are detected in the plaque that is present. Other species related are *Capnocytophaga sputigena, Mycoplasma* subspecies and *Spirochetes.*

Several investigators have shown that patients with aggressive periodontitis display functional defects of polymorphonuclear leukocyte, monocytes, or both, but without any systemic manifestations. Because of this, their defensive ability against some of the periodontal pathogens is defective. The bactericidal activity against *Actinobacillus actinomycetemcomitans* is particularly faulty in localized form.

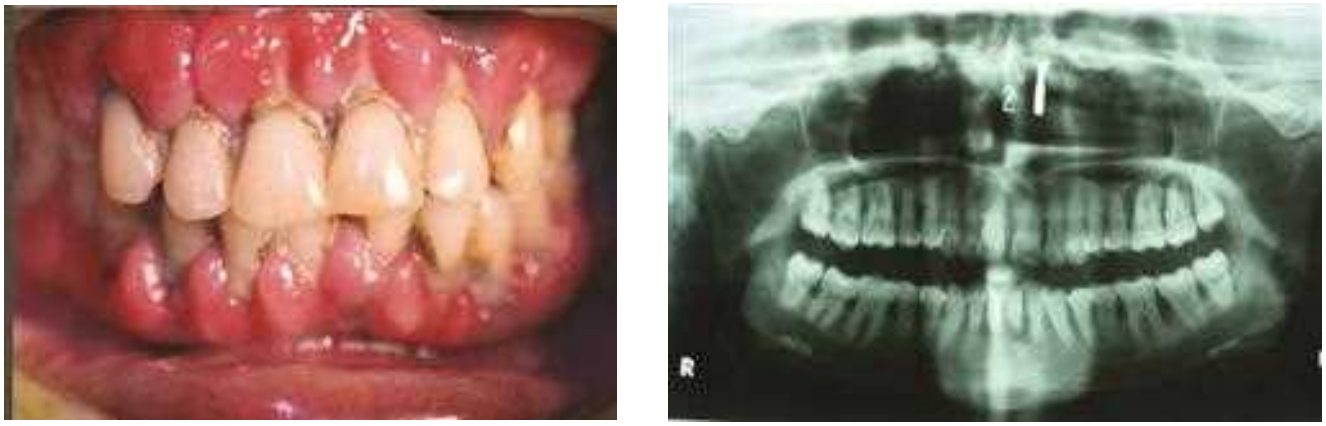
Clinical Features

Localized form. This usually occurs around puberty and has a strong familial tendency. It is localized to the first molars and incisors; there is attachment loss in at least two permanent teeth, one of which is the first molar. A striking feature is the absence of clinical inflammation with minimal local factors despite the presence of a deep periodontal pocket. The rate of alveolar bone loss is considerably higher than in chronic periodontitis. The disease is associated primarily with *A. actinomycetemcomitans*.

Generalized form. This form usually affects patients under 30 years of age. It involves at least three teeth other than the first molar and incisor, and exhibits poor serum antibody response to infecting agents. Many cases represent the localized form which becomes generalized with time. The marked distinction between this and the localized form is the presence of large accumulation of plaque, calculus, and gingival inflammation (Fig. 8-36A). The organism associated with the generalized form is more complex and closely resembles chronic periodontitis.

A definitive diagnosis can be made based on family history, clinical, radiographical, microbiological, and histological examination with leukocyte function tests.

Papillon-Lefèvre syndrome is an autosomal recessive disorder that is characterized by cutaneous and oral manifestations. The characteristic skin lesions consist of keratotic lesions of palmar and plantar surfaces. The oral lesions are characterized by aggressive periodontitis leading to severe



A B

Figure 8-36. Generalized aggressive periodontitis.
The presence of a large amount of plaque, calculus and gingival infection, **(A)**. Loss of bone support involving more than three teeth other than first molars and incisors, **(B)** *(Courtesy of Dr KL Vandhana, Department of Periodontics, College of Dental Sciences, Davanagere).*

destruction of the alveolar bone involving both the deciduous and permanent dentitions. Due to rapid bone loss, mobility and pathological migration occurs, which results in loss of the entire dentition at a much younger age.

Radiographic Features. In the localized form, vertical loss of alveolar bone is seen around the first molar and incisor at around the age of puberty in otherwise healthy patients. An arc-shaped alveolar bone loss extends from the distal surface of the second premolar to the mesial surface of the second molar, and there is widening of the periodontal ligament space (Fig. 8-36B). This 'vertical' pocket formation, with the bone loss often more extensive on one tooth than on an adjacent tooth, differs from the 'horizontal' type of bone loss seen in chronic periodontitis. In chronic periodontitis, many teeth are involved in about the same degree, so that the bone loss appears to be 'horizontal.' In the generalized form, bone loss may range from the involvement of one or two teeth to a maximum number of teeth (Fig. 8-36B).

Histologic Features. These closely resemble the features of chronic periodontitis (Fig. 8.37).

Management. Antibiotics should be administered in combination with mechanical removal of plaque and inflamed periodontal tissues. Periodontal surgery should be performed with prophylactic antibiotic cover and postoperative usage of chlorhexidine mouthrinse. Periodic follow-up is necessary since there is possibility of reinfection.

Figure 8-37. Aggressive periodontitis.

One finds normal width of the periodontal membrane on the distal surface of the tooth on the left and degenerative connective tissue replacing the periodontal ligament on the mesial surface of the tooth on the right. Note also the alveolar bone loss and the lack of inflammation *(Courtesy of Dr B Orban and J Periodontol).*

Necrotizing Ulcerative Periodontitis

Necrotizing ulcerative periodontitis occurs in younger patients than those with chronic periodontitis. This, along with necrotizing ulcerative gingivitis, is grouped as necrotizing periodontal diseases. These diseases may be accompanied by fever, malaise, and lymphadenopathy. Necrotizing ulcerative gingivitis is discussed under gingival diseases since it does not always present with attachment loss. Necrotizing ulcerative periodontitis shows attachment and bone loss and may be associated with immune suppression or malnutrition. Recent reviews of the etiologic and clinical characteristics suggest that necrotizing ulcerative periodontitis and necrotizing ulcerative gingivitis represent the same disease with a different degree of clinical manifestations. Immune dysfunction plays a major role and may predispose patients to develop necrotizing ulcerative gingivitis

Figure 8-38. Necrotizing ulcer periodontitis in an HIV-positive patient.
(Courtesy of Dr R Saravanakumar, Department of Periodontics, Meenakshi Ammal Dental College, Chennai).

and necrotizing ulcerative periodontitis, especially when associated with an infection of microorganisms such as *Treponema* and *Selenomonas species, Fusobacterium nucleatum, Prevotella intermedia,* and *Porphyromonas gingivalis*.

Necrotizing ulcerative periodontitis may be observed in HIV-positive patients (Fig. 8-38). The CD4+ cell count is below 200 cells/mm in more than 90% of the HIV-infected patients with necrotizing ulcerative periodontitis. In HIV-positive patients, it causes ulceration and necrosis of gingiva with pain and spontaneous bleeding. The exposed underlying bone then undergoes rapid destruction.

Management and Prognosis. If the underlying immunosuppression and malnutrition is corrected, it usually responds to oral hygiene and antibiotics. Roughly 72.9% of the HIV-infected patients have the cumulative probability of death in 24 months from the time of the diagnosis of necrotizing ulcerative periodontitis.

Lateral Periodontal Abscess
(Lateral abscess)

The lateral periodontal abscess is related directly to a pre-existing periodontal pocket. Precipitating factors include subgingival flora, host resistance, or both. When such a pocket reaches sufficient depth, around 5–8 mm, the soft tissues around the neck of the tooth approximate the tooth so tightly that the orifice of the pocket is occluded. Bacteria multiply in the depth of the pocket and cause enough irritation to form an acute abscess with exudation of pus into this area. A foreign body, particularly food debris, may also lead to abscess formation. This may result in enough swelling to destroy the cortical plate of bone, if it still exists, allow the abscess to balloon the overlying tissues, forming a 'gum boil', or parulis (Fig. 8-39).

Clinical Features. It usually occurs in adults and is rare in children. The most common cause of periodontal abscess is foreign bodies. The acute periodontal abscess will cause the afflicted tooth to be tender to percussion. Pain, foul taste, mobility of the involved tooth, tenderness over the corresponding gingiva, and lymphadenopathy are the other symptoms.

The occurrence of periodontal abscesses of both lateral and periapical types was reported by Dinsdale and Holt in a group of 34 children treated with cortisone for rheumatic fever. The abscesses appeared within two weeks after therapy had been discontinued. The cortisone apparently actuated pre-existing periodontal lesions, but the abscesses were unusual in that pain

A B

Figure 8-39. Periodontal abscess.
(Courtesy of Dr Joshua Sheih,Emmanuel Dental Clinic, Chennai).

was very mild or even absent, and there was no local swelling or cellulitis. Lymph node involvement was also rare. In some cases the only clinical manifestation of the abscess was the release of pus from the neck of a loose deciduous tooth upon pressure. It was noted that the erythrocyte sedimentation rate, which is seldom elevated in normal children with a periodontal abscess, was usually elevated in cortisone treated children with rheumatic fever with a periodontal abscess.

Histologic Features. Microscopically, the abscess resembles an abscess elsewhere. It consists of a central cavity filled with pus walled off on one side by the root of the tooth and on the other by connective tissue; because it is likely that in most instances that the epithelial lining of the crevice would have been destroyed by the inflammatory process.

Treatment of a periodontal abscess is similar to that of an abscess elsewhere. A direct incision, perpendicular to the long axis of the involved tooth, releases pus. If the abscess does not drain spontaneously through the gingival crevice, and if it is not treated, a fistula may develop to release the pus spontaneously onto the mucosal surface (Fig. 8-39B). Careful insertion of a dull probe into the pocket along the tooth will usually induce drainage, and the acute symptoms will subside. The abscess will recur; however, unless the cause is removed and the depth of the pocket is reduced. Cases in which normal tissue contours cannot be developed and maintained, extraction of the tooth is advised after the acute symptoms have subsided.

PERI-IMPLANTITIS

Inflammation of the soft tissues surrounding the osseo integrated implant in function and progressive bone loss is termed as peri-implantitis. It is a multifactorial process. Clinical studies have documented that peri-implantitis may lead to implant failure and loss. Implant failure is usually associated with high degree of plaque accumulation. Bacterial plaque and smoking are the risk factors resulting in implant failure.

Microbial plaque is the major factor which causes inflammation in soft tissue around dental implants. Bacterial infection and biomechanical factors in relation to extra load on implants are the main cause for crestal bone loss around the implants. Gram-negative anaerobic rods, spirochetes and fusiform bacteria are found in higher proportions at peri-implant sites as compared with healthy sites.

Contributory factors include the status of the peri-implant tissue, implant design, degree of roughness, the poor alignment of implant components, external morphology and excessive mechanical load, and oral hygiene.

The response of the gingiva and the peri-implant mucosa to early and more long standing periods of plaque formation has been analyzed. In a study by Berglundh et al (1992), similar amount and composition of the developing plaque that accumulate on the tooth surface were noted around implant segments. Leonhardt et al, in subsequent studies, concluded that the microbial colonization on titanium implant followed the same pattern as that on teeth. Similar observations were made by Pontoriero et al (1994), who concluded that in a given individual, the only soft tissue response to plaque in the mucosa at the site of implant placement is similar to that seen in gingiva around the teeth. With increasing duration of plaque build up, it was noted that the lesions in the peri-implant mucosa expanded more and progressed further apically than gingiva. The composition of the lesion in the two tissues also differed with respect to their content of fibroblasts. The lesion in peri-implant mucosa was found to have a much smaller number of fibroblast than the corresponding compartment in gingiva.

It was also noted that, in the gingival lesion, the amount of tissue destruction that occur during a breakdown phase was more or less compensated by tissue build up which occurred during a subsequent phase of repair. However, in lesion within the peri-implant mucosa, the tissue break down which occurred was not fully recovered by the reparative phase. The small number of fibroblasts present in this lesion may have been unable to produce enough collagen and matrix during the reparative phase. It was concluded that peri-implant mucosa seems less effective than gingiva in encapsulating plaque-associated lesion.

The key bacterial virulence factor for destruction of periodontal tissue is endotoxin, a ubiquitous component of the cell walls of all gram-negative bacteria. Endotoxin-activated macrophages produce proteases that can degrade collagen and proteoglycans, ultimately producing degradation of extracellular matrix. Furthermore, activated macrophages produce the cytokines, interleukin-1 (IL-1) and prostaglandin E2 (PGE2).

The PGE2 produced by endotoxin-activated macrophages and IL-1-activated fibroblasts has as it target, the osteoclast. PGE2 activates osteoclasts, leading to resorption of alveolar bone and results in loss of support. This completes the circuits leading to destruction of soft and hard periodontal tissue.

Clinical Features. Symptoms of peri-implantitis relate to infectious/inflammatory nature of the lesion. Implants showing the signs and symptoms of infectious failure but not yet mobile may be called 'ailing'. An ailing implant displays progressive bone loss and pocketing, but no clinical mobility. A failing implant displays feature similar to the ailing implant, but is refractory to therapy and continues to become worse. The term **ailing** suggests a somewhat more favorable prognosis than the term **failing**. A failed implant is one that is fractured, has been totally refractory to all methods of treatment, or demonstrates clinical mobility or circumferential peri- implant radiolucency.

All failing implants are characterized by mobility and peri-implant radiolucency. Implants failing as a result of infection are additionally characterized by pain, bleeding on probing, suppuration, increased probing depth, high gingival and plaque indices, attachment loss, and granulomatous tissue on removal. Implants failing for traumatic reasons (surgical trauma, faulty design of prostheses, or overloading) may be painful, but otherwise lack the additional characteristics associated with infectious failure

Few cases present with the proliferation of gingival tissues in and around peri-implant area or inflammation of surrounding soft tissue as redness are called **Peri-implant mucositis**. Various indices like plaque index, gingival index, bleeding index, probing pocket depth, and probing attachment level are used frequently to evaluate the health of soft tissues around implants.

Intra-oral periapical radiographs are used to determine the peri-implant bone status. Radiographically there is vertical destruction of crestal bone.

Histologic Features. Large number of polymorphonuclear leukocytes are noted in the peri-implant lesion. In comparison with the periodontitis, these lesions lack an epithelial lining between lesion and biofilm. These lesions are poorly encapsulated, extend into the marginal bone tissue, and if allowed to progress may lead to the loss of implant. Peri-implantitis is associated with opportunistic periodontal pathogens such as *Actinobacillus actinomycetemcomitans, Porphyromonas gingivalis, Bacteroides forsythus, Prevotella intermedia, Peptostreptococcus micros and Fusobacterium nucleatum.* Proliferation of these opportunistic pathogens results in an inflammatory response and may lead to peri-implant infection. This emphasizes the importance of establishment of healthy periodontal condition prior to placement of implant, and the importance of a regular maintenance program thereafter.

Management. Combination of systemic antibiotic administration with meticulous removal of biofilm from the contaminated implant surface is effective in management of peri-implantitis. Local therapies which include mechanical brushing of the surface, use of air powder abrasives, application of chemicals like citric acid, chlorhexidine and delmopinol are effective in cleaning the titanium surface to allow soft tissue healing and bone fill.

The goal of therapy is suppression of opportunistic pathogens associated with infection, and establishment of a local environment and microflora compatible with health.
